Posterior component separations are preferred for lateral hernias or hernias associated with ostomy. In addition, a posterior component separation avoids the large skin flaps and wound complications associated with anterior component separation. In a posterior component separation, the retrorectus space is entered and dissected out to the semilunar line. The transversus abdominis is divided, preserving the transversalis fascia if possible, allowing the posterior rectus fascia to be pulled medially. Thus, the components must be "separated": the posterior layers (peritoneum, transversalis fascia, and divided portion of transversus abdominis) must be gently dissected free and away from the anterior layers. This allows wide release of the posterior layer and space for a large piece of mesh to be placed in the sublay position as described previously. Posterior component separation can be more technically challenging than anterior component separation and risks damaging the posterior sheath/peritoneum, destabilizing the semilunar line, or denervating the rectus muscle. When done properly, it can provide wide posterior space with lower wound complication rates compared to traditional anterior component separation.

There is increasing interest in the role of robotic ventral incisional hernia repair. Port placement is similar to what is described previously for primary ventral hernias, with few exceptions (Fig. 3). For lower abdominal incisional hernias (especially infraumbilical and suprapubic hernias), ports placement across the upper abdomen (right and left upper quadrant and off midline in the epigastric region) is preferred. For high incisional hernia defects, such as in the subxiphoid position, ports placed across the lower abdomen allow for easier suturing. The robotic platform is docked, and adhesiolysis is performed.

There are two possible methods for robotic ventral hernia repair: first, is replicating a laparoscopic repair. A 12 mm port is placed through the defect, a mesh is unable to be placed through an 8 mm robotic trocar, and two or three 2-0 barbed sutures, an appropriately sized coated synthetic mesh, and one to three 0 barbed sutures are inserted. The defect is closed with 0 barbed suture subcutis. The 0 barbed suture(s) are also used to position the mesh. The mesh is sutured circumferentially with 2-0 barbed sutures.

The second method is replicating an open repair. Ports are typically placed along the right and left lateral positions. Right and left rectus completes are incised to enter the retrorectus space. For larger defects, a robotic, posterior component separation can be performed. A 12 mm port is placed through the defect and an appropriately sized uncoated synthetic mesh and four to six 0 barbed sutures are inserted. The anterior fascia is closed with running 0 barbed sutures. The mesh is placed in the retrorectus space and can be centered and fixated with the 0 barbed sutures. The posterior sheath is closed with running 0 barbed sutures. If robotic posterior component separation is performed, the posterior sheath is typically closed first, followed by introduction and positioning of mesh and closure of the anterior fascia.

EMERGENT AND CONTAMINATED CASES

With each hernia repair, there is a risk of complications and hernia recurrence. As a result, cases with a high risk of surgical complication require special surgical planning. In some cases, it may be best to do as little as possible. Examples of this include emergent cases and cases with contamination. Emergent hernia repairs are associated with higher risk of complication and hernia recurrence than elective repairs. This may be due to lack of patient selection because patients with comorbidities are prohibited from undergoing elective surgery and can present to an emergent fashion and require surgery. It may also be due to the presence of contamination. Examples of contamination in ventral hernia repair include a strangulated hernia with necrotic bowel, a hernia repair in the setting of an ostomy, or a hernia encountered during an operation for another indication such as diverticulitis.

In these high risk settings, the surgeon may consider a staged repair. This means leaving a planned ventral hernia (closing skin and

leaving fascia open or placing an inlay with an absorbable mesh with plans to perform a definitive repair at a later time. This allows for a better repair to be done in an elective setting, but it subjects the patient to additional surgery.

If the surgeon decides to repair the hernia at the initial operation, he or she must decide whether to perform a suture or mesh repair. A suture repair eliminates the possibility of mesh-related complications; however, in this setting, the risk of hernia recurrence may be extremely high. The recurrence rate is likely extremely high even with mesh repair.

If mesh is used, mesh type must be considered. Synthetic mesh is often avoided in contaminated settings because of the increased risk of infection and fear of future need for mesh explantation. Furthermore, intraperitoneal synthetic mesh is contraindicated in contaminated cases. However, a low- or mid-density synthetic mesh in a sublay position can be considered. Another option is to use biologic or bioabsorbable mesh. Biologic and bioabsorbable mesh may be more resilient to infection than synthetic mesh, but they are generally considerably more expensive than synthetic mesh. Our typical practice is to place a biologic mesh in the sublay position when an experienced hernia surgeon is performing the case and there is limited contamination. When the situation is suboptimal (e.g., substantial contamination, patient or technique issues), we follow the practice that "less is more" and perform suture repair, bridge repair, or leave the abdomen open depending on the individual setting. When surgeons who do not have hernia expertise are performing emergency or are working with contaminated cases, we recommend the same "less is more" practice and advise either suture repair or underlay (intraperitoneal) repair with biologic mesh.

POSTOPERATIVE CARE

Postoperative care can vary significantly depending on the size of hernia repaired and the approach taken. Most of our small- and medium-sized hernia repairs go home on the day of surgery. We do not typically place strict restrictions on these patients with regard to activity but caution them against doing anything that is painful. Patients are managed with perioperative blocks (transversus abdominus plane and rectus sheath blocks) along with multimodal pain regimen (acetaminophen, ibuprofen, gabapentin, ± tramadol), and a bowel regimen (docusate, polyethylene glycol). For larger hernias or open retromuscular repairs, patients are typically kept in the hospital for pain control. We follow an enhanced recovery after surgery style approach to which diet is started immediately after surgery, early mobilization is encouraged, and narcotics are minimized. For very large hernias (>10 cm), we consider placement of an epidural to aid in pain control. In cases where drains are placed, they are removed after 2 consecutive days with less than 30 mL output per day.

MANAGEMENT OF SPIGELIAN, LUMBAR, AND OBTURATOR HERNIATION

Robert J. Fitzgibbons, Jr, MD, ACS, Gary Anthone, MD, ACS, and Myles L. Jones, MD, FACS

The anatomy, clinical presentation, and treatment of these unusual hernias are the subject of this chapter. Most of the literature devoted to Spigelian, lumbar, and obturator hernias consists of case reports with associated reviews of the literature. Because of the relative rarity of these hernias, high-quality, level 1 data from randomized controlled trials are not practical or possible. Nevertheless, the available literature provides some consistent themes, and they will be presented here.

SPIGELIAN HERNIA

Anatomy

The key to understanding a Spigelian hernia is a working knowledge of the location of two anatomic structures. A discussion of these anatomic structures can be confusing because of the numerous synonyms with similar names (Box 1). The first is the arcuate line, which is a transverse line that marks the point where the posterior surface of the rectus abdominus muscle is only covered by the transversalis fascia and peritoneum and is the site of entry of the inferior epigastric vessels into the rectus muscle. Above the arcuate line, the rectus abdominus is surrounded by an anterior layer of the rectus sheath and a posterior layer. The anterior layer is derived from the external oblique aponeurosis and the anterior lamina of the internal oblique aponeurosis. The posterior layer is made up of the posterior lamina of the internal oblique aponeurosis and the transversus abdominus aponeurosis. Inferior to the arcuate line, all three muscle aponeuroses contribute only to the anterior rectus sheath (the rectus sheath). The other important anatomic structure is the semilunar line, which can also be confusing because of varying definitions in the literature, such as a line marking the transition from transverse abdominis muscle to its aponeurosis; from the costal margin to pubis; tubercle versus the site of splitting of the internal oblique aponeurosis at the lateral edge of rectus abdominis muscle. From a surgical standpoint, the Spigelian

fascia, which is a small strip of aponeurosis of the transversus abdominis muscle bounded laterally by the linea semilunaris and medially by the lateral margin of the rectus abdominis muscle; it is most important (Fig. 1). This fascia was described by Adriaan van den Spiegel (1578–1625), a Flemish anatomist. The first description of a hernia through this area was by Klinkosch in 1764. Spigelian hernias usually are located at the junction of the arcuate line and the semilunar line in the Spigelian fascia. However, the exact location of the arcuate line is variable, which gave rise to the concept of the "Spigelian hernia belt," which is located between horizontal lines drawn just below the umbilicus cranially and at the anterior superior iliac spines caudally and is usually about 6 cm in length. Spigelian hernias can occur anywhere along the Semilunar line, but 90% occur in the Spigelian hernia belt.

Clinical Presentation

The hernia, which is also called a *spontaneous lateral ventral hernia* or *hernia of the semilunar line*, can be congenital or acquired. Associated conditions include collagen disorders, aging, rapid weight loss, chronic obstructive pulmonary disease, trauma, and a history of surgery. The reported incidence ranges from 0.1% to 2%, with a slight predilection to women. They are usually small in diameter, typically measuring 1 to 2 cm but can be as large as 14 cm. They tend to develop during the fourth to seventh decade of life. Patients may be completely symptom free, with the diagnosis only being made with imaging studies done for another indication. Symptomatic patients may have a localized palpable mass along the semilunar line with or without chronic pain, which may be intermittent. The pain tends to be worse with movement. The diagnosis can be elusive when there is no mass, which is common because the hernia is commonly interparietal and does not penetrate the external oblique fascia and therefore is difficult to feel (Fig. 2). Cross-sectional imaging or ultrasonography can be helpful for patients with localized pain in the Spigelian belt and no palpable mass but are not definitive because false negative results have been reported. Laparoscopy or laparotomy is the only completely reliable diagnostic method. Approximately 20% will have an acute presentation with bowel obstruction. Because of this, a strategy of watchful waiting is not recommended when they are found incidentally in children, the hernia has been associated with an ipsilateral undescended testicle. The differential diagnosis includes an arcuate line hernia, which is an internal hernia where a fold of peritoneum invaginates medial to the arcuate line beneath the posterior lining of the rectus muscle. Another unusual hernia, which can be a source of confusion, is a spontaneous posterior rectus sheath hernia, which protrudes through the posterior rectus sheath, sometimes forming a mass in the rectus muscle.

Treatment

Open Approach, Nonprosthetic

The initial step is to ascertain the location of the hernia. This can be problematic if the hernia is not palpable. In the past, a midline or paramedian laparotomy has been recommended to avoid an extensive preperitoneal dissection to find the hernia. Today laparoscopy would be preferred. However, with modern imaging techniques the hernia can usually be precisely identified. The skin can be marked with ultrasound guidance, which accurately identifies the location of the incision. An oblique incision is made, and the subcutaneous tissue is explored if the hernia has penetrated the external oblique fascia. Because these hernias are commonly interparietal, the next step is to incise the fascia of the external oblique muscle (Fig. 2). The hernia sac is then dissected free from surrounding structures and its contents reduced. If the contents of the sac are incarcerated, it may be necessary to incise the neck of the hernia, and this is best done medially toward the rectus muscle. The sac can then be either opened and

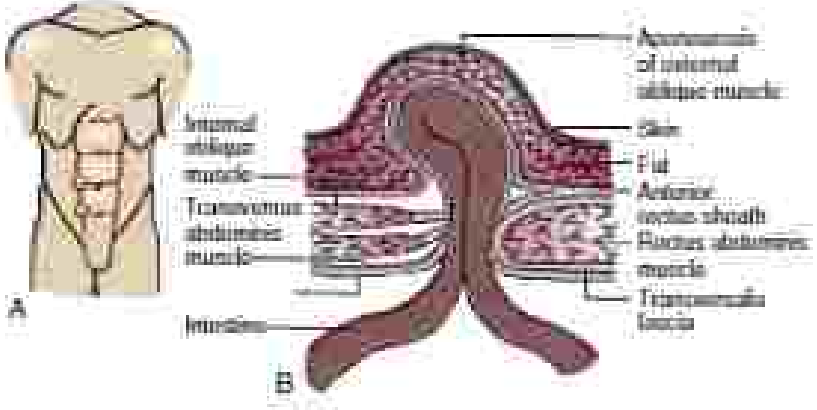

FIG. 2 (A) Typical incision of a Spigelian hernia along the Spigelian belt. (B) Cross-sectional diagram showing the most common sites of the hernia with the external oblique fascia intact. [illegible] Philadelphia: Lippincott Williams & Wilkins; 2011.]

excised or reduced into the abdominal cavity. If there is any suspicion that the contents of the hernia have been compromised, the sac must be opened to allow inspection. Because these hernias can be multiple with bilateral direct defects, the surrounding abdominal wall should be bimanually palpated either through the abdominal cavity if the sac has been excised or through the invaginated sac if it has only been reduced. A primary repair of the separated transversus and internal oblique muscles can be accomplished with either running or interrupted sutures. The external oblique aponeurosis is then repaired followed by skin closure.

Open Approach, Prosthetic

Most surgeons today prefer to reinforce the repair with prosthetic material. There are three basic types of repair. The first uses a preshaped polypropylene cone plug. Using the same approach as described above, the hernial sac is dissected free and excised or inverted. If the sac has been excised, the peritoneum is closed with running sutures, and the mesh plug is then inserted into the defect and sutured to its edges with interrupted sutures. The musculoaponeurotic layers are then closed over the plug. The second method uses a flat sheet of prosthetic material placed between the repaired internal oblique muscle and the external oblique, with a 2- to 3-cm underlap. This may be the best method in cases where there is too much tension to close the internal oblique. The mesh then serves to bridge the separated internal oblique with the external oblique closed over it (Fig. 3). The third technique requires the development of a preperitoneal space to allow for the placement of a large prosthesis with wide underlap. The mesh is secured with sutures or tacks placed circumferentially around the prosthesis. If the preperitoneal space has been dissected widely enough to allow at least a 5-cm overlap of the defect, no fixation is required. This is considered absolute by some because the same procedure can be performed more effectively laparoscopically, as will be described below. Once the prosthesis is in place the transversus and internal and external oblique muscles are reapproximated as in the preceding techniques. The advantage of this is that a relatively inexpensive prosthesis such as polypropylene mesh can be used. A simpler approach is to place the prosthesis intraabdominally, but this requires the use a more expensive product with antiadhesive properties approved for intraabdominal placement. Some examples are listed in Table 1.

Laparoscopic Approach

Inguinal hernias are readily visible at laparoscopy (Figs. 4 and 5). If the hernia is small, it can be closed primarily with one of the many available trocar site fascial closing devices. One or two 5-mm laparoscopic cannulas are placed in the contralateral lower quadrant opposite the hernia. The trocar site closure device is introduced percutaneously as demonstrated in Fig. 6. All but the smallest defects

TABLE 1 Examples of Prosthetic Products Acceptable for Intraabdominal Placement

Brand Name (Manufacturer)	Prosthesis	Adhesion Barrier
Parietex Composite (Covidien)	Polyester	Collagen, polyethylene glycol, glycerol
C-Qur (Atrium)	Lightweight polypropylene	Omega-3 fatty acid
Proceed (Ethicon)	Lightweight polypropylene + polydioxanone + polyglecaprone 25	Oxidized regenerated cellulose
Sepramesh (Genzyme)	Lightweight polypropylene	Sodium hyaluronate, carboxymethylcellulose, and polyethylene glycol (hp)
Composix EX (Bard)	Heavyweight polypropylene	ePTFE
Composix LP (Bard)	Lightweight polypropylene	ePTFE
Dulex (Bard/Davol)	ePTFE	The prosthesis is approved for intraabdominal use
DualMesh, OvalMesh plus (W.L. Gore)	ePTFE	The prosthesis is approved for intraabdominal use
Ventralight ST Mesh (Bard)	Medium-weight monofilament polypropylene mesh	Based on Separation technology

ePTFE, Expanded polytetrafluoroethylene.

FIG. 4 Typical appearance of an incarcerated lipoma from a laparoscopic perspective. [From Modesto A, Carbajo JM, Maroto J, et al. Laparoscopic diagnosis and repair of epiploic hernias: case report and review of the literature. Surg Case Rep. 2015;1:104.]

should be reinforced using an intraperitoneal onlay mesh technique (IPOM). This requires the addition of a third cannula, usually 10 to 12 mm, because this size is necessary to accommodate the mesh. The prosthesis should be large enough to widely overlap the defect in all directions. Sutures are attached circumferentially around the prosthesis with long tails. The device is rolled tightly along its long axis and introduced into the abdominal cavity through the largest cannula in the configuration. It is then unrolled in the abdomen and secured to the abdominal wall using a trocar site fascial closure device. The long suture tails are brought out of the abdomen through separate myofascial/peritoneal sites but the same skin punctures. This allows for full thickness myofascial attachment with the knot resting in the subcutaneous tissue. Alternatively, tacks or fibrin glue can be used. For larger defects, a combination of these fixation techniques is advised, for example, sutures plus tacks. The mesh material should not have the tendency to erode into bowel because it is being placed intraabdominally. Expanded polytetrafluoroethylene (ePTFE) is acceptable, but more popular now is polypropylene or polyester that has one of several types of adhesion barriers incorporated into the side facing the viscera (Table 1).

Increasingly surgeons are moving away from IPOM techniques for any ventral hernia because of concern about leaving prosthetic material in the abdomen. A totally extraperitoneal approach can also be used that has the advantage of isolating the abdominal contents from the prosthesis. The procedure is similar to a totally extraperitoneal (TEP) inguinal herniorrhaphy, but the balloon dissector is placed more laterally to create the space needed for mesh location. An infraumbilical incision is made to accommodate a larger cannula for the balloon dissector and mesh insertion. The rectus sheath is opened on the side of the hernia and the balloon dissector introduced into the space between the rectus muscle and the posterior rectus sheath under direct vision with an indwelling 0-degree telescope. The balloon is directed inward (to hernia rather than the pubic tubercle, as would be done for an inguinal hernia repair). Once the space is large enough, two additional 5-mm cannulas are placed along the midline between the symphysis pubis and the umbilicus. The dissection then can be completed using standard laparoscopic instruments, making the size and positioning for mesh overlap with a mesh prosthesis after the defect is closed primarily as was described above with the IPOM approach. The procedure can also be performed using a transabdominal preperitoneal technique (TAPP), which is particularly well suited for robotics. Cannula positions are similar to the IPOM, which allows the peritoneum above the hernia defect to be incised transversely, followed by a dissection of the preperitoneal space as in the TEP. Regardless of the technique chosen, an adequate mesh overlap of more than 3 cm is required.

LUMBAR HERNIA

Lumbar hernias develop through a weakening of the posterolateral abdominal wall and can contain intraperitoneal or extraperitoneal contents. They occur in an area bordered superiorly by the twelfth rib, inferiorly by the iliac crest, medially by the lateral edge of rectus sheath, and laterally by the psoas muscle. There are three types: (1) superior, (2) inferior, and (3) diffuse. Superior and inferior lumbar hernias occur through classical anatomic triangles described below and are referred to as *primary or spontaneous*. This makes up only about 10% of lumbar hernias, with fewer than 300 reported cases since 1900. Diffuse lumbar hernias are much more common, usually the result of trauma, infection, or poor healing of flank incisions for renal or adrenal procedures. Previous flank incisions can also cause a "pseudo hernia" because of the ablation of lower thoracic nerves resulting in paralyzed muscle with loss of muscle control and tone, but there is no actual fascial defect.

Anatomy

Primary lumbar hernias occur through one of the two lumbar triangles (Figs. 5 to 8). The superior lumbar triangle, also known as the

FIG. 6 Thoracoabdominal view of the defect after the examination has been retracted. The small diameter of the defect is typical and probably accounts for the high rate of strangulation on presentation. [From Modena R, Luneau R, Moscatelli P, et al. Laparoscopic repair of lumbar hernia: a case report and literature review. Int J Surg. 2012;10(4):211–214.]

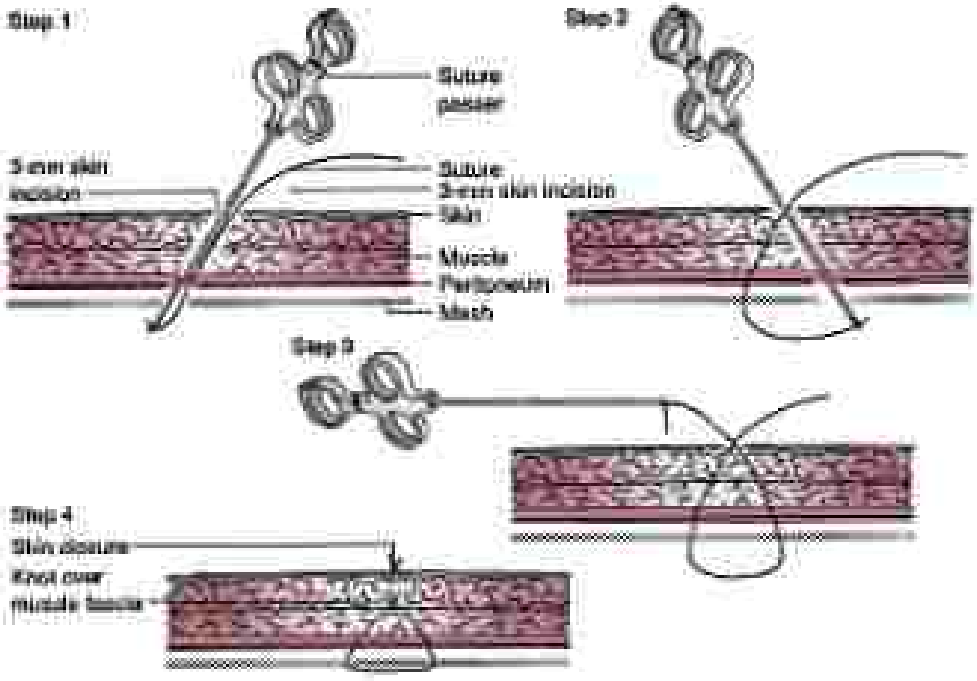

FIG. 8 Closure of a small lumbar hernia defect using a laparoscopic suture device. In step 1, the closure device with a needle is passed through a 5-mm skin incision and brought into the abdominal cavity on one side of the hernia defect. In step 2, the device is then right back to the anterior cavity leaving the suture in the abdomen. The device is then advanced at a different angle to secure the abdomen. In step 3, the suture is tied closing the hernia defect, and the device is removed. Both sutures are secured. In step 4, the suture is tied closing the hernia defect, and the device is removed. Both sutures are secured. [From Modena R, Luneau R, Moscatelli P, et al. Laparoscopic repair of lumbar hernia: a case report and literature review. Int J Surg. 2012;10(4):211–214.]

Grynfelt triangle, is bounded laterally by the posterior border of the internal oblique muscle, the medial border of the quadratus lumborum and superiorly by the twelfth rib. The floor of the triangle is the transversalis fascia, and the roof is made up of the external oblique and latissimus muscle. The inferior lumbar triangle, also known as Petit's triangle, is bounded by the anterior border of the external oblique muscle, the posterior border of the latissimus dorsi muscle, and the inferior border of the iliac crest. The superficial fascia and the internal oblique muscle make up the roof and the floor, respectively.

Clinical Presentation

Congenital lumbar hernias occur from birth mainly as the result of defective development of the musculoskeletal system or the posterior abdominal wall. These hernias are usually associated with other congenital abnormalities, including undescended testes, bilateral renal agenesis, and abnormalities of the spine, ribs, and other viscera. Congenital hernias are more common in the superior lumbar triangle. Lumbocostovertebral syndrome is a rare disorder characterized by congenital absence of ribs, myelomeningocele, scoliosis, hemivertebrae, and hypoplasia of the truncal and abdominal wall and is associated with an increased incidence of lumbar hernias. The syndrome may also be associated with vertebral defects, anal stenosis, cardiac defects, tracheoesophageal fistula, renal abnormalities, and limb abnormalities. Malrotation of the left kidney and hydronephrosis can also be associated with an increased risk of congenital lumbar herniation.

Acquired primary lumbar hernias are uncommon, with an increased risk with older age, rapid weight loss, muscular atrophy,

FIG. 10 Axial computed tomography image showing the typical appearance of a traumatic lumbar hernia. (From Kobbe I, Dasco T, Houghton D, Carey S. Limiting of traumatic lumbar hernia repair: a delayed sac, or wait? Report of two cases and review of the literature. Hernia. 2011;15:1.)

chronic bronchitis, extremes of body mass, chronic debilitating disease, and severe physical activity. An Internet search has described a mnemonic that may be helpful in the ED to play a role because we don't, above pubic hair, and medial to the anterior superior iliac spine. The acronym mnemonic triangle of pain (groin, testicular pain) and groin bulge (incarceration and strangulation) are common symptoms of inguinal hernia. Surgical management is not always necessary in the ED, but it is important to recognize the presence of a hernia and to consult a surgeon. Patients with incarcerated hernias should be admitted to the hospital for surgical repair. Patients with strangulated hernias require emergent surgical repair.

Inguinal hernias can be classified as direct or indirect. Indirect hernias are the most common and occur when the peritoneum protrudes through the internal inguinal ring, which is lateral to the inferior epigastric vessels. Indirect hernias can descend into the scrotum. Direct hernias occur through the posterior inguinal wall (Hesselbach triangle) medial to the inferior epigastric vessels. Direct hernias do not descend into the scrotum. Femoral hernias occur below the inguinal ligament and medial to the femoral vein. Femoral hernias are more common in women than in men. Femoral hernias are the most likely to present with incarceration or strangulation because of the narrow neck of the hernia sac. Femoral hernias can be difficult to diagnose because they can be confused with inguinal lymphadenopathy or a psoas abscess. Ultrasound can be helpful in differentiating these entities. Femoral hernias are usually repaired through an inguinal approach. Patients with femoral hernias should be placed in the supine position with the hip flexed, abducted, and externally rotated. The surgeon should stand on the patient's left side. The skin incision is made over the femoral canal, which is located inferior to the inguinal ligament and lateral to the pubic tubercle. The hernia sac is identified and dissected free from the surrounding tissues. The sac is opened and its contents are examined. If the contents are viable, they are reduced into the abdomen. The hernia sac is then ligated and excised. The femoral canal is closed with a suture. Incarcerated hernias can be reduced in the ED by applying gentle pressure to the hernia while the patient is sedated. Reduction should be attempted only if the hernia is tender, firm, and irreducible. If the hernia is not tender, it may be necessary to wait for the swelling to subside before attempting reduction. Strangulated hernias require emergent surgical repair.

Ventral hernias can occur at any point along the ventral abdominal wall. They can be classified as epigastric, umbilical, incisional, or spigelian hernias. Epigastric hernias occur in the midline between the xiphoid process and the umbilicus. They are caused by a defect in the linea alba. Umbilical hernias occur through the umbilical ring. They are common in infants and children. Incisional hernias occur at the site of a previous surgical incision. They are caused by a defect in the fascia. Spigelian hernias occur through the spigelian fascia, which is the aponeurosis of the transversus abdominis muscle. They are rare and usually occur in the lower abdomen.

Ventral hernias can be reducible or irreducible. Irreducible hernias can be painful and can lead to a variety of complications, including bowel obstruction and strangulation. Ventral hernias are usually repaired through an open approach. The patient is placed in the supine position with the arms tucked at the sides. The surgeon makes an incision over the hernia sac. The sac is opened and its contents are examined. If the contents are viable, they are reduced into the abdomen. The hernia sac is then ligated and excised. The fascial defect is closed with sutures. Mesh may be used to reinforce the repair.

After the repair, the patient is placed in the dorsal decubitus position. A sterile prep and drape is performed. A local anesthetic is injected into the skin and subcutaneous tissues. A small incision is made in the skin overlying the hernia. The hernia sac is identified and dissected free from the surrounding tissues. The sac is opened and its contents are examined. If the contents are viable, they are reduced into the abdomen. The hernia sac is then ligated and excised. The fascial defect is closed with sutures. Mesh may be used to reinforce the repair. The skin incision is closed with sutures or staples. A sterile dressing is applied.

Postoperatively, the patient is placed in the dorsal decubitus position. A sterile prep and drape is performed. A local anesthetic is injected into the skin and subcutaneous tissues. A small incision is made in the skin overlying the hernia. The hernia sac is identified and dissected free from the surrounding tissues. The sac is opened and its contents are examined. If the contents are viable, they are reduced into the abdomen. The hernia sac is then ligated and excised. The fascial defect is closed with sutures. Mesh may be used to reinforce the repair. The skin incision is closed with sutures or staples. A sterile dressing is applied.

subcutaneous tissue extended caudally to the iliac crest, where several bone anchors were placed again with long suture tails. The lateral edge of the rectus muscle and the psoas muscle were also exposed. Next the peritoneum was closed completely, isolating the intra-abdominal viscera from the abdominal wall. A heavyweight polypropylene mesh was secured to the iliac crest with the bone anchors. It was stretched tightly across the closed peritoneum and attached to the previously placed rib sutures. Laterally the mesh was attached to the psoas muscle and medially to the lateral edge of the rectus sheath with continuous suture. The superficial muscles, which were quite attenuated, were closed over the prosthesis in an imbricating fashion to minimize any residual bulge.

OBTURATOR HERNIA

Obturator hernias are rare, most commonly occurring in thin, elderly women, and for this reason it is sometimes referred to as the "little old lady's hernia." The mortality rate for repair is high, especially when complicated due in no small part to the frailty of the patients. Thus prompt diagnosis and treatment is crucial for a successful outcome but is often difficult to achieve because of the lack of the obvious physical findings that occur with other abdominal wall hernias.

Anatomy

The obturator canal is a 1- to 2-cm wide and 2- to 3-cm long opening in the superior part of the obturator membrane covering the foramen formed by the union of the pubic bone and ischium, through which the obturator nerve, artery, and vein pass. It starts in the pelvis and follows an oblique downward course, exits the pelvis, and ends in the obturator region of the thigh. An obturator hernia will occur through the obturator canal (Fig. 12). The sac usually follows the course of the obturator nerve, which has an anterior and posterior branch (Fig. 1.1). Visualizing this laparoscopically, the defect is inferior to the iliopubic tract and the pectineal (Cooper) ligament and quite medial to the femoral canal (Fig. 14). This should not be confused with a femoral hernia, which also occurs below the iliopubic tract but is superior to the pectineal ligament, with the defect immediately medial to the femoral vein.

Clinical Presentation

Obturator hernia is an infrequent hernia characteristically difficult to diagnose on examination. The incidence has historically been noted to be between 0.07% and 0.14% of all abdominal wall hernias; however, in a more recent retrospective review of 1,127 patients undergoing laparoscopic repair of inguinal hernias, obturator canal defects were discovered in 0.8% of patients, 9.1% of whom were women. The typical patient presenting with obstruction due to incarceration is female, in her 70s or 80s, and with a body mass index below 25. The hernia is more frequent on the right and is occasionally bilateral. Presentation and diagnosis are often made acutely in a thin, elderly woman presenting with bowel obstruction. Nonacute symptoms are often vague, characterized by intermittent lower abdominal pain, transient episodes of obstruction with spontaneous resolution, or nonspecific gastrointestinal complaints, such as early satiety, anorexia, and weight loss. The hernia may compress the obturator nerve, causing obturator neuralgia, which is neuropathic pain in the region of the medial thigh that radiates behind the knee. Physical examination findings are also nonspecific and unlikely to identify the hernia because the associated mass is concealed beneath the adductor muscles of the thigh. The Howship–Romberg sign, neuropathic pain originating from compression of the obturator nerve elicited on the ipsilateral inner thigh with extension, adduction, or medial rotation and relieved by hip flexion, is said to be pathognomonic. The diagnosis may also be made by palpation of the hernia mass on vaginal or rectal examination, or rarely a groin mass may be palpable, with the patient supine, with the thigh flexed and the hip adducted and laterally rotated. But distinguishing this from the more common femoral hernia or large inguinal hernia is difficult. Plain roentgenograms of the abdomen may confirm bowel obstruction but are not diagnostic of an obturator hernia as the cause. CT scan or MRI of the abdomen/pelvis will likely identify a transition point near the obturator canal and possibly an overt hernia (even in cases of obstruction but is less reliable in nonobstructed patients. The hernia most often contains small bowel, but the sigmoid, appendix, mesentery, colon, and preperitoneal fat can also be involved.

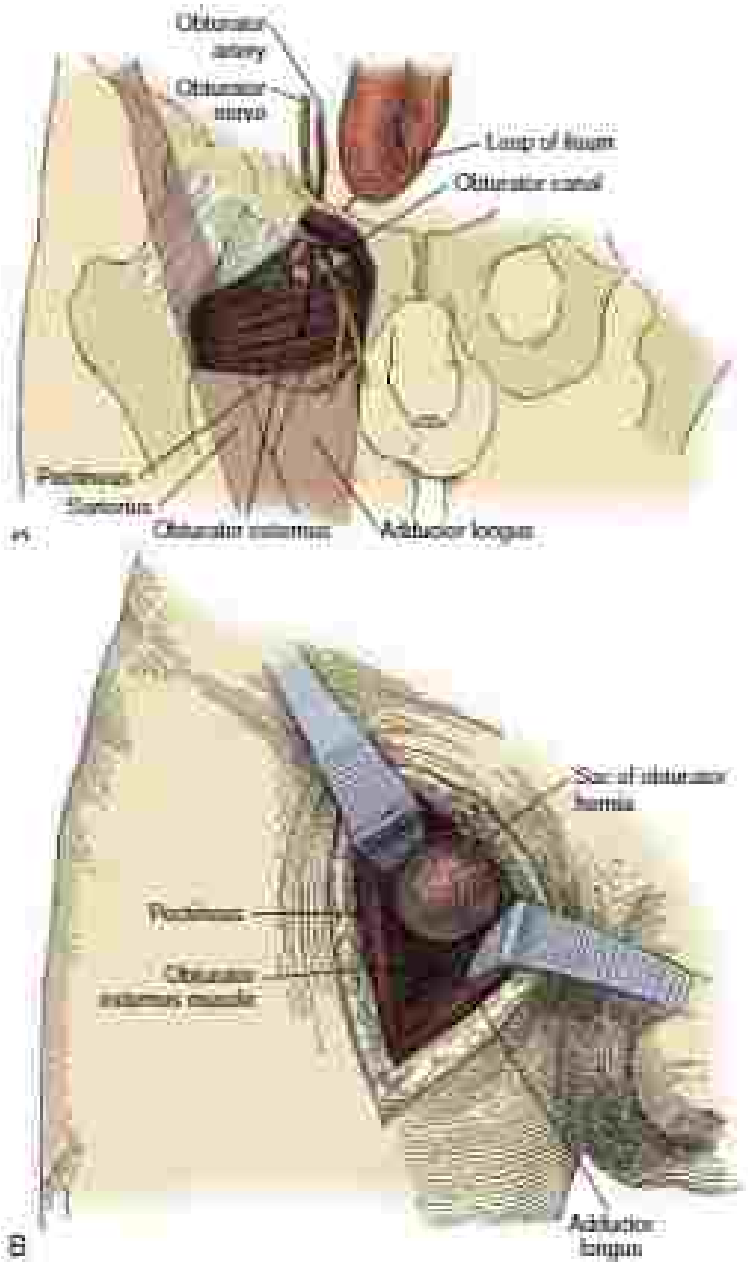

FIG. 12 (A) Portions anatomy of the obturator canal. B) Obturator hernia.

Treatment

The hernia should be repaired at diagnosis in patients at acceptable risk because of the significant incidence of complications if untreated. The choice of the type of repair is dependent on clinical factors, as well as surgeon experience and preference. In elective cases and even urgent cases when there is minimal concern of potential contamination caused by prolonged bowel strangulation, a robotic or pure laparoscopic TAPP would be the approach of choice. Essential in the operation is reduction of hernia content with evaluation for nonreducible ischemia, a complete reduction of the peritoneum and associated preperitoneal fat, and then closure of the defect with either direct suture closure using permanent ligatures or placement of prosthetic mesh with closure of the peritoneal defect overlying the fixated mesh. A laparoscopic TEP would also be an option if no concern existed for ischemia with the advantage of not opening the peritoneum and potentially avoiding intraabdominal adhesions but with the disadvantage of not visualizing for potential compromised hernia content. A Richter-type antimesenteric incarceration of small bowel with potential for later tissue compromise should always be a consideration. In either case, if a prosthetic mesh is selected and adequate visualization obtained, use of a large prosthesis to cover the inguinal, femoral, and obturator orifices is optimal.

Urgent repair of an obturator hernia associated with bowel obstruction is mandatory because mortality rates between 11% and 30% have been reported. The typical patient has significant comorbidities and a high frailty index. A minimally invasive approach can minimize these associated risk factors but in the case of overt sepsis, strangulation, high-grade obstruction with distended edematous bowel, and factors typically prompting safe laparoscopic surgery an open operation would be deemed best. The open approach is best performed through a low midline incision. The hernia content is reduced, which sometimes requires dividing the obturator membrane in the direction of the Cooper ligament. Incarcerated hernia contents are inspected with appropriate management of ischemia. Primary closure is performed

Cranial view of the obturator canal demonstrating that the hernia sac can follow either the anterior or the posterior branch of the obturator nerve. *(From Hamman R, Iskandarani Q, Fares O, Mehta P. Obturator hernia: medical surgical evolving embryology diagnosis, and technique of repair. Ann Surg. 2015;261:47–57.)*

FIG. 14 Laparoscopic view of an obturator hernia defect. *(From Lamb J, Robbins T, Lapsley M, Lapsley C. Novel classification to obturator hernia: a clinical imaging diagram. Int J Surg Case Rep. 2018;51:154–157.)*

if adjacent tissue can be approximated, either muscle to muscle or muscle to periosteum of the pubic bone or a patch formed to cover the defect with omentum, bladder or other local tissue. Alternatively, a mesh is placed over the defect, with fixation to the Cooper ligament superiorly and the obturator muscle inferiorly. If the defect cannot be covered with peritoneum, either dPTFE or one of the newer adhesion barrier products should be used to avoid later bowel complications (Table 1). In the event of contamination, a biologic mesh can be considered. Care needs to be taken in the closure of the defect or fixation of mesh to not incorporate the obturator nerve branches. Recurrence rates are low after obturator hernia repair.

Athletic Pubalgia: The "Sports Hernia"

[illegible] MD, MA

The diagnosis and management of athletic pubalgia is a complex undertaking. Over the terminology to describe the condition has been controversial, primarily because the most commonly used term, sports hernia, is not an accurate description of the underlying disease for most cases. For most patients who are diagnosed with a sports hernia, no true hernia defect is present. More recently, the term core muscle injury has been applied to this condition. The management can be a long and frustrating process, and the decision to proceed with more aggressive treatment, including surgery, can be complex. The basic strategies and techniques for surgical management also vary, and although most patients do well with surgical management from those surgeons who are experienced treating this condition, failures still exist regardless of the approach. This chapter discusses the background, diagnosis, and management of athletic pubalgia, and it presents a concept for learning and improving care for treating complex conditions such as athletic pubalgia.

BACKGROUND

Athletic pubalgia is defined as chronic groin pain (lasting more than

It seems without improvement, or the patient not able to return to normal athletic activities) in an individual who frequently engages in athletic and/or strenuous activity. It is diagnosed in the absence of a palpable hernia and when other causes of inguinal pain are excluded. Because of the lack of a visible or palpable hernia defect, this syndrome has not been well understood by many general practitioners. With the advent of social media and increasing news coverage about professional athletes whose careers have been interrupted or ended as a result of this condition, attempts to better understand the complex nature of this problem have been made. Although this condition has been popularized by the experience of professional athletes, it also affects athletes in college and high school, as well as recreational athletes and people who perform strenuous activities.

In 1970, Gilmore recognized chronic groin pain in professional athletes, mainly soccer players, and undertook surgically repairing the disruption. This condition was subsequently referred to as Gilmore's groin. A similar condition was also reported in Europe and Australia. Many investigators have described the chronic lower abdominal and groin pain in professional athletes as a syndrome secondary to muscular injury or incipient inguinal hernias. In 1991, Taylor and colleagues concluded that the majority of groin pain in athletes was caused by muscle strains, inguinal hernias, or subclinical abdominal wall defects without herniation. In a smaller subset of cases, however, there was no palpable hernia or any other cause of groin pain. Following the terminology used in the European literature, they referred to this condition as pubalgia.

ANATOMY, PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Etiology

Gilmore identified tears external oblique aponeurosis, torn conjoint tendon, and defects between the torn conjoint tendon and inguinal ligament as the underlying causes of chronic groin pain. Meyers and colleagues suggested that hyperextension injury, with the pivot point being the anterior pelvis or pubic symphysis, is the most likely etiology of athletic pubalgia, and used the term core muscle injury.

Tendons of the rectus abdominis and adductor longus insert on the pubic symphysis and antagonize each other. This anatomic apparatus, when combined with sport activities that involve rapid pelvic movements such as hyperextension, can potentially injure weaker abdominal wall muscles. This group has documented more than 20 distinct anatomic defects from magnetic resonance imaging (MRI) results, with surgical recommendations based on each abnormality (Table 1).

A different perspective on the mechanism of this condition focuses on the notion that the syndrome is an occipital hernia, with the defect being in the transversalis fascia, which comprises the posterior wall of the inguinal canal. Polglase and colleagues found substantial derangement in the posterior wall of the inguinal canal in 43 of 50 professional athletes (mostly Australian rules football players who presented with chronic groin pain and underwent surgical exploration of the inguinal canal).

Although a consensus on the complex nature of chronic groin pain in an athlete is yet to be established, a third viewpoint combines both mechanisms of muscle tear and occipital hernia, or groin floor weakness, and categorizes this condition as one component of a broader pattern of core disruption injury. According to this school of thought, this problem consists of an occult or incipient direct hernia, which is derived from pelvic instability. This underlying mechanism also gives rise to other groin syndromes such as iliopsoas pain, contralateral adductor tendinopathy and/or tear, adductor tendinopathy and/or tear, and nerve entrapment and/or irritation of the variety of nerves in the groin and pelvic area.

Concepts at Risk

Chronic groin pain is more likely to occur in athletes who engage in sports that require sudden turns and pelvic movements and/or those that require the athlete to push hard against resistance. It is thought that the highest prevalence occurs in athletes who are professional soccer players, ice hockey players, and in athletes who play American or Australian rules football and rugby. There seems to be an increase in the number of female athletes experiencing chronic groin pain as more women engage in competitive sports. It has also been postulated that gender specific anatomic variation may play a role in predisposing male athletes, more than female athletes, to developing chronic groin pain. Women typically have a broader pelvis and a wider pubic symphysis that allows for more surface area of muscle insertion and more stability than the narrower, less stable male pelvis. Brophy and colleagues demonstrated that male soccer players tend to generate a greater activation of the elastic muscles in the kicking limb; this difference may contribute to a higher susceptibility to developing chronic groin pain. Other risk factors include limb length discrepancy, poor pelvic muscle balance, reduced hip range of motion, and pelvic instability.

Presentation and Differential Diagnosis

Athletes with chronic groin pain often present with lower abdominal pain on exertion. Most can recall a distinct injury during exertion before the onset of the pain; however, this condition can sometimes occur gradually from overuse and chronic repetitive injury. The pain is usually located in the inguinal region around the insertion point of the rectus abdominis muscle on the pubis or along the course of the ilioinguinal nerve. Most patients experience unilateral pain, although in some athletes, their symptoms begin with unilateral pain and progress to bilateral pain. The pain may also radiate to the lower abdomen, perineum, scrotum, or thigh. At rest, there is usually minimal or no pain. Valsalva maneuvers such as coughing or bearing down may sometimes reproduce the pain. Adduction against resistance can exacerbate the pain in some patients. The majority of these patients report that their groin pain preceded their adduction pain. Patients will experience these symptoms for many months, and some persons

TABLE 1 Surgical Management of Core Muscle Injuries

Structure or Syndrome	Incidence (%)	Defect	Possibly Indicated Procedure
Unilateral rectus abdominis/ unilateral adductor	22	Tear and compartment syndrome	Repair and compartmental decompression
Adductor longus	16		
Pectineus	12		
Adductor brevis	8		
Pure adductor syndromes	11	Usually compartment syndrome	Compartmental decompression
Unilateral rectus abdominis	10	Tear	Repair
Bilateral rheumatoid arthritis	15	Tears	Repair
Lower rectus variant	8	Usually tears, compartment syndrome, and hernia	Repair, compartmental decompression, and steroid injection
Hogmose variant	4	Impingement and hernia	Lengthening procedure
Turnbull pitcher/hockey goalie syndrome	4	Adductor tear and adductor muscle belly compartment syndrome	Compartmental decompression
Inguinal hernia	4	Tear	Repair
Rectus forearis variant	3	Impingement	Compartmental decompression
High rectus abdominis variant	2	Tear	Repair
Female variant	2	Medial disruption with lateral thigh compression	Repair and compartmental decompression
Rectal ligament syndrome	1	Inflammation with tear	Repair and excision
Jansen's variant	1	Obturator foramen/external	Compartmental decompression
Rutten's rib syndrome	1	Subluxation	Excision and rest
Avulsions		Usually acute adductor injury	Repair and compartmental decompression
Adductor/rectus abdominis calcification syndrome	1	Chronic avulsion	Excision, compartmental decompression
Midline rectus abdominis variant	1	Tears and muscle separation	Repair
Anterior pubic tuberosity variant	1	Posterior perineal inflammation, groin, hamstrings	Compartmental decompression
Adductor contractures	1	Often associated with hip pathology	Compartmental decompression and hip repair

Modified from Meyers WC, McKechnie A, Philippon MJ, et al. Experience with "sports hernia" spanning two decades. Ann Surg 2008;248:656–665.

with having suffered from their groin for more than 1 year. At the time of presentation, the majority of athletes have stopped competitive physical activity or they are limited in their ability to compete.

On physical examination, a localized tenderness can be elicited near the rectus abdominis insertion above the pubic tubercle on the affected side or on both sides, depending on the course of the pain progression. This finding is more pronounced during a resisted sit up. Additional findings may include inguinal canal tenderness or tenderness at the hip adductor origin. A pain along the adductor longus tendon on the affected side may also be elicited on forceful adduction. Occasionally, a cough impulse can be palpated at the rectus abdominis origin when the patient is standing. It is uncommon to palpate a cough impulse at the external inguinal ring. A thorough physical examination should generally rule out inguinal hernia.

The differential diagnosis for groin pain without a hernia bulge can be extensive (Fig. 1). The patient can have more than one condition, including inguinal (direct and/or indirect), femoral, obturator, or other rare hernias in the groin and pelvic region. A lipoma of the spermatic cord may also be present. For most athletes with chronic groin pain, however, they are otherwise healthy and the duration of the pain, the location of the pain, and the activities that bring on the pain will differentiate this problem from other conditions.

Diagnostic Approach

Chronic groin pain in athletes is primarily diagnosed by history and physical examination. Most data in the literature indicate that imaging studies have relatively poor diagnostic value. They can be helpful, however, to rule out other causes of groin pain and may identify specific musculoskeletal injuries causing pain in some cases.

MRI is an imaging modality that can occasionally provide helpful data in diagnosing chronic groin pain in athletes, particularly when the underlying mechanism is muscle or tendon tear. Yet, its reported sensitivity can vary greatly, likely because of the experience of the radiologist reading the film and to the many false positives that may occur when injuries are identified but are not actually causing the symptoms. MRI may also be helpful to rule out occult pubic, sacral, sacral or pubic fracture, and other etiologies of groin pain.

Another imaging technique that may be helpful in diagnosing sports hernia in the setting of inguinal canal posterior wall defect is

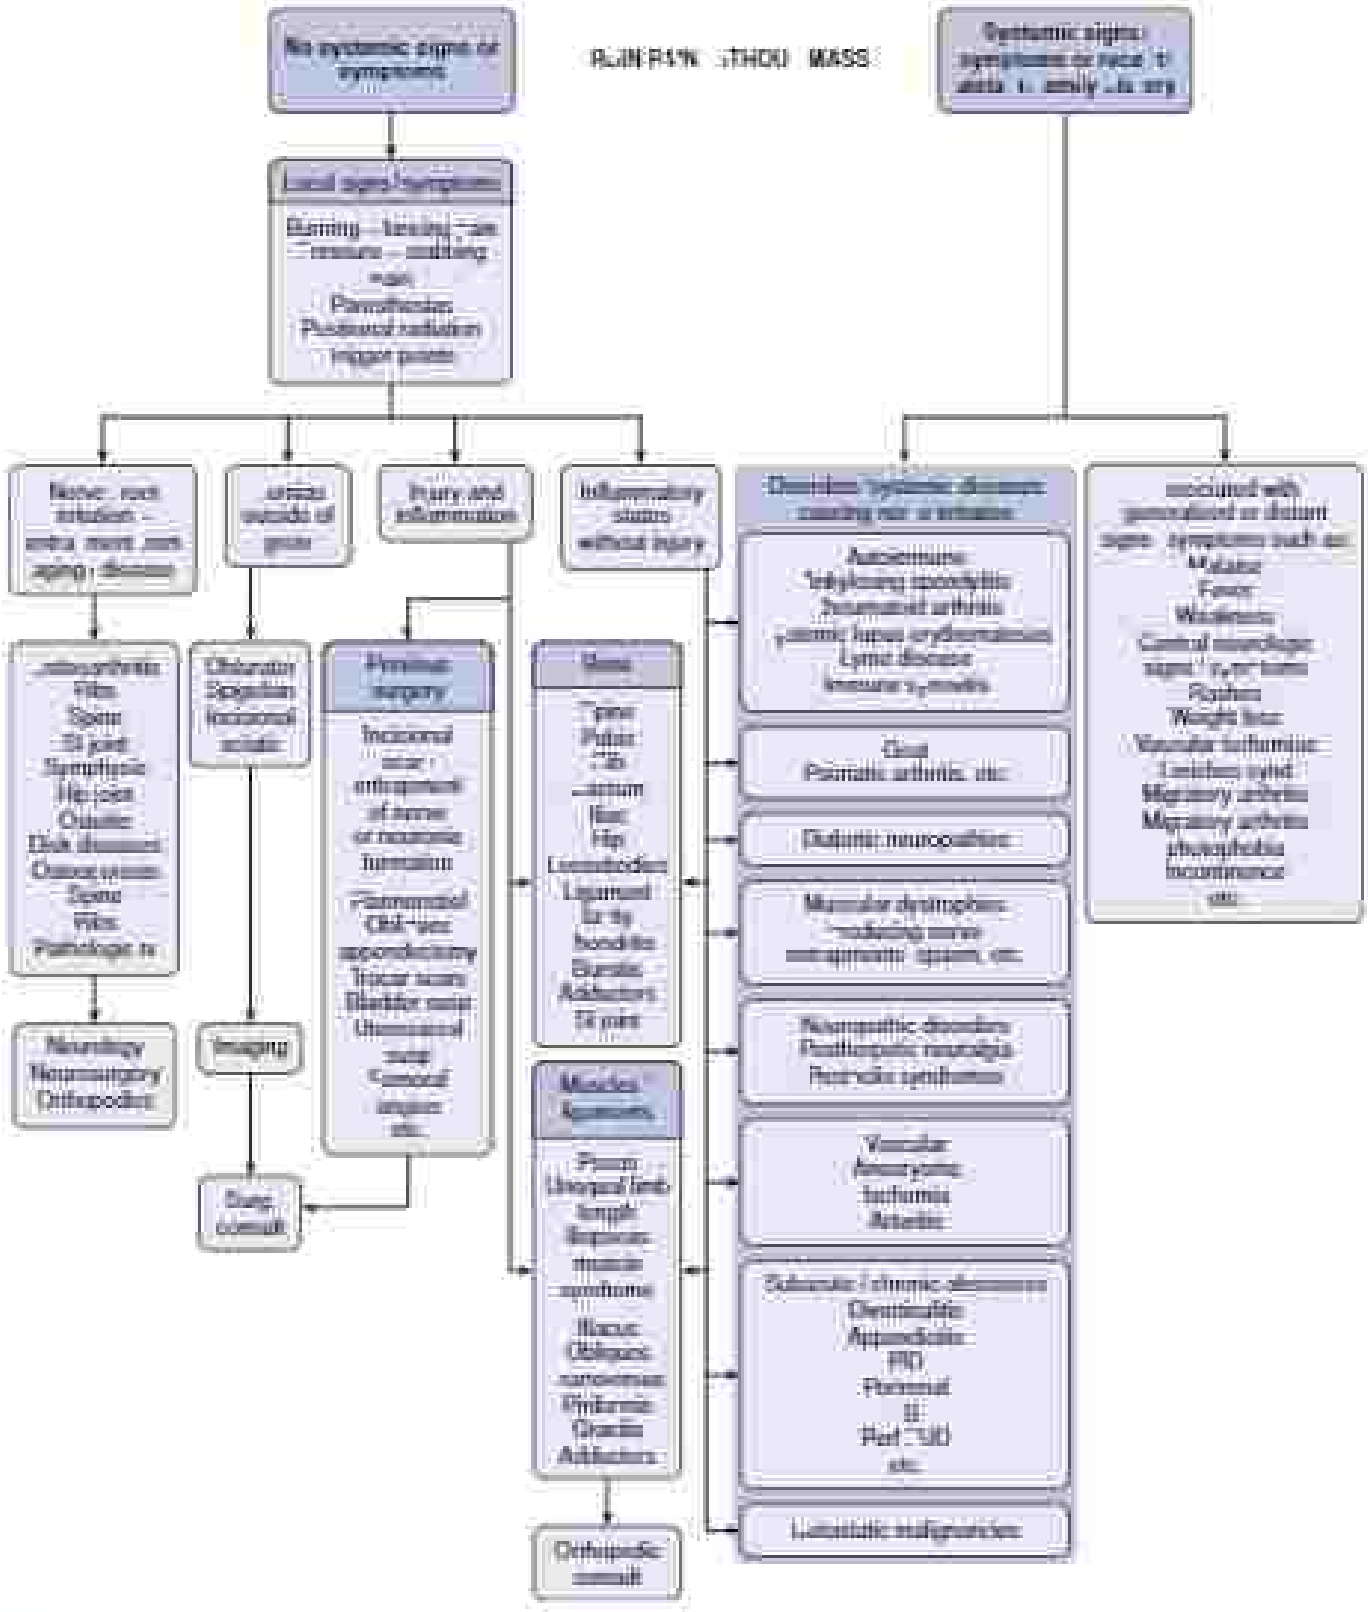

FIG. 1 Possible differential diagnoses and potential referral specialties/symptoms for a patient with groin pain and no groin mass. ↓, ↓ signs/symptoms; ↑, increased; PeriF (PUD), perforated peptic ulcer disease; PID, pelvic inflammatory disease; TURP, transurethral prostatectomy; ↑, laboratories.

dynamic ultrasonography. In this technique, the probe is placed on the medial aspect of the inguinal region, first along the plane of the inguinal canal and then perpendicular to the initial position. At each position, the patient is asked to cough or bear down; if a defect is present, ballooning of the posterior wall of the inguinal canal will be present.

Computed tomography scan or plain radiograph are usually normal in athletes with chronic groin pain from athletic pubalgia. They may, however, provide information to rule out bony fractures or other causes of pain.

MANAGEMENT

Nonsurgical

Most cases of groin pain in athletes will resolve with conservative strategies. When pain does not resolve after a 6- to 8-week period of rest and conservative management strategies, surgery to obtain the most definitive management for patients with athletic pubalgia. Conservative management includes rest, core strengthening exercises, stretching, and antiinflammatory medications. The initial rest period is usually 1 to 8 weeks, and during this period, the athlete may receive steroids or platelet rich plasma injections to the rectus abdominis, adductor longus origin, or both. If injections are not desired, the patient may receive a short course of oral steroids, which is quickly tapered. At the end of the 4-week period, a functional trial of an athletic regimen appropriate for the athlete's sport is performed to evaluate the patient's response to the conservative management. Core strengthening exercises may emphasize the development of a strong single limb stance and pelvic rotation exercises against resistance. Some of the works in Suggested Readings describe in more detail the prophylactic and conservative physical training exercises and strategies to prevent and manage sports hernias nonoperatively.

As most athletes know, the power of the mind is especially important in overcoming obstacles. In recent years, the research on cognitive brain changes that occur from traumatic events and other forms of suffering such as chronic pain has revealed that many of these patients can benefit from many tools from the field of cognitive behavioral therapy. These additional resources for patients will potentially allow them to develop coping mechanisms to deal with their pain instead of or in addition to using surgery or medications as the primary treatment options. Many of these patients have been trying to deal with this problem on their own for a significant period. To help cognitively rewire their brain pain pathways, our hernia program frequently refers patients to clinical therapists as part of a "prehabilitation" program. This may be especially important in patients who suffer from chronic pain and other complex problems. By approaching this very complex issue from the standpoint of systems science, patients will receive a more holistic healthcare management plan.

Surgical

There are a variety of surgical approaches based on the philosophies about the causes and the documented pathologies found for patients with an athletic pubalgia. We present the laparoscopic approach first; the various open methods are then described.

Laparoscopic Approach

The concept behind a laparoscopic approach for a sports hernia is to reinforce the groin from the inside or behind the groin to block intra-abdominal pressure and allow healing of any musculoskeletal injury. This approach may be most helpful for patients with groin weakness and occult hernias, which might contribute to the patient's symptoms. Although a total extraperitoneal approach is typically used, a transabdominal approach may be used in patients with atypical pain or two different types of pain for which a diagnostic laparoscopy may be indicated.

The technique involves exposure of the entire myopectineal orifice, including reduction of any preperitoneal fat from the indirect space (hernia of the cord), the femoral space, or obturator foramen. Other rare hernias of the groin may also be visualized and reduced. The most common finding during a laparoscopic approach to a weak transversalis over the direct space. Occasionally, actual tears can be visualized. A mesh is used to cover the entire myopectineal orifice that provides a barrier to intraabdominal pressure that may contribute to the lack of healing of the groin. This would also cover any true hernia defects. The type of mesh used may be extremely important. Chronic groin pain after mesh hernia repair can be a devastating complication. Our hernia program has evaluated hundreds of mesh explants for the patient with athletic pubalgia, we now offer a variety of alternatives to the standard heavyweight polypropylene mesh. The wider pore, lightweight polypropylene mesh has become a popular option. There are also other polymers, such as polyester that is relatively hydrophilic, and nanowoven polypropylene and coated polypropylene, both of which may result in less inflammation and better biocompatibility within the body. Richer, long term resorbable meshes (synthetic and biologic) are available that can provide the necessary support for the groin during healing and recovery and will mesh over many months or years to have no permanent material in the groin (although some types of biologic mesh may not fully resorb). We provide patients with these options with the most current information available, so they can make their own mesh decisions. A polyester mesh and a long term resorbable synthetic mesh used for a laparoscopic approach to athletic pubalgia are shown in Fig. 2. Fixation of mesh may include no fixation, absorbable tack fixation, or glue fixation. Although permanent tack or staple fixation might be used, this may increase postoperative pain.

FIG. 2 Polyester mesh used for laparoscopic sports hernia repair at the right groin.

Open Mesh Approach

Similar to the laparoscopic approach, the focus of an open mesh placement is to reinforce the floor of the groin to allow for groin stability and musculoskeletal healing. A lightweight polypropylene mesh is typically used and placed similar to a Lichtenstein approach for inguinal hernia repair. Other mesh alternatives described for the laparoscopic approach could also be used. One advantage of the open mesh approach is the opportunity to divide the genital branch of the genitofemoral, the ilioinguinal, and/or the iliohypogastric nerves if they are entrapped in scar tissue or in the tissue disruption caused by musculoskeletal injury. Alternatively, a neurolysis may be performed if a scar tissue release appears appropriate.

Combined Laparoscopic and Open Approach

Although this technique has been described in the literature for patients with previous hernia repair who developed chronic groin

FIG. 2 Long-term mechanistic mesh used for laparoscopic sports hernia repair of the left groin.

pain, a combined laparoscopic and open approach could be used in patients with athletic pubalgia. As stated, patients with athletic pubalgia typically have been dealing with chronic pain for many months before seeking treatment. In a study by Lindsay and colleagues, when comparing strictly laparoscopic versus strictly open repair versus a combined open and laparoscopic technique, patients who underwent a combined laparoscopic and open surgery had better resolution of their pain postoperatively.

Open Nonmesh Approaches

A variety of open nonmesh approaches have been described. One approach popularized by Muschaweck is presented as an open minimal repair technique. The procedure involved a repair of the posterior inguinal floor with two running sutures, including imbrication of the rectus muscle with the second suture. Selectively, the genital branch may be divided if it is impinged by the scar or damaged in use. The internal ring is reinforced with a buttress of internal oblique muscle to protect the pampiniform plexus.

Meyer has promoted a more targeted approach to repair of the groin with a variety of techniques used, depending on the findings on the MRI and at surgery. General descriptions of these approaches include a variety of repair, release, and excision procedures that may include the reconstruction of the rectus abdominis to the pubis and a selective adductor tenotomy as indicated by the radiographic, clinical, and surgical findings. An adductor tenotomy may include partial release of the fibers approximately 1 to 2 cm from its attachment to the pubis. Transection with or without reattachment of the adductor longus has also been described.

Postoperative Course

In general, the postoperative recovery is quicker with the less invasive approaches. The laparoscopic approach is the least invasive and has the quickest recovery, with the open reconstructive approaches often requiring the longest recovery. Many factors, however, can affect recovery. The degree of preoperative pain, the nature of the athletic activity, and the dictates of the athlete's trainer, athlete, team owner, coach, and so on all play a role in the timing of return to full activity. In general, athletes may return to light activity in the first 1 to 2 weeks and may try their regular training regimen within 3 to 4 weeks. After appropriate strength, endurance, and flexibility are attained, return to full competition is appropriate. For very high level athletes, appropriate game conditions may be simulated to test the appropriateness of a return to full competition.

As mentioned, when performed by surgeons with experience treating sports hernias, all the procedures described achieve a relatively high rate of success in returning an athlete to his or her sport, but all of these techniques have failures as well. This demonstrates the reality that an athlete with chronic groin pain, as with most problems in health care, is a complex medical problem. For complex problems, a one size fits all solution will not work for every patient. In addition, the most aggressive, costly treatment cannot be used for every patient because of wasteful use of limited resources. The ideal situation would be to learn which patient subpopulations would be best treated with nonsurgical approaches, which would be best treated with minimally invasive approaches, and which would require the most aggressive or costly approaches requiring the longest recovery.

A relatively new science is now being applied to health care that can begin to determine the appropriate indications for the various presentations of complex medical problems such as chronic groin pain in athletes. Complex systems science tools such as continuous learning and clinical quality improvement can potentially lead to lower costs and better outcomes when the value of care is measured for the whole cycle of care for each definable problem such as chronic groin pain in an athlete. The first step in applying clinical quality improvement is to define the dynamic processes for the entire cycle of care in the context of a specific medical problem. In this case, the processes of care would be defined for an athlete from the time of the initial symptoms of groin pain until the ability to return to full competitive activity with no future incidence of groin pain. All appropriate treatment options would be included in the dynamic care processes, and the outcome measures that determine the value of care would be determined and documented. These outcome measures would include the cost for the entire cycle of care, quality measures, such as the relief of pain and the ability to return to full activities, and the patient's experience with his or her care process. By defining and documenting the care process and measuring the outcomes that determine the value of care, we can then use these results to provide feedback to improve the processes of care relentlessly over time. With more and more data and experience, this will allow for a better understanding of what the best value of care will be for each patient subpopulation.

Another element of complex systems science applied to health care is the emergence of care communities on the Internet for guidance in caring for complex medical problems, such as chronic groin pain in an athlete. Through websites, blogs, chat rooms, and other communication methods, more and more athletes experiencing the symptoms of chronic groin pain substituting the ability to play their sport are sharing their stories and experiences with symptoms and treatments. For complex medical problems, these groups and this body of information have been a relatively untapped resource as we strive to improve the value of care for athletes with chronic groin pain and other complex medical problems.

SUMMARY

Athletic pubalgia or core muscle injury is a problem that can be very frustrating for athletes suffering from pain and the inability to return to an activity they enjoy. This is usually a quality of life issue, but for high-level athletes, this can also be a serious economic problem as well. As with any complex medical problem, we will need models for continual learning and the application of complex systems science to better understand which patients will receive the most value from the variety of surgical and nonsurgical treatment options available based on their respective subpopulation. Ultimately, the goal of improving the value of care will lead to the development of innovative strategies to prevent this condition and to continuously improve outcomes for this group of patients.

Abdominal Wall Reconstruction

Adam Fra[illegible], MD, and Ale[illegible]y P. Tu[illegible], DO, MA, FACS

Abdominal wall hernia repairs are among the most common operations performed by general and plastic surgeons worldwide, and it is estimated that over 350,000 ventral hernia repairs are performed annually in the United States. Generally speaking, abdominal wall hernias are classified as incisional, epigastric, or umbilical depending on the hernia's location and underlying etiology but can be classified as "complex" with the addition of certain attributes such as loss of abdominal domain, associated enterocutaneous fistulas, parastomal location, mesh/graft location, bony abutment, and recurrence. The surgical management of simple abdominal hernia repair has been discussed elsewhere in this text and is not discussed in this chapter. In cases requiring advanced techniques for complex hernia repair, the term abdominal wall reconstruction (AWR) is a vastly more accurate appropriation and will be the focus of this chapter.

Complex abdominal wall hernias develop from multiple factors and scenarios. Whether a patient's hernia is simply a large defect associated with a stoma or enterocutaneous fistula, or the result of an abdominal catastrophe from trauma with a prolonged open abdomen has little impact on the goals of the reconstructive surgeon. These goals are the restoration of the integrity of the abdominal wall and its function to eliminate or prevent symptoms and/or complications. The etiology and presentation do, however, delineate the available options for reconstruction. In this chapter, following review of the relevant anatomy and preoperative evaluation, we will discuss the acute management of abdominal defects resulting from abdominal catastrophe, a frequent precursor to the development of complex abdominal wall hernias, and then review multiple surgical technical options for AWR.

ANATOMY

Successful reconstruction of the abdominal wall is based on a sound comprehension of the involved anatomy, especially the details regarding abdominal wall innervation and correct surgical dissection planes. It is also important to delineate the precise anatomy of the semilunar line, as its role in the correct execution of the traditional component separation, along with its many modifications cannot be overstated. Component separation techniques will be discussed further in the operative techniques section of this chapter.

The neurovascular supply of the anterior abdominal wall is important to understand in complex AWR. The motor and sensory innervation stems from T7–11, the fibers of which course in a plane between the internal oblique (IO) and the transversus abdominis (TA). They then penetrate the posterior rectus sheath roughly 3 cm medial to the semilunar line (Fig. 1). These structures are important to identify and protect during reconstruction to preserve the innervation and function of the abdominal wall. The primary blood supply is derived from the deep inferior epigastric artery, which is a branch of the external iliac artery prior to its travel beneath the inguinal ligament and its transition into the common femoral artery. The deep inferior epigastric artery travels cephalad within the lateral umbilical fold until passing anterior to the arcuate line and the posterior rectus sheath, and then provides a medial and lateral row of musculocutaneous perforators. The highest density of these perforators lies in the periumbilical region. Preservation of this blood supply during reconstruction will help to optimize the resulting skin perfusion and lessen chance of wound breakdown from flap ischemia.

The semilunar line is a composition of the aponeuroses of the external oblique (EO), IO, and the TA. Rises dissection the abdominal wall and the anatomy of the semilunar by separating it into thirds. In the upper third of the abdominal wall, the posterior lamellae of the IO aponeurosis and the muscle belly of the TA extend medial to the semilunar line (Fig. 1). In the middle third, the muscle belly of the TA ends laterally to the semilunar line, but its aponeurosis joins with the posterior lamellae of the IO aponeurosis as they form the posterior rectus sheath. This configuration continues in the lower third until the arcuate line, where both structures join the remaining lateral abdominal wall aponeuroses as part of the anterior rectus sheath, leaving only the transversalis fascia and peritoneum deep to the rectus below this level. The knowledge of the relationship of the TA muscle belly and the IO aponeurosis is key when performing the release of the TA in posterior component separation (PCS). The details of this technique will be discussed later in this chapter.

PREOPERATIVE OPTIMIZATION

When not in the setting of acute abdominal wall management, preoperative optimization is necessary to mitigate modifiable risk factors known to negatively impact AWR. These modifiable factors include smoking, obesity, diabetes, and malnutrition. The influence of smoking on postoperative complications is well known and includes decreased blood and tissue oxygen tension levels, impaired oxygen metabolism, increased platelet adhesiveness, and vasoconstriction. Patients undergoing AWR should quit smoking at least 4 weeks prior to surgery, as this amount of time has been shown to be the minimal effective time for reducing 30-day complications in surgical patients. Nicotine replacement therapy can be allowed as this seems to provide

Abdominal Wall Reconstruction

Adam Franklin, MD, and Anthony F. Tufaro, DDS, MD, FACS

Abdominal wall hernia repairs are among the most common operations performed by general and plastic surgeons worldwide, and it is estimated that over 350,000 ventral hernia repairs are performed annually in the United States. Generally speaking, abdominal wall hernias are classified as incisional, epigastric, or umbilical depending on the hernia location and underlying etiology but can be classified as "complex" with the addition of certain attributes such as loss of abdominal domain, associated enterocutaneous fistulas, parastomal location, mesh/graft location, bony abutment, and recurrence. The surgical management of simple abdominal hernia repair has been discussed elsewhere in this text and is not discussed in this chapter. In cases requiring advanced techniques for complex hernia repair, the term abdominal wall reconstruction (AWR) is a vastly more accurate appropriation and will be the focus of this chapter.

Complex abdominal wall hernias develop from multiple factors and scenarios. Whether a patient's hernia is simply a large defect associated with a stoma or enterocutaneous fistula, or the result of an abdominal catastrophe from trauma with a prolonged open abdomen has little impact on the goals of the reconstructive surgeon. These goals are the restoration of the integrity of the abdominal wall and its function to eliminate or prevent symptoms and/or complications. The etiology and presentation do, however, delineate the available options for reconstruction. In this chapter, following review of the relevant anatomy and preoperative evaluation, we will discuss the acute management of abdominal defects resulting from abdominal catastrophe, a frequent precursor to the development of complex abdominal wall hernias, and then review multiple surgical technical options for AWR.

ANATOMY

Successful reconstruction of the abdominal wall is based on a sound comprehension of the involved anatomy, especially the details regarding abdominal wall innervation and correct surgical dissection planes. It is also important to delineate the precise anatomy of the semilunar line, as its role in the correct execution of the traditional component separation, along with its many modifications cannot be overstated. Component separation techniques will be discussed further in the operative techniques section of this chapter.

The neurovascular supply of the anterior abdominal wall is important to understand in complex AWR. The motor and sensory innervation stems from T7–11, the fibers of which course in a plane between the internal oblique (IO) and the transversus abdominis (TA). They then penetrate the posterior rectus sheath roughly 3 cm medial to the semilunar line (Fig. 1). These structures are important to identify and protect during reconstruction to preserve the innervation and function of the abdominal wall. The primary blood supply is derived from the deep inferior epigastric artery, which is a branch of the external iliac artery prior to its travel beneath the inguinal ligament and its transition into the common femoral artery. The deep inferior epigastric artery travels cephalad within the lateral umbilical fold until passing anterior to the arcuate line and the posterior rectus sheath, and then provides a medial and lateral row of musculocutaneous perforators. The highest density of these perforators lies in the periumbilical region. Preservation of this blood supply during reconstruction will help to optimize the resulting skin perfusion and lessen chance of wound breakdown from flap ischemia.

The semilunar line is a composition of the aponeuroses of the external oblique (EO), IO, and the TA. Rises dissection the abdominal wall and the anatomy of the semilunar by separating it into thirds. In the upper third of the abdominal wall, the posterior lamellae of the IO aponeurosis and the muscle belly of the TA extend medial to the semilunar line (Fig. 1). In the middle third, the muscle belly of the TA ends laterally to the semilunar line, but its aponeurosis joins with the posterior lamellae of the IO aponeurosis as they form the posterior rectus sheath. This configuration continues in the lower third until the arcuate line, where both structures join the remaining lateral abdominal wall aponeuroses as part of the anterior rectus sheath, leaving only the transversalis fascia and peritoneum deep to the rectus below this level. The knowledge of the relationship of the TA muscle belly and the IO aponeurosis is key when performing the release of the TA in posterior component separation (PCS). The details of this technique will be discussed later in this chapter.

PREOPERATIVE OPTIMIZATION

When not in the setting of acute abdominal wall management, preoperative optimization is necessary to mitigate modifiable risk factors known to negatively impact AWR. These modifiable factors include smoking, obesity, diabetes, and malnutrition. The influence of smoking on postoperative complications is well known and includes decreased blood and tissue oxygen tension levels, impaired oxygen metabolism, increased platelet adhesiveness, and vasoconstriction. Patients undergoing AWR should quit smoking at least 4 weeks prior to surgery, as this amount of time has been shown to be the minimal effective time for reducing 30-day complications in surgical patients. Nicotine replacement therapy can be allowed as this seems to provide

no negative effect on surgical outcomes, and in all patients undergoing smoking cessation, blood or urine testing should be used for confirmation before surgery. Obesity is a significant risk factor for surgical site occurrence (SSO) including seroma, hematoma, dehiscence, abscess, and fistula. Multiple articles have displayed the association between increased body mass index (BMI), postoperative complications, and hernia recurrence. Most surgeons would delay elective AWR in patients with BMI greater than 40 without the presence of acute surgical indications. Weight loss counseling and bariatric surgery referrals are necessary in these patients. Perioperative glycemic control is extremely important in reducing infection risk and other postoperative complications. A hemoglobin A1C level of 7.5% is a common cut off for elective AWR, and those patients with difficulty in achieving this level should be referred for endocrine evaluation and management. Postoperative glucose levels should never exceed 200 mg/dL with a target range of 110 to 180 mg/dL. Next, poor nutritional status has also been closely associated with higher rates of postoperative complications and worse outcomes. Patients with albumin levels less than 3.0 g/dL and prealbumin levels less than 15 mg/dL should undergo a complete nutritional assessment, including vitamin deficiencies with counseling and supplementation as needed before elective AWR. All patients should be administered a first generation cephalosporin within 1 hour of incision to decrease surgical site infection risk. Bowel preparation before AWR has been shown to be associated with an increased risk for SSO and should be avoided.

ACUTE MANAGEMENT

In cases in which definitive AWR cannot be performed, the management of the acute abdominal wall defect and control of abdominal

viscera are the primary objectives. These cases include those with hemodynamic instability, gross contamination, an elevated risk of complications, the need for reoperation, and surgeon inexperience and are usually associated with trauma and damage control laparotomy in which patients are left with an open abdomen. There are numerous available options for temporary abdominal closure in these situations including skin only closure, interposition intravenous fluid bag (Bogota bag), bridging permanent or absorbable mesh, biologic mesh, artificial liner or Wittman Patch, and vacuum assisted closure systems. Each of these temporary closure methods is employed to accomplish the same goals of preventing evisceration and contamination, evacuating abdominal fluid and decreasing bowel edema, avoiding damage to bowels, fascia, or skin, preventing fistula formation, allowing easy access to the abdominal cavity, and preventing the loss of abdominal domain while preventing abdominal compartment syndrome. The ideal situation will result in delayed primary closure of the fascia by 8 days, as closure achieved beyond 8 days is associated with increased complications. At our institution, we commonly use the ABThera (KCI) negative pressure system. If delayed primary fascial closure remains impossible, several options exist for managing these defects and transitioning to the accepted ventral hernia with plans for future AWR. First and foremost is simple closure of the skin and subcutaneous tissues. We believe that this is not a viable option in current therapy because of the larger risk for evisceration. Next, the fascia can be bridged with absorbable synthetic or biologic mesh covered by closure of the skin and subcutaneous tissues. Either mesh type can be used with an expected hernia occurrence of 50% to 100%. Because of the greater expense of biologic matrices, the majority of surgeons at our institution will use absorbable synthetic mesh in these cases (Vicryl, polyglactin 910, Ethicon Inc.). A valid concern for the use of synthetic mesh in bridging cases is the risk for fistula formation. It seems that literature discussing this topic acknowledges fistula formation being because of either the lack of underlying omentum, the presence of an enteral feeding tube, or the breakdown of intestinal sutures and anastomoses. Reported fistula occurrence rate in these situations is 0% to 11%, similar to or better than those reported with prolonged use of abdominal vacuum assisted closure systems. Further investigation regarding complication occurrence with the use of bridging biologic and synthetic mesh in these types of cases is needed.

In the remainder of patients in which there is not sufficient overlying skin or soft tissue to cover the bridged repair, options include the continuing of local wound management (vacuum systems or traditional dressings) with or without placement of a bridging synthetic absorbable mesh. Both options can be expected to lead to eventual granulation across the exposed viscera and the option for split thickness skin grafting. In our experience, the time for formation of an appropriate bed of granulation tissue after Vicryl mesh placement is 2 to 3 weeks. Again, fistula rates are 0% to 11% or higher, but definitive data are lacking. An additional option is the use of a bridging biologic matrix with the hope for full thickness integration and eventual skin grafting, but this technique is unfounded and expensive. Integration of a biologic matrix without complete soft tissue coverage has not been studied, and unless a significant improvement in complication rates, such as fistula formation, compared with traditional techniques can be displayed, the expense of this option cannot be justified. Some may consider the use of fascial advancement in these settings, but we would argue against the use of component separation techniques simply to achieve fascial edge approximation as potential future options for AWR may be lost. Following skin graft coverage or skin closure, a delay of 6 to 12 months before AWR is typical, during which time comorbidities can be optimized. Prior to AWR, the skin graft should be able to be pinched away from the underlying viscera on examination, indicating reasonable safety for intra-abdominal dissection.

OPERATIVE TECHNIQUES

Component Separation

Component separation techniques are commonly employed to repair complex abdominal wall hernias and are generally described according to the anatomic location of the myofascial release that is performed (anterior vs posterior). Anterior component separation (ACS) and PCS techniques have similar rates of hernia recurrence (~10%), but comparative studies between these techniques are challenging. Some authors suggest that there are fewer wound complications associated with the posterior technique, but definitive results are lacking, and there are no comparative studies regarding quality of life or function.

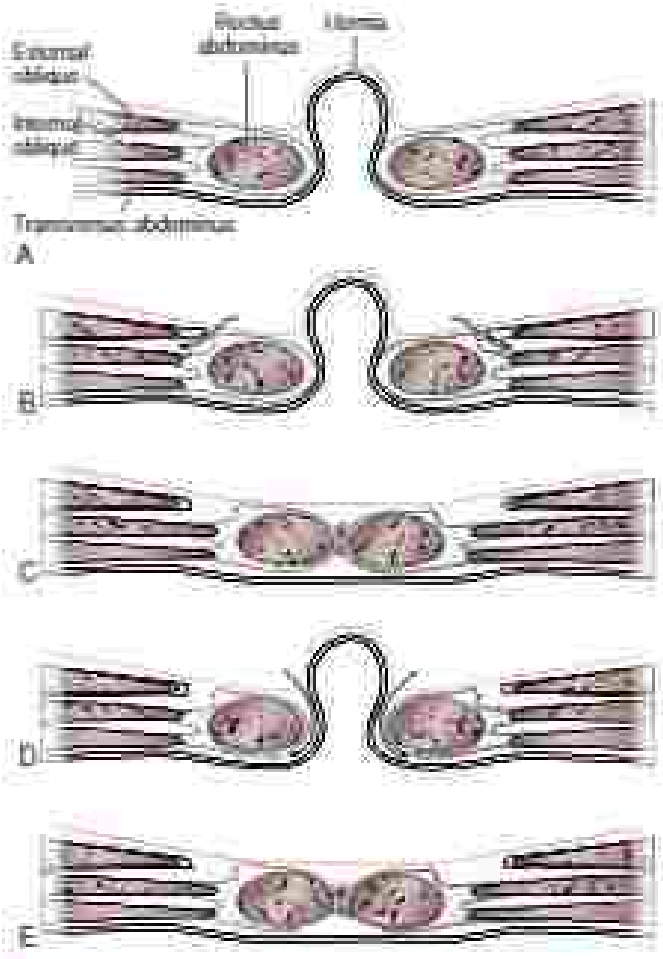

FIG. 2 (A) External oblique (EO), internal oblique (IO), transversus abdominis (TA), rectus abdominis (RA), EO aponeurosis. (B) EO aponeurosis is incised and a plane is developed between the EO and IO muscles (arrow). (C) Lateral edge of rectus sheath is incised, revealing the EO aponeurosis. (D) Medial edge of rectus sheath is incised, revealing the [illegible] plane between the EO and IO muscles. (E) Midline closure of the EO aponeurosis, and closure of the skin and subcutaneous tissues.

Anterior Component Separation

The ACS (Fig. 2) was first described in 1990 by Oscar Ramirez. Following mobilization and reduction of the abdominal viscera, large bilateral myofascial flaps of skin and subcutaneous tissue are elevated to expose the EO aponeurosis and its junction with the semilunar line. The aponeurosis is then opened longitudinally 1 to 2 cm lateral to the semilunar line from the costal margin superiorly to the external inguinal ring inferiorly. A plane can be bluntly developed between the EO muscle belly and the underlying IO to facilitate fascial mobilization. Next, the medial aspect of the rectus sheath is incised longitudinally from the sternum to the arcuate line, and a plane is bluntly

developed separating the rectus muscle belly from the posterior sheath [illegible] to the midline [illegible] posterior to the [illegible] [illegible] commonly [illegible] [illegible] with [illegible] looped or unlooped [illegible] suture. [illegible] closed suction drains are placed [illegible] [illegible] [illegible] [illegible] [illegible] to some studies [illegible] [illegible] [illegible] [illegible] [illegible] separation and [illegible] separation [illegible] [illegible] of the [illegible] repair of [illegible]

Posterior Component Separation and Transversus Abdominis Release

The PCS has evolved from the classic [illegible] retromuscular hernia repair and was first described in [illegible] and [illegible] before later modification with the addition of the transversus abdominis release (TAR) in 2012. This technique allows for advancement of the [illegible] midline closure with the placement of prosthetic mesh in an underlay fashion beneath the abdominal wall muscles but on top of the peritoneum. The technique also does not require creation of large abdominal wall lipocutaneous flaps. The initial PCS technique [illegible] [illegible] from the [illegible] retromuscular dissection beyond the semilunar line to open the plane between the [illegible] and the [illegible]. This allowed for myofascial advancement of the [illegible] and posterior rectus sheath to the midline over which a large prosthetic mesh could be placed. Similarly, the [illegible] and [illegible] sheath could be advanced to the midline. [illegible] this dissection involves the division of the neurovascular bundles passing through the semilunar line, and thus the TAR technique is now commonly employed during PCS.

The TAR dissection first begins with meticulous intra-abdominal dissection, minimizing enteral contamination and damage to the peritoneal lining as damage to these structures can lead to difficulty in the later dissection. Next, the medial aspect of the rectus sheath is opened from the xiphoid to the arcuate line to gain access to the retrorectus plane (Fig. 3). This plane is easily bluntly dissected until reaching the semilunar line where the neurovascular bundles can be seen perforating the posterior lamellae of the [illegible] aponeurosis (Fig. 4). These bundles are preserved and the posterior lamellae are incised just medial to them exposing the underlying TA muscle (Fig. 5). The TA muscle only extends behind the [illegible] in the upper abdomen, so this portion of the dissection should be performed there [illegible] [illegible] muscle fibers are divided with electrocautery to expose the underlying transversalis fascia and peritoneum (Fig. [illegible]). This plane between the [illegible] and the peritoneum can be developed all the way to the psoas muscle laterally (Fig. [illegible]). The dissection plane can extend to the central tendon of the diaphragm superiorly and Cooper's ligament inferiorly. Any perforations in the peritoneal

FIG. 3 Posterior rectus sheath incised just medial to the linea alba.

FIG. 7 Permacol is separated from the transversus abdominis creating the posterior rectus sheath for closure and creating a sublay pocket for mesh placement.

lining should be repaired with absorbable suture if possible. If large holes are present, grafts from the resected hernia sac or synthetic plugs can be used for interposition. The posterior sheath is then closed in the midline with absorbable suture, and a large prosthetic mesh is placed in the dissection plane and fixated at its boundaries using a transfascial suture passer to the anterior abdominal wall using multiple stab incisions in the skin along the periphery of the mesh. Similarly, a nonirritating, self gripping mesh can be used. Surgical drains are placed overlying the mesh and the linea alba is closed in the midline with large caliber absorbable suture followed by the skin and subcutaneous tissue in layers.

Staged Reconstruction

When there is concern for prosthetic contamination at the time of AWR, a staged procedure may be the most appropriate course. Difficult stoma reversal procedures and those involving complex adhesiolysis or with bowel injury should warrant concern for breaches in sterility and prosthetic contamination. In these cases, we will place an ADM in underlay fashion to temporize the abdominal wall closure with plans for prosthetic reinforcement in the future. First, a limited suprafascial

FIG. 8 Large angiolipoma of the left rectus abdominis muscle.

dissection is performed to facilitate placement of transfascial delayed absorptive sutures, providing 5 cm of ADM extension beyond fascial edges. This fixation could also be performed using a suture passer, but we feel a limited suprafascial dissection does not lead to the increased morbidity associated with large flaps developed in traditional AWR. If fascial edges are not able to be approximated in this setting, we refrain from performing myofascial advancement and instead let the ADM underlay act as a fascial bridge as well and accept the definitive hernia until delayed repair or reinforcement. It is important to have soft tissue coverage when using this bridge to promote integration of the ADM. Two drains are placed, one on top of the ADM and one above the fascial closure, and the skin and subcutaneous tissues are closed in layers. The second stage is performed after a 6 month recovery period and begins with excision of the laparotomy scar. Next, bilateral suprafascial dissection is performed for 10 cm bilaterally, and a large piece of permanent prosthetic mesh is sutured in an onlay fashion, taking care to ensure complete apposition between the mesh and the underlying fascia using numerous quilting sutures between the mesh and the underlying soft tissue. Surgical drains are left in place for 3 to 5 days, and the patient is allowed to go home from the recovery room. We have achieved hernia recurrence rates of less than 5% with this staged method along with minimal wound complications.

COMPOSITE ABDOMINAL WALL RESECTION AND RECONSTRUCTION

Composite defects of the abdominal wall can be considered to fall into two categories, acute and chronic. Acute defects are often the consequence of resection of a tumor, such as a sarcoma or desmoid, resulting in a defect of skin and subcutaneous tissues, fascia, muscle, and peritoneum (Figs. ...). The main goal of the reconstructive exam would be to obtain a closed abdominal cavity, protection for the visceral organs, control of wound loss, and some plan for stable soft coverage. The advantage of reconstruction of these defects is that there is often an opportunity for the surgeon to fully assess the patient and the planned defect prior to reconstruction. Also, often this will be managed by two teams, the ablative team and the reconstruction team. One of the most important aspects of successful management of these complicated problems is coordination of the two teams so that realistic expectations are discussed prior to the surgery. The size of the anticipated defect, the tissues involved, and the use of available local regional tissues for reconstruction should be understood by the members of the teams. The use of the standard techniques of lateral release of the ED muscles and component separation can assist in reducing the size of the acute defect. However, it may be better to carry out a complex reconstruction as described later in conjunction with a components separation rather than depend on a reconstruction under undue tension that will fail.

FIG. 9 Composite defect after resection.

FIG. 10 Permacol mesh strip sutured to native fascia and the dermal matrix that has been used as a bridge between the fascial edges with 3 cm of excursion beyond these edges.

The reconstruction of a peritoneal layer is the first step in reconstruction. Our choice is to use an underlay of ADM. First, we make a paper template of the defect. This template is transferred to a sheet of ADM. About 2 to 3 cm of extension is planned around the template for suturing of the material. A 2-0 monofilament absorbable suture in an interrupted horizontal mattress fashion is used to anchor the ADM. Particular care is taken to lay out our sutures in an organized fashion so that there is even spacing and the bowel cannot become trapped between the interrupted sutures and the margin of the defect. The sutures are placed through-and-through the abdominal wall and the ADM is anchored to the peritoneal surface. The sutures are positioned so that the ADM is taut without ridges or excess material. The ADM must be covered with a more permanent material to ensure that the abdominal wall will remain in integrity when faced with constant load bearing. We have used a wide pore polypropylene mesh. The mesh is sutured across the abdominal wall and anchored to stable structures such as the inguinal ligament, costal margin, and anterior superior iliac spine. The mesh is pulled tautly across the abdominal wall and fixed to the surrounding normal fascia with interrupted 2-0 monofilament absorbable sutures. The mesh is then quilted to the fascia and ADM with interrupted sutures (Fig. 10). This will create a single construct with the two materials fixed to each other, further stabilizing the abdominal wall. By fixing the mesh to the ADM, we eliminate fluid collection between the two layers and avoid seroma and potential infection. Over time, the mesh will be anchored to the native tissues by soft tissue ingrowth through the wide pores. The use of a wide pore size will decrease the stiffness and chronic fibrosis encompass tissue associated with the inflammatory reaction to the polypropylene. If the skin was spared in the resection it can be closed as normal over closed suction drains. The skin and subcutaneous soft tissue flaps are anchored to the mesh and fascia to reduce dead space and seroma formation.

If the skin is resected, a negative pressure wound dressing can be placed over the mesh to generate granulation tissue that can be skin grafted. Smaller skin defects can be addressed with local tissue rearrangement and flaps. Tissue expansion can be used in these situations. It is important to remember to place the expander over a bony base, ribs, pelvis, or sternum if employed. This avoids the problem of expanding the soft tissue beneath the expander that cannot be mobilized into the defect. The local flap donor site can then be closed with a split thickness skin graft. Larger soft tissue defects can be addressed with free tissue transfers such as an anterior lateral thigh flap or a latissimus dorsi flap. The standard ADM and polypropylene construct will need to be used prior to placing the free flap. Thin soft tissue flaps will not be able to stand up to the forces placed on it by the underlying viscera and the forces of normal function.

POSTOPERATIVE CARE

Following AWR, oral intake should be advanced depending on the nature of any coincident visceral procedures, otherwise early enteral feeding should be initiated. Nasogastric tubes are not routinely used. Pain control consists of multimodal therapy with use of acetaminophen, gabapentin, nonsteroidal anti-inflammatory drugs, and antagonists to limit the use of narcotics. Additionally, the use of local and regional anesthesia before and during surgery including transversus abdominis plane blocks have shown a reduction in postoperative pain, narcotic usage, and length of inpatient stay. Some institutions will employ the use of epidural anesthesia before AWR, and it has been demonstrated to decrease systemic narcotic usage, improve postoperative nausea and vomiting, and improve postoperative pulmonary function. We believe that routine epidural use in AWRs is not necessary with the use of adequate local and regional blocks and multimodal therapy. Serum glucose is closely controlled not to exceed 200 mg/dL to reduce wound complications. After skin closure in clean cases, there is no benefit to the use of prolonged antibiotics, and these should be avoided. There are no clear data to support or deny the use of prophylactic antibiotics in the setting of surgical drains, but the use of prolonged antibiotics is associated with adverse consequences such as *Clostridium difficile* diarrhea and bacterial antibiotic resistance. We advocate *not* to use postoperative antibiotics for prophylactic drain coverage. Drains are removed once

the output is less than 30 mL over a 24-hour period, which is typically 3 to 5 days in cases with synthetic mesh, and 7 to 10 days with AWM. Patients are discharged to home with strict activity restrictions against strenuous activity, straining, and heavy lifting that will continue for 8 weeks. First clinic follow up visit is generally within 1 week from hospital discharge.

BREAST

BENIGN BREAST DISEASE

Richard C. Gilmore, MD, and Julie R. Lange, MD, ScM

S[illegible]

EVALUATION OF COMMON BREAST COMPLAINTS

[illegible]

[illegible] complaint begins with a focused history and clinical breast examination. [illegible] should involve a complete assessment of the patient's symptoms including duration, severity, and the presence of aggravating/alleviating factors in addition to pertinent obstetric, gynecologic [illegible] personal or family history of cancer.

Physical examination should begin with visual inspection for asymmetry and skin lesions [illegible]. [illegible] palpation should be systematically cover all areas of both breasts including the axillary tail and should include examination of the axillary and supraclavicular nodal basins. If nipple discharge is present, it should be characterized [illegible] and location as well as whether it comes from a single duct or multiple ducts [illegible].

Although many breast complaints [illegible] imaging [illegible] it is important to [illegible] imaging evaluation. For most [illegible] younger than age 30 [illegible] ultrasound [illegible] mammography is not usually [illegible] in this patient group. For patients age [illegible] mammography is indicated [illegible] because they [illegible] breast tissue [illegible]. At age [illegible] should include bilateral mammography with diagnostic views of the area [illegible] and targeted ultrasound as needed. In general, mammography and ultrasound are [illegible] imaging for evaluation of [illegible]. [illegible] imaging such as magnetic resonance imaging should be reserved for [illegible] clinical or imaging findings that remain indeterminate despite complete mammographic and sonographic evaluation [illegible] an image-guided [illegible] needle biopsy is generally preferred [illegible].

Breast Mass

A breast mass [illegible]. The most common breast complaint [illegible] is accompanied by substantial anxiety [illegible] because women [illegible] that breast cancer [illegible] with a palpable mass [illegible] women, most [illegible] found to [illegible] be cysts, fibrocystic change, or fibroadenomas [illegible] minority are [illegible] cancer [illegible]. [illegible] is an essential part of the evaluation [illegible] postmenopausal women [illegible] should be assumed to be cancer until proven otherwise. [illegible] findings [illegible] smooth [illegible] well circumscribed [illegible] round, well-marginated firm rubbery mass in a premenopausal woman [illegible] can be distinguished from a cancer [illegible] density. Today, most solid masses are evaluated [illegible] image-guided core needle biopsy [illegible] well visualized on ultrasound, ultrasound-guided core needle biopsy is usually the preferred technique.

Nipple Discharge

Nipple discharge is common and usually of benign cause. Most women who have lactated can induce a small amount of discharge, usually from both nipples and multiple ducts; this type of induced discharge requires no further evaluation other than age-appropriate screening imaging. True galactorrhea is uncommon and characterized by larger volume, bilateral, spontaneous, milky nipple discharge arising from multiple ducts in a nonlactating woman. Diagnostic evaluation includes obtaining a serum prolactin level and age-appropriate breast imaging. Patients with an elevated prolactin level should be referred to an endocrinologist for further management.

Nipple discharge that is spontaneous, persistent, unilateral, and involving a single duct requires further diagnostic evaluation and occasionally surgical intervention. It may be sanguinous or serous. Evaluation begins with physical examination as well as mammogram and ultrasound. If a specific, targetable suspicious lesion such as abnormal microcalcifications or a solid mass is found, the lesion can be targeted for core needle biopsy. If no suspicious lesion is found, an excisional biopsy of the discharging duct is necessary to make a specific diagnosis and rule out a cancer. A ductogram (galactogram) is sometimes useful in preoperative planning to identify ductal filling defects. The fluid-producing duct is cannulated and contrast material is injected, followed by a mammogram to identify the location of filling defects within the duct. Cytology and hemoccult testing are seldom of significant value in the evaluation of patients with nipple discharge.

Surgical duct excision is sometimes needed for diagnosis and to remove the source of the discharge. The duct producing the discharge can be marked by placing a structure such as a stiff large monofilament suture or a small lacrimal duct probe into the duct in question. Then the duct can be approached from a periareolar incision and the offending duct excised. Younger patients should be aware of the potential for difficulty in future breastfeeding after this procedure.

Most causes of nipple discharge are benign, especially in younger women. Benign causes include intraductal papilloma, mammary duct ectasia, and fibrocystic change. The risk of cancer in patients presenting with nipple discharge is between 5% and 15% overall and increases with age.

Breast Pain

Breast pain (mastalgia) is common throughout life, especially during the reproductive years. It is most often related to fibrocystic and hormonal changes, cyclic in nature, and is uncommonly associated with cancer. In premenopausal women, a history of breast pain that is cyclic and improves significantly after the onset of menses is reassuring. If there are no other findings on physical examination or age-appropriate imaging, no further evaluation is required. Ultrasound may be reassuring, or may detect problems such as a breast cyst as the cause of pain. Breast pain may resolve on its own without intervention. Conservative measures are often helpful and can include well-fitting support bras and dietary modifications to reduce fat and caffeine intake. Nonsteroidal antiinflammatory agents can provide relief for persistent pain. Additional agents reported to sometimes help alleviate breast pain include vitamin E, fish oil, and evening primrose oil, but they are not routinely effective.

Pain that is unrelated to menses, is new onset in a postmenopausal age, or is associated with a mass or other physical examination or radiologic abnormality requires further diagnostic evaluation. Common benign causes of noncyclic breast pain include cysts, fibrocystic changes, abscess, and mastitis.

Skin Changes

Benign skin changes may include erythema as a sign of infection or a rash resulting dermatitis. Most breast infections are exquisitely painful and present with significant erythema and warmth. If infection is clinically suspected, ultrasound is a simple way to clarify whether an abscess is present.

Worrisome skin changes of the breast include skin dimpling, nipple retraction, nipple excoriation or scaling, and skin thickening with erythema. These findings should prompt further mammographic and sonographic evaluation to rule out a cancer, with biopsy as indicated by imaging evaluation. If the radiologic evaluation is negative, a skin punch biopsy may be indicated for diagnosis.

Abnormal Screening Mammogram

With increased use of routine screening mammography and improvement in mammographic technology, many women may have abnormalities reported without associated physical examination changes, most of which are of benign origin. These can include developing masses or densities, new microcalcifications, or architectural distortions. The most important issue to be addressed is whether the finding represents a cancer.

A screening mammogram with a new abnormal finding requires evaluation by a radiologist specializing in breast imaging and usually an initial diagnostic mammographic views, including spot compression or magnification views, and often diagnostic ultrasound. If the lesion is concerning, an image-guided core biopsy is often indicated. Correlation of the mammographic finding with the physical examination is important because it is sometimes possible to detect subtle physical changes if attention is directed to the vicinity of the mammographic finding. In patients with abnormal mammographic findings that do not meet criteria for biopsy, follow-up mammography in 6 months can be indicated.

MANAGEMENT OF BENIGN BREAST LESIONS

Fibroadenoma

Fibroadenoma is the most common benign solid mass of the breast. They are often mobile, well circumscribed with smooth edges and have a rubbery consistency. They are most commonly seen in the reproductive years, may increase in size during pregnancy, and often involute after menopause. Their identity can be confirmed with ultrasound-guided core needle biopsy. Most can be left in place and observed over time with serial ultrasound. A fibroadenoma should be excised if it is large (>3 cm at diagnosis), symptomatic, if it increases in size, or if it significantly contributes to patient anxiety. If the pathology of the core biopsy does not clearly confirm the clinical impression of fibroadenoma the lesion may need to be excised to rule out more serious findings.

Benign Phyllodes Tumor

A benign phyllodes tumor is a fibroepithelial tumor with a variable range of behavior. Most benign phyllodes tumors present similarly to a fibroadenoma but can grow more rapidly and become locally aggressive. Ultrasound alone cannot distinguish a fibroadenoma from a phyllodes tumor so core needle biopsy is required. A core biopsy reported as cellular fibroepithelial lesion could represent either a fibroadenoma or a phyllodes tumor and should be excised for diagnosis and local control. All benign phyllodes tumors should be excised in a clear margin to reduce the chance of local recurrence.

Cysts

Cysts are a common cause of breast pain or a focal mass; they are usually seen in the reproductive years but can occasionally occur in postmenopausal women as well. By ultrasound, cysts that are well circumscribed, thin walled, and without septations or an associated solid component are referred to as simple cysts and are unlikely to be associated with a cancer. Ultrasound- or palpation-guided aspiration is appropriate for simple cysts that are large or symptomatic. Routine aspiration of small, asymptomatic simple cysts is not needed. Cyst fluid that is bloody should be sent for cytopathology, additionally cyst fluid is usually discarded. Cysts that by ultrasound have septations, debris, or an associated solid component are known as complex cysts and should be biopsied. Ultrasound-guided core needle biopsy should be performed with a clip left in place to mark the location in the event that excisional biopsy is subsequently required.

Fibrocystic Changes

Fibrocystic change is the most common benign breast entity and occurs commonly in women of reproductive age. Women often present with a history of bilateral, menstrual-related cyclic pain, with tender, nodular breasts often most prominent in the upper outer quadrants. If the diagnostic evaluation is complete with no suspicious lesion found, then symptom control and reassurance is the most appropriate management strategy.

Diabetic Mastopathy

This uncommon, dense, fibrous lesion usually occurs between ages 30 and 50 in patients with a long history of type 1 diabetes, particularly those with microvascular complications, although it has been described in type 2 diabetics as well. Patients present with a dense,

hard mass, both the physical examination and radiologic studies may appear suspicious for carcinoma. In the correct clinical setting, a core needle biopsy may be diagnostic, with excisional biopsy occasionally needed for confirmation. No active intervention is required beyond confirmation of the diagnosis.

Infection

Breast infections are common and can be painful and difficult to clear. Mastitis can be divided into lactational and nonlactational. Lactational mastitis is common in the postpartum period in lactating women. The most common causative agents are *Staphylococcus* and *Streptococcus*. Breast ultrasound should be used to evaluate for abscess. Antibiotic choice empirically should have good gram positive coverage, such as dicloxacillin, cephalexin, or other broad spectrum antibiotics. In settings where there is suspicion for methicillin resistant *Staphylococcus aureus*, antibiotics such as clindamycin or trimethoprim/sulfamethoxazole may be preferred. In addition to antibiotics, other conservative measures such as warm compresses and nonsteroidal antiinflammatory agents are helpful to reduce local pain and swelling in mastitis without abscess. Continuation of breastfeeding or pumping should be encouraged because this may significantly reduce symptoms. Complete resolution of uncomplicated mastitis may take a few weeks; however, mastitis that fails to resolve on antibiotics or worsens could be secondary to an undrained abscess. Follow-up ultrasound may be diagnostic.

Nonlactational mastitis can be divided into periductal mastitis and idiopathic granulomatous mastitis (IGM). Periductal mastitis is more common in women who are smokers, have large breasts, are overweight, or have had previous surgery or radiation to the breast. As with lactational mastitis, *Staphylococcus* and *Streptococcus* are the most common pathogens and treatment should involve symptom relief, antibiotics, ultrasound to rule out an abscess.

IGM is a rare benign inflammatory breast disease of unclear etiology. Patients may present with a painful mass sometimes in association with fistulas, abscesses, and inflammatory changes. Its presentation is sometimes similar to inflammatory breast cancer and appropriate diagnostic workup with biopsy may be required. IGM usually behaves as an inflammatory mastitis that generally resolves within 9 to 24 months, although recurrences are common. There are reports of medical management with steroids, methotrexate, or antibiotics, and yet it is unclear whether the underlying course of the disease can be improved with medical management. Management should be pursued for treatment of any associated infections.

Abscess

If a discrete abscess is present in association with either lactation or nonlactational mastitis, drainage is indicated. Ultrasound can be used to further characterize the abscess and facilitate adequate drainage. Limited simple abscesses can usually be adequately managed by serial needle aspiration, antibiotics, and close follow up. It is important to document sonographic resolution of the abscess after aspiration because unilocular collections can lead to recurrent infection. Recurrent or deep seated loculated collections may require open incision and drainage, often with general anesthesia or deep sedation because this is often a very painful procedure. Mastitis and breast abscesses can usually be managed on an outpatient basis. One occasional exception is in patients with diabetes in whom severe breast infection can be accompanied by systemic sepsis requiring hospitalization and intravenous antibiotics.

Lipoma

Lipomata can be found in the breast as elsewhere. If large or symptomatic, they can be managed with simple excision.

Fat Necrosis

Fat necrosis in the breast can result from injury to the soft tissues. Typical radiologic characteristics include a rounded density with or without calcifications. Fat necrosis sometimes cannot be distinguished from cancer radiographically and core needle biopsy can be necessary. A large area of fat necrosis can form a focal hard mass that can cause anxiety and some patients prefer to have it excised.

Proliferative Lesions without Atypia Requiring Excision

Today, most core needle breast biopsies of benign lesions are definitive and no excision is required; however, some lesions found on core breast biopsy should be excised to rule out a coexisting malignancy. Some proliferative lesions without atypia usually recommended for excisional biopsy include complex sclerosing lesion, radial scar, and intraductal papilloma. The chance of finding a malignancy on excision of these lesions is generally about 5%. In the future, it may be possible to define some such lesions with core biopsy results that may safely be managed by observation and repeat imaging rather than excision at original presentation.

Proliferative Lesions with Atypia

Atypical hyperplasia includes both atypical ductal hyperplasia and atypical lobular hyperplasia (ALH). Its both identify a patient as being at increased risk of breast cancer diagnosis, especially if the patient also has a first degree relative with breast cancer. Atypical ductal hyperplasia found on core needle biopsy requires excisional biopsy because between 3% and 10% are found to have ductal carcinoma in situ or invasive cancer on excisional pathology. On the other hand, the chance of finding cancer on excision following a core biopsy diagnosis of ALH is lower. Patients with ALH, diagnosed on core biopsy may not require excision if the imaging and pathology are concordant. If a decision is made to forego excision, the patient should return for short term diagnostic imaging follow up to assess for stability.

Patients with Benign Findings Who are at Increased Cancer Risk

Patients with benign findings that indicate increased risk of breast cancer should be offered enrollment in high risk screening program with the goal of early detection of subsequent cancers. There are many different statistical models that can estimate an individual patient's relative risk of breast cancer. Women with increased risk of breast cancer can be encouraged to make lifestyle modifications that include dietary fat and alcohol reduction, attention to maintaining a normal body weight, smoking cessation, and exercise. Drugs such as tamoxifen and raloxifene are approved for use in chemoprevention in high-risk women. They can be considered in the context of a high risk screening program and with careful consideration of risks and calculation of the chance that an individual patient might benefit.

SPECIAL CIRCUMSTANCES

Male Breast Complaint

Male breast cancer is rare, but gynecomastia is common. Changes suggestive of cancer in the male breast include skin or nipple changes, particularly nipple retraction or nipple discharge, and a firm, painless mass. Gynecomastia usually presents with a firm, sometimes painful thickening of the subareolar tissues and may be bilateral or unilateral, core if caused by systemic factors. Gynecomastia has been associated with estrogen excess or testosterone deficiency. It may be associated with cirrhosis of the liver, primary hypogonadism, testicular tumors, obesity, and numerous drugs including steroids, estrogens, flutamide, ketoconazole, digoxin, spironolactone, phenothiazines, and marijuana use. Radiologic evaluation includes diagnostic mammography and ultrasound. Mammography may be helpful to rule out

findings such as abnormal microcalcifications that may suggest cancer. If a discrete mass can be seen by ultrasound, it can be targeted for a core biopsy. If evaluation is consistent with benign gynecomastia and the medical history implicates a specific drug, discontinuation of that drug (if medically acceptable) with reevaluation in 3 to 6 months may be reasonable. Gynecomastia can also sometimes regress spontaneously. A persistent mass, particularly if painful, may be most appropriately managed by excisional biopsy for definitive diagnosis and symptom relief.

Pregnancy and Lactation

Most pregnancies occur in healthy young women, and any physical changes are likely to be benign. Common benign breast changes include fibroadenomata, which may enlarge in response to the stimulation of pregnancy-related hormones, and lactating adenoma, a benign, well-circumscribed mass. Either may be diagnosed with ultrasound and core biopsy during pregnancy. If an excisional biopsy is necessary during pregnancy, local anesthetics can be used in most cases. If a biopsy must be performed during the months a woman is lactating, a milk fistula may occur regardless of whether the biopsy is an excisional biopsy or a core needle biopsy, particularly if the biopsied area is central within the breast. Some women choose to continue to lactate and manage the fistula locally during that time, knowing that it will close after lactation ceases. Galactoceles are caused by an obstructed milk duct leading to cyst formation. Diagnosis is based on clinical history and ultrasound; they can be managed conservatively with warm compresses and continued lactation.

With increased use of reproductive technologies, more women are pregnant in their late 30s and 40s, when the incidence of breast cancer begins to rise. Attention to abnormal physical breast changes is particularly important because such women will not be receiving screening mammography during that time, and the changes of pregnancy may mask the early physical signs of cancer.

Surgical Planning

Women often view their breasts as part of their identity and any procedure, no matter how minor, represents a change to physical appearance and identity. Thus, surgical planning for benign breast disease should be considered carefully to minimize cosmetic defect. A well-placed surgical incision allows the woman an aesthetically pleasing result. If, on the other hand, further surgical procedures are required,

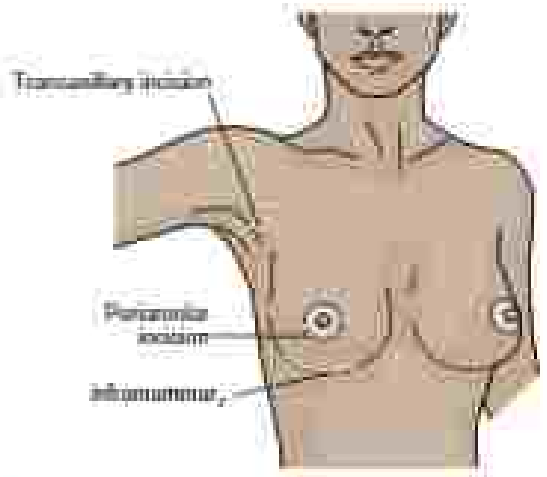

FIG [illegible]

the same incision can be used or extended as appropriate to complete a formal surgical resection. Some cosmetically favorable incisions are illustrated in Fig. 1. With few exceptions, it should possible to avoid making an unfavorably placed incision given careful preoperative consideration of the options. The transaxillary incision can be used to access lesions in the upper outer quadrant of the breast or axilla. The circumareolar or periareolar incision is made at the edge of the areola, allowing the scar to blend in with the darker skin of the areola. It can be used to access lesions circumferentially around and deep to the nipple areolar complex. The inframammary incision can be used to access lesions in the lower quadrants of the breast. These incisions can be technically more challenging, but they award the patient a worthwhile, durable, and cosmetically favorable result.

Screening for Breast Cancer

Richard C. Gilmore, MD, Paul Cartwright, MD, Sara Zia, MD, and D. Kay Jacobs, MD, MSPH

Breast cancer is the most common noncutaneous malignancy diagnosed in women with more than 230,000 new cases reported in 2015. The disease is responsible for more than 41,000 deaths yearly and continues to be the second leading cause of cancer mortality in women. Cases between the ages of 55 and 64 years are most frequently diagnosed, with a median age of death at 68. In 1–39, the American Cancer Society (ACS), the National Cancer Institute, and nine other organizations joined to issue a uniform set of guidelines for breast cancer screening. Since, these organizations would add guidelines for screening of women at high to moderate risk. More recently, based on accumulated evidence from long-term follow-up of randomized controlled trials and observational studies of population-based screening, several organizations have published revisions, in some cases diverging significantly from prior recommendations and contemporary guidelines from other societies. This has been driven by a trend of placing a greater emphasis on estimating harms from screening and recognizing the interplay between published recommendations and an individual woman's values, preferences, and informed decision making.

This chapter reviews the advantages and limitations of screening modalities used to identify early breast cancer in asymptomatic women. This includes women without a personal history of breast cancer, a confirmed or suspected genetic mutation known to increase risk of breast cancer, or a history of previous radiotherapy to the chest at a young age. We then review the recommendations for screening generated by government-sponsored groups, medical societies, and institutions in the United States.

findings such as abnormal microcalcifications that may suggest cancer. If a discrete mass can be seen by ultrasound, it can be targeted for a core biopsy. If evaluation is consistent with benign gynecomastia and the medical history implicates a specific drug, discontinuation of that drug (if medically acceptable) with reevaluation in 3 to 6 months may be reasonable. Gynecomastia can also sometimes regress spontaneously. A persistent mass, particularly if painful, may be most appropriately managed by excisional biopsy for definitive diagnosis and symptom relief.

Pregnancy and Lactation

Most pregnancies occur in healthy young women, and any physical changes are likely to be benign. Common benign breast changes include fibroadenomata, which may enlarge in response to the stimulation of pregnancy-related hormones, and lactating adenoma, a benign, well-circumscribed mass. Either may be diagnosed with ultrasound and core biopsy during pregnancy. If an excisional biopsy is necessary during pregnancy, local anesthetics can be used in most cases. Screening for Breast Cancer

Richard C. Gilmore, MD, Paul Cartwright, MD, Sarah Zak, MD, and Lisa K. Jacobs, MD, MSPH

Breast cancer is the most common nonmelanoma malignancy diagnosed in women with more than 230,000 new cases reported in 2015. The disease is responsible for more than 41,000 deaths yearly and continues to be the second leading cause of cancer mortality in women. Women between the ages of 55 and 64 years are most frequently diagnosed, with a median age of death at 68. In 1980, the American Cancer Society (ACS), the National Cancer Institute, and nine other organizations joined to issue a uniform set of guidelines for breast cancer screening. Since, these organizations would add guidelines for screening of women at high to moderate risk. More recently, based on accumulated evidence from long-term follow-up of randomized controlled trials and observational studies of population-based screening, several organizations have published revisions, in some cases diverging significantly from prior recommendations and contemporary guidelines from other societies. This has been driven by a trend of placing a greater emphasis on estimating harm from screening and recognizing the interplay between published recommendations and an individual woman's values, preferences, and informed decision making.

This chapter reviews the advantages and limitations of screening modalities used to identify early breast cancer in asymptomatic women. This includes women without a personal history of breast cancer, a confirmed or suspected genetic mutation known to increase risk of breast cancer, or a history of previous radiotherapy to the chest at a young age. We then review the recommendations for screening generated by government-sponsored groups, medical societies, and institutions in the United States.

SCREENING MODALITIES

There is more scientific evidence regarding screening for breast cancer than for any other cancer. As with all cancers, screening practices for breast cancer should be based on evidence regarding the prevalence of disease in the screened population, the effectiveness of the screening procedure, and any attendant harms, including the risks and costs associated with the screening test, and any additional tests and procedures that follow a positive screen. In breast cancer, this translates into debates about who should be screened, at what age, and with what method. As more data have emerged regarding the frequency and consequences of false positive test results (leading to unnecessary biopsy procedures) and overdiagnosis (i.e., the diagnosis of low grade, nonaggressive tumors that likely would not affect a person's life), and as breast cancer treatments become more effective, the tradeoff between benefits and harms of screening has shifted.

Breast Palpation

Breast Self-Examination

Although monthly breast self-examination (BSE) was recommended for many years, it recently has been recognized to have limited value in detecting early cancer. Large randomized clinical trials have failed to demonstrate reduction in breast cancer–specific or all-cause mortality from BSE in populations at average risk. Organizations such as the ACS, American College of Obstetrics and Gynecology, and US Preventative Service Task Force (USPSTF) have found insufficient evidence to recommend for or against performance of BSE. The emphasis on monthly BSE has been replaced by the concept of "breast self-awareness" in which women become knowledgeable about the normal appearance and feel of their breasts but without a specific schedule or examination technique. We share the opinion still held by many, however, that BSE has value. Physicians should educate women to enhance their awareness to report any skin changes, dimpling, nipple discharge, or presence of new lumps or bumps. The limitation of using BSE as a screening tool is related to the increased number of biopsies performed for benign breast disease, which comes at a financial and emotional cost.

Women who choose to perform BSE should do so when their breasts are least likely to be tender or swollen, often a few days immediately after a menstrual period. The examination is best done in both supine and upright positions using the finger pads of the three middle fingers. Different pressure levels (light, medium, firm) are used to examine the breast. Although various techniques can be used, women should be consistent in their technique used. One of the easier techniques involves palpating the breasts in a circumscribed clockwise fashion and working from the nipple outward, alternatively, a vertical (up down) pattern can also be used.

Clinical Breast Examination

Because recent randomized trials have included both clinical breast examination (CBE) and mammography, the utility of CBE on early detection of breast cancer remains unclear. However, 10% to 20% of breast cancers are not visible on screening mammography and CBE performed by trained personnel has been shown to increase breast cancer detection over mammography alone. Factors associated with greater accuracy of CBE include longer durations and a higher number of specific techniques used for the examination. Guidelines vary with regard to CBE in breast cancer screening. The ACS does not recommend CBE for screening at any age among average risk women. The American College of Obstetrics and Gynecology recommends CBE every 3 years for patients age 20 to 39 years and annually thereafter. The USPSTF states that current evidence is insufficient to assess the contribution of CBE beyond screening mammography in patients age 40 and older. We believe it provides an important clinical opportunity to discuss breast health, to instruct patients on BSE technique, and to review findings with them that should prompt a clinical visit and CBE.

Mammography

Mammography is the primary imaging modality for the early detection of breast cancer among asymptomatic women because it is the only method of breast imaging that consistently has been found to decrease breast cancer–related mortality. Screening mammograms provide two views of each breast: the mediolateral oblique projection images the breast from an oblique medial to lateral approach, and the craniocaudal projection images the breast from a superior to inferior view. The use of two views allows physicians to localize an abnormality to a particular quadrant within the breast and increases the sensitivity of mammography. The mammography interpretation always is appended by an American College of Radiology Breast Imaging Reporting and Data System (BI-RADS) classification (Table 1). In 2014, the fifth edition of the BI-RADS lexicon was released to further

TABLE 1 Breast Imaging Reporting and Data System Classification

Category		Management	Likelihood of Cancer in the Mammographic Finding
0	Need additional imaging or prior examinations	Recall for additional imaging and/or await prior examinations	
1	Negative	Routine screening	
2	Benign	Routine screening	Essentially 0
3	Probably benign	Short interval follow-up (6 months)	0 but >2%
4	Suspicious	Tissue diagnosis	4a: Low suspicion for malignancy (>2% to <10%)
			4b: Moderate suspicion for malignancy (>10% to <50%)
			4c: High suspicion for malignancy (>50% to <95%)
5	Highly suggestive of malignancy	Tissue diagnosis	>95%
6	Known, biopsy proven malignancy	Surgical excision when clinically appropriate	

standardize the classification of mammographic findings and to provide a level of suspicion for clinicians. Each category is associated with specific guidelines for patient management to assess the need for subsequent biopsy and follow up recommendations. The use of this lexicon has also aided the field in quality assurance, communication, research, and improved patient care.

Screening mammograms are performed without a radiologist present, and suspicious findings are never classified as representing malignancy but prompt a call back for a diagnostic mammogram, which is performed with a radiologist present, who decides whether additional spot or magnification views are necessary to interpret the positive finding on screening mammography. Diagnostic mammography (which is more expensive than screening mammography) should be the first test ordered in the case of a palpable abnormality.

Nine randomized controlled trials, including more than 650,000 asymptomatic, average risk women have been conducted on screening mammography and have reported data on mortality. With long term follow up, pooled results from these studies found a 20% relative risk reduction for breast cancer mortality in women invited to screening compared with controls, with the benefit most pronounced in older age groups (all >50 years). Pooled estimates from observational studies have demonstrated an even greater effect. The magnitude of these estimates is influenced by a number of factors, including whether they are based on invitation or exposure to screening and on the heterogeneity of the studied populations. Estimates of the number needed to invite or number needed to screen to prevent a breast cancer death—increasingly cited as meaningful measures of benefit by organizations drafting guidelines—depends heavily on the relative risk reduction applied in the modeling, the underlying risk of mortality in the modeled population, and the duration of projected follow up. As a result, they can be disparate (more information about number needed to invite and number needed to screen calculations can be found in the ACS and the USPSTF guidelines). Further complicating interpretation of existing evidence is that most of the trials and observational studies were performed in the 1990s, before significant advances in the adjuvant treatment of breast cancer, and with the use of film mammography. Although the majority of breast cancers in the United States are diagnosed as a result of an abnormal screening study, and death rates from breast cancer in the United States have decreased by 30% since the 1990s, it is estimated that approximately one third of that effect is due to screening, with the rest attributable to treatment advances.

There are several limitations specific to mammography as a screening tool. First is that mammography uses radiation, which is itself carcinogenic, although models suggest that the radiation risk from mammography is low enough to result in a net benefit from screening with respect to lives saved. Another limitation is that of overdiagnosis: the detection of disease by screening that would not have become clinically important in a woman's lifetime, including ductal carcinoma in situ (DCIS; which may not progress to invasive cancer), a slow growing cancer, or one that regresses. Results from randomized trials and cohort studies consistently demonstrate a higher rate of cancer diagnosed in a population screened by mammography versus an unscreened population, despite a long follow up. Depending on method of estimation and definition (e.g., whether DCIS is included as an event), estimates for overdiagnosis and thus overtreatment of breast cancer resulting from mammography range from less than 10% to more than 30%. Not unique to mammography but central to the controversy surrounding screening recommendations is the risk of false positive screening tests, which result in additional imaging and procedures, potentially even surgical excision, all for a benign condition. False positive screening tests are more common in younger women because mammography is less specific in this population and because cancer is less common.

Breast Density

The density of breast tissue reflects the estimated amount of fibrous and glandular tissue relative to fat and is important because mammographic sensitivity is lower in dense breasts. In addition, there is suggestion that breast density is an independent risk factor for breast cancer. This importance tends to be overestimated in studies that compare women with the highest density to those with the lowest density, resulting in an estimated fourfold to sixfold increase in risk. With use of average breast density as a reference point, the risk among women with heterogeneously dense breasts is 1.2 times as great as the average, and with extremely dense breasts, 2.1 times as great. This is equivalent to the elevated risk of breast cancer associated with having a first degree relative with unilateral, postmenopausal breast cancer. Breast density does not appear to be associated with increased mortality from breast cancer. It is not clear at this time whether breast density represents a modifiable risk factor for cancer, whether screening recommendations should be altered for women with dense breasts, or how women who have dense breasts should be counselled. Because breast density influences cancer risk and the performance of mammography as a screening tool, the American College of Radiology includes classification of breast density as a mandatory component of mammographic interpretation. The fifth edition of the BI-RADS lexicon states that breast density characterization is entirely subjective and can be described as four categories: almost entirely fatty, scattered areas of fibroglandular density, heterogeneously dense, and extremely dense. In a development that some feel to be premature, there also have been laws passed in 22 states mandating that women found to have dense breasts on mammography be notified in writing of the finding and be encouraged to consider additional testing. These policies have attracted criticism because there are no data that additional testing in women with dense breasts is effective in preventing breast cancer death and because they do not address insurance coverage for and reimbursement issues surrounding additional screening tests.

Digital Mammography

All of the randomized controlled trials addressing the effectiveness of screening used film mammography, and there is no direct evidence that digital mammography reduces breast cancer–related deaths. Nonetheless, digital mammography has replaced film as the primary screening modality in the United States. In addition to facilitating remote reading and more efficient storage, the real advantage of digital image collection over film systems is higher contrast resolution and the ability to postprocess the image to enlarge it or change contrast and brightness, helping radiologists more easily detect subtle abnormalities, particularly in a background of dense breast tissue. Most studies that have compared the performance of digital and film mammography have found little difference in cancer detection rates. With digital mammography, there is a suggestion of an increase in detection of invasive cancer in premenopausal and perimenopausal women and in women with dense breasts, but also an increase in false-positive findings.

Tomosynthesis

Tomosynthesis (or three dimensional [3D] digital mammography) is a rapidly emerging technology that involves the acquisition of multiple images of the breast recorded at different angles while the detector is held stationary, providing the radiologist with a series of thin slice (1 mm) images through the breast. Recent data have shown an improvement in cancer detection rate up to 6.5 per 1000 with 3D versus 5 per 1000 with two dimensional (2D) imaging; additionally, the recall rate may decrease as much as 20% to 40% with 3D compared with 2D imaging, particularly for baseline examinations. Although this modality has been found to decrease false-positive and false-negative rates, before performing reconstructed synthesized 2D as part of the 3D mammogram, there was

an increase in the radiation dose compared to a traditional 2D digital mammogram. Several manufacturers now offer the capability to reconstruct synthesized 2D (s2D) mammograms from digital breast tomosynthesis datasets as a replacement for digital mammography. In this way, patients only receive radiation from the tomosynthesis components with elimination of the digital mammographic component, decreasing the overall radiation exposure by up to 45%. Early studies have shown that screening with s2D mammography and digital breast tomosynthesis is not inferior to screening with digital mammography and tomosynthesis. Additionally, s2D imaging has been associated with decreased recall rates and multicenter cancer detection rates. Because this is a relatively new imaging modality, further study is needed to confirm these early results.

Magnetic Resonance Imaging

Nearly all invasive breast cancers are visible on gadolinium contrast–enhanced magnetic resonance imaging (MRI), and the reported sensitivity of MRI is between 88% and 100%. Unfortunately, benign lesions can also enhance on MRI, and low specificity currently limits MRI as a screening tool. The positive predictive value of any test is enhanced as the prevalence of disease rises, and it follows that MRI would have higher utility in patients at higher relative risk for breast cancer. Indeed, the efficacy of MRI as a screening tool in patients at high risk has been validated in multiple studies. In 2007, the ACS recommended annual screening MRI as a supplement to screening mammography for women with high risk for breast cancer, based either on a known *BRCA* mutation, a first-degree relative of a known *BRCA* mutation carrier, or a predicted lifetime risk of 20%–25% or greater according to risk modeling. On the basis of expert consensus opinion, the National Comprehensive Cancer Network (NCCN) also recommended annual MRI screening for those individuals who received radiation to the chest between the ages of 10 and 30 years, those with Li-Fraumeni, Cowden's, or Bannayan-Riley-Ruvalcaba syndromes, and their first-degree relatives. Data are still insufficient for recommendation for or against MRI screening for individuals with a lifetime risk of 15% to 20%, those with lobular carcinoma in situ, atypical ductal or lobular hyperplasia and dense breast on mammography, and those with a personal diagnosis of breast cancer, including DCIS. The downsides to MRI include the significant cost of the test, as well as discomfort on the part of the patient, which may be a limiting factor in a non-insignificant subpopulation.

Other Technologies and Adjuncts to Screening

Whole-Breast Ultrasound

Although ultrasound does not yet have a proven primary role in breast cancer screening, it is often used as a supplemental screening modality after mammography, CBE, or MRI. Focused breast ultrasound characterizes palpable or image-detected lesions on screening studies and can be used to perform image-guided biopsies of mammographically visible lesions. Additionally, multiple studies have demonstrated the effectiveness of sonography as an adjunct to mammography for screening women with dense breast tissue; these lesions were often small (<1 cm) and node negative. Supplemental screening with whole-breast ultrasound has been shown to increase mammographic sensitivity by about 20%–30%. The American College of Radiology Imaging Network whole-breast ultrasound screening trial (ACRIN 6666) assessed the role of whole-breast ultrasound for screening of high-risk women with dense breasts and found only 4 cancers/1000 women were detected with ultrasound alone; additionally, there were a high number of false-positive findings. Considering the increased number of false-positive findings, the length of time it takes to perform, and its operator dependent variability, it remains useful as a supplemental and not a primary screening modality.

Molecular Breast Imaging

Molecular breast imaging (MBI) is a technology used most commonly in women with dense breasts, in whom screening mammography has decreased sensitivity. MBI is based on the observed preferential uptake of a radiotracer (such as ^{99m}Tc sestamibi) in tumors relative to normal tissue, independent of breast density. This modality offers the advantage of detecting the physiologic changes that manifest in early breast cancer as the radiotracers can diffuse into interstitial space and be taken up by the abnormal cells before the presence of a distinct mass or neovascularity. The major disadvantages of MBI include the high radiation dose associated with the injection of radiotracer as well as the long imaging time (6 × 10 minute images). Early results indicate that MBI has comparable sensitivity to breast MRI, but at a fraction of the cost while maintaining an acceptably low false-positive rate. In a screening study of high-risk women with dense breast tissue, MBI detected three times as many tumors as mammography while maintaining a lower false-positive rate. Currently, there is not enough evidence to support MBI as a breast screening tool, but it remains under investigation as a modality that may be useful, especially in patients with dense breasts.

SCREENING GUIDELINES

The recommendations from the ACS, USPSTF, and the NCCN for asymptomatic women who do not have a preexisting breast cancer or a previously diagnosed high-risk breast lesion and who are not high risk for breast cancer because of a known underlying genetic mutation or a history of chest radiation at a young age are summarized in Table 2.

Past screening recommendations from the USPSTF (http://www.uspreventiveservicestaskforce.org/Page/Document/UpdateSummaryFinal/breast-cancer-screening1) included annual mammography starting at the age of 40, however, recent analyses of data pooled from screening trials have suggested that there is an elevated number of false-positive results and unnecessary biopsies for women aged 40 to 49 years. These trends have led to an increased risk of overdiagnosis and overtreatment. Specifically, in their recommendations, the USPSTF estimates that 1904 women ages 50 to 69 would need to be screened to prevent one death from breast cancer after at least 11 years of observation, compared with 1339 women in their 50s and 377 women in their 40s. Additional analyses suggested that annual versus biennial mammography also did not carry a survival advantage. Thus, in their 2009 revision, the USPSTF raised the age at which they recommended initiating mammographic screening from 40 to 50 and revised their recommendations to include screening mammograms only every 2 years for women between the ages of 50 and 74 years of age. Critics of this decision pointed out that the false-positive rate and number needed to prevent a breast cancer death were substantially different between women in their 40s and women in their 50s and that the decision to alter screening recommendations at this age cutoff was somewhat arbitrary. Moreover, it did not provide patients with the knowledge necessary to contribute to the decision. The most recent USPSTF guidelines were released in 2016 (https://www.uspreventiveservicestaskforce.org/Page/Document/RecommendationStatementFinal/breast-cancer-screening1). The statement maintains the recommendation for biennial screening for women age 50 to 74. It softens the language of the recommendations surrounding screening among women age 40 to 49, stating that the decision to perform mammography in this group should be an individual one based on considerations of the risks and benefits of screening in this population, and notes that women age 40 to 49 with a first-degree relative with breast cancer may benefit potentially more than average-risk women in this age group.

The USPSTF also concluded that current evidence is insufficient to assess the balance of benefits and harms for women age 75 years and older. The USPSTF maintains its 2009 recommendation against routine screening MRI and finds insufficient evidence to make recommendations

TABLE 2 Screening Guidelines for Asymptomatic Women of Average Risk for Invasive Breast Cancer From the ACS, the Current USPSTF, and the NCCN

Age	ACS	USPSTF	NCCN
25 but <40			CBE every 1–3 years (25 but <40) Breast awareness
40–44	Women should have the opportunity to begin annual screening between the ages of 40 and 44 years[a]	Through age 50: The decision to start regular, biennial screening mammography before the age of 50 years should be an individual one and take patient context into account, including the patient's values regarding specific benefit and harm.	Through age 50: Annual CBE Annual screening mammogram Breast awareness
45–50	Women should undergo regular screening mammography beginning at age 45 years[b] Screening should be annual[b]		
51–54	Women should undergo regular screening mammography[b] Screening should be annual.	Through age 74: Biennial screening mammography Current evidence is insufficient to assess the additional benefit and harm of CBE beyond screening mammography	Through age 74: Annual CBE Annual screening mammogram Breast awareness
55–74	Women age 55 and older should transition to biennial screening or have the opportunity to continue screening annually[a] Women should continue screening mammography as long as their overall health is good and they have a life expectancy of 10 years or longer	Current evidence is insufficient to assess the benefit and harm of screening in this age group	
75+	Anatomy	Current evidence is insufficient to assess the benefit and harm of screening in this age group	Annual CBE Annual screening mammogram Breast awareness The upper age limit for screening is not yet established; consider life expectancy and whether therapeutic interventions are planned
All women	CBE is not recommended for breast cancer screening among average risk women at any age.[c] All women should become familiar with the potential benefits, limitations, and harms associated with breast cancer screening.	The USPSTF recommends against teaching BSE.	Women should be counselled regarding potential benefits, risks, and limitations of breast screening. Women should be familiar with their breasts and promptly report changes to their healthcare provider.

The USPSTF recommendations are currently under review for revision.

[a]Qualified recommendations; qualified recommendations indicate that there is clear evidence to favor it in screening but less certainty about the balance of benefits and harms, or about patients' values and preferences, which could lead to different decisions.

[b]Strong recommendations; a strong recommendation conveys the consensus that the benefit of adherence to that intervention outweighs the undesirable effects that may result from screening.

[c]ACS, American Cancer Society; BSE, breast self-examination; CBE, clinical breast examination; NCCN, National Cancer Comprehensive Network; USPSTF, United States Preventive Services Task Force.

regarding CBE, although it does support all patients being aware of changes in their bodies.

The ACS recommendations for breast cancer screening are maintained on the ACS website (http://www.cancer.org/healthy/findcancerearly/cancerscreeningguidelines/index). The recommendations were updated in October 2015 from earlier guidelines published in 2003. The major departure is that BSE and CBE, previously suggested for all women starting at the age of 20, were eliminated from the recommendations entirely. The recommended age to start mammography also was raised, reflecting changes to the USPSTF recommendations published in 2009. The reasoning for this change was the same, based on an analysis of the risks of false positives and overdiagnosis versus the small incremental benefits with respect to preventing breast cancer deaths in a relatively low prevalence age group. Whereas previous recommendations suggested annual mammography start at the age of 40, the current expression qualifies this recommendation as a choice, and one that should be made with consideration of risks and benefits of screening. Strong recommendation for annual mammography starts at the age of 45 years. This decision was based on (1) clear data regarding the benefits of screening mammography to women between the ages of 50 and 75 and (2) the observation that the incidence of breast cancer and proportion of incident breast cancers in women 45 to 49 more closely resembled the 50 to 54 group than did the 40 to 44 group. Annual screening mammography should continue while a woman's life expectancy is at least 10 years, with the option to transition to biennial screening at the age of 55. There is no age after which the ACS recommends halting screening for breast cancer.

Concerns surrounding these new guidelines echoed some of the criticisms of the USPSTF guidelines, including that the recommendations of the USPSTF and ACS focus primarily on the outcome of breast cancer lives saved. Other outcomes that may be important to patients were sparsely (if at all) addressed, and some may be undervalued. These include quality of life, although the ACS found the quality of evidence regarding the effect of screening on quality adjusted life years to be too low to incorporate this outcome into their screening recommendations, and the stage at which a breast cancer is diagnosed, which may influence a woman's options for breast conserving therapy. These issues and questions as to the magnitude of overdiagnosis that results from screening continue to pose a challenge in providing complete and accurate information to women about what to expect from breast cancer screening.

As of July 2015, the screening guidelines of the NCCN still recommends CBE every 1 to 3 years and states that women of all ages should be familiar with their breasts and promptly report changes to their healthcare provider. Annual screening mammogram begins at the age of 40 and is accompanied by annual CBE. The NCCN does not support an upper age limit for screening but does note that comorbidity, life expectancy, and the expectation that a positive examination finding would be followed by invasive treatment be incorporated into decision making in this age group. These recommendations are classified as evidence level 2A, "based on lower level evidence, [and] there is uniform NCCN consensus that the intervention is appropriate."

Many other organizations have issued recommendations about mammography screening of asymptomatic women not known to be at increased risk for breast cancer. The American College of Physicians recommends that clinicians should inform women ages 40 to 49 years about the potential benefits and harms of screening mammography and that screening decisions should be based on individualized assessment of risk for breast cancer and the benefits and harms of screening in this age group. They also should incorporate the woman's preferences and breast cancer risk profile. The American Congress of Obstetricians and Gynecologists recommends that mammography screening be offered annually to women beginning at age 40 years. The American College of Radiology and the Society for Breast Imaging, in a 2018 joint recommendation, also advise screening begin annually at 40 and continue until life expectancy is less than 5 to 7 years or when abnormal results of screening would not be acted on because of age or comorbid conditions. In addition, the statement is the first to recognize that African American women are at high risk and as such should begin risk assessment at age 30. The Canadian Task Force on Preventive Health Care recommends routine screening mammography every 2 to 3 years in women ages 5 to 74 years and recommends against screening women ages 40 to 49 years.

Screening in High-Risk Individuals

Several national medical organizations have developed guidelines and recommendations for screening women at high risk. The greatest evidence-based risk is in those women with *BRCA1* and *BRCA2* mutations. *BRCA1* or *BRCA2* mutation carriers are at the highest risk: 57% to 87% will be diagnosed with an invasive breast cancer by the age of 70. In 2017, a prospective cohort of 9676 women revealed the estimated cumulative risk for developing breast cancer by age 80 with *BRCA1* and *BRCA2* mutations was 72% and 69%, respectively. Women who have had a prior diagnosis of breast cancer, atypical ductal hyperplasia, atypical lobular hyperplasia, or lobular carcinoma in situ are also considered higher than average risk, as are women with a family history suggestive of familial breast and/or ovarian cancer, or a first degree relative who has tested positive for a breast cancer–associated genetic mutation are also at high risk. Additionally, women who received mantle-cell irradiation between the ages of 10 and 30 years of age qualify them for the high risk screening approach. Finally, special screening schedules apply to those women who are calculated to have an elevated lifetime risk of being diagnosed with invasive cancer according to the predictive model. A variety of models are available to predict risk, of which the most widely used is the Gail model. This prediction algorithm assesses breast cancer risk based on age, number of first-degree relatives with breast cancer, age of menarche, age of first live birth, number of previous biopsies (including presence of atypia), and race or ethnicity. The Claus model includes a more comprehensive family history. The BRCAPRO model is a statistical model for assessing the probability that an individual carries a germline deleterious mutation of the *BRCA1* and *BRCA2* genes based on personal history and family history data, including a history of breast and ovarian cancer, male breast cancer, and Jewish ancestry. The Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm model includes family history of prostate and pancreatic cancer in addition to breast and ovarian cancer family history. Finally, the Tyrer-Cuzick model incorporates family history and gynecologic history.

Table 3 contains a summary of screening recommendations based on high risk category. Whereas NCCN guidelines are specific with respect to the age and modality of screening recommended, the ACS has only published guidelines for screening with MRI as an adjunct to mammography (see Table 3). In general, annual screening mammography is recommended for women of appropriately high risk beginning at 30 years, supplemental screening with breast MRI is recommended for a cohort with very high risk, and screening ultrasound scan is recommended for women in whom MRI is unavailable. The results of a recent study with computer simulated modeling concluded that annual MRI at age 25 years, alternating every 6 months with digital mammography beginning at age 30 years, may be the most effective screening strategy for mutation carriers.

TABLE 3 NCCN and ACS Guidelines for Women With Elevated Risk for Breast Cancer

NCCN	Prior history of breast cancer	History and physical examination 1–4 times per year as clinically appropriate for 5 years after diagnosis, then annually Annual screening mammography starting at diagnosis
	5-year risk[a] ≥1.7% in women ≥35 years of age according to the Gail model	Annual screening mammogram and CBE every 6–12 months
	History of LCIS or ADH/ALH	Annual screening mammogram and CBE every 6–12 months, consider annual MRI Beginning at diagnosis but no earlier than age 30
	Lifetime risk[a] ≥20% according to models largely dependent on family history (e.g., Claus, BRCAPRO, BOADICEA, Tyrer-Cuzick)	Annual screening mammogram and CBE every 6–12 months, recommend annual MRI Beginning 10 years before youngest family member but not earlier than age 20 Referral to genetic counseling
	Prior thoracic RT (e.g., mantle irradiation) between ages 10 and 30 years old	Age ≤25: annual CBE to start 8–10 years after RT Age >25: Annual screening mammogram and CBE every 6–12 months, recommend annual MRI Begin 8–10 years after RT
	Pedigree suggestive of or known genetic predisposition	Refer for genetic counseling, genetic testing as appropriate Screening recommendations depend on the cancer syndrome identified[b]
ACS[c]	*BRCA* mutation First-degree relative of BRCA carrier but untested Lifetime risk ~20% or 25% or greater, as defined by BRCAPRO or other models that largely depend on family history Radiation to chest between ages 10 and 30 years	Annual MRI screening (based on evidence from nonrandomized screening trials and observational studies)
	(1) Treatment syndromic and first-degree relatives: Cowden's and Bannayan-Riley-Ruvalcaba syndromes and first-degree relatives	Annual MRI (based on expert consensus opinion)

[a]If invasive breast cancer.

Role of Stereotactic Breast Biopsy in the Management of Breast Disease

Ronald F. Jones, MD, and Michael D. Grant, MD

It is estimated that there will have been 240,120 cases of new breast cancer diagnosed in 2010 in the United States. This is in addition to 63,960 cases of ductal carcinoma in situ (DCIS) and lobular carcinoma in situ, representing 30% of all new breast cancers, and more than 2,000 cases of male breast cancer. Screening has improved early breast cancer detection in early stage cancer that is often nonpalpable. The preferred initial biopsy is percutaneous. There are now four percutaneous methods: ultrasound, stereotactic, magnetic resonance imaging, and (unsynthesized) biopsies. Surgical biopsies should generally be used only if percutaneous image guided biopsy is not feasible. Approximately 80% of breast biopsies are now performed percutaneously. Of these, 25% will reveal breast carcinoma; thus, three fourths of patients will have benign disease, avoiding an open surgical biopsy. There is a significant reduction in cost using percutaneous biopsy over open surgical biopsy. The procedure can be performed in approximately 30 minutes and the patient does not require a general anesthetic or going into the operating room. It is an outpatient procedure and the patient can return to work the following day. There are no stitches required, and there is less scarring and less deformity of the breast than with surgical biopsy. Future mammograms will not look significantly different following needle biopsy; however, the radiologist should be informed that the patient has had a breast biopsy. There is almost no confusion diagnosing possible breast cancer as a result of scarring from a previous percutaneous biopsy.

Women with multiple lesions within a breast may benefit from stereotactic biopsy because multiple areas can be biopsied as part of a single biopsy procedure. Different clips can be placed in the different biopsy sites in the event that one is carcinoma. If the mass biopsied with a needle turns out to be a cancer, the breast surgeon can plan the surgical treatment and biopsy of lymph nodes in a single trip to the operating room.

In 1977, stereotactic fine needle aspiration was first reported in Sweden and in 1987 ultrasound guided fine needle aspiration was first described by Burrage. In the late 1980s, Dowlat introduced stereotactic breast biopsy technology in the United States. As breast biopsy tools became more advanced and spring loaded and later vacuum assisted core devices were developed, the image-guided biopsy approach has become predominant for initial tissue diagnosis. More than one half of all breast biopsies are performed stereotactically. It is endorsed by the American Society of Breast Surgeons and a quality measure for National Accreditation Program for Breast Centers.

The sensitivity of core needle biopsies performed stereotactically or with ultrasound guidance is 87% to 99%. The accuracy of stereotactic biopsy can be increased with a larger needle size (i.e., 9 to 11 gauge) and with the use of vacuum assisted devices.

INDICATIONS

There are six Breast Imaging Reporting and Data System (BI-RADS) categories: (1) negative, (2) benign finding, (3) probably benign finding, (4) suspicious, (5) highly suggestive of malignancy, and (6) known biopsy proven malignancy. Depending on the clinical suspicion, patient anxiety, or physician preference, BI-RADS 3 group lesions may be referred for biopsy. BI-RADS 4 and 5 lesions require histologic sampling to rule out malignancy. Lesions visible by ultrasound typically are biopsied with ultrasound guidance because it is less expensive, more easily tolerated by the patient, and does not require exposure to additional radiation. Mammographic lesions (such as ultrasound most commonly are calcifications, but also may include masses, developing asymmetries, and architectural distortions) that may require stereotactic biopsy (Box 1).

CONTRAINDICATIONS

A cooperative patient is imperative to performing a successful stereotactic biopsy. It requires the patient to lie immobile as the breast remains in compression for approximately 30 minutes; therefore, any physical limitations of the patient, such as movement disorders, limited range of motion, kyphosis, or weight, must be considered. A patient who weighs more than 300 pounds is not a candidate for stereotactic breast biopsy if a prone table is used. If a patient has thin or small breasts, adequate breast tissue thickness may not be available while in compression to allow access for the computerized biopsy equipment. There may not be enough breast tissue to compress to safely biopsy without the needle penetrating through to the other side of the breast. If the breast is too large and the lesion is deep, stereotactic biopsy may not be technically feasible. If the lesion is too close to the nipple, superficial in the skin, or posterior and near the chest wall, or if patient has a breast implant, stereotactic biopsy may be contraindicated (Box 2). Stereotactic core biopsy is also not indicated in pregnant women.

In the relatively small number of patients not suitable for stereotactic biopsy, the patients should be referred for surgical biopsy. Surgical biopsy may also be recommended for those patients who had core needle biopsy showing high risk abnormalities such as atypical hyperplasia, radial scar, papilloma, or lobular carcinoma in situ.

It is important to ensure adequate pain control with local anesthetic for patient comfort and technical success. Anxiety and vasovagal reactions are symptoms commonly reported. Occasionally antianxiety medication given before the procedure may assist with patient cooperation.

EQUIPMENT

Stereotactic biopsy can be performed with a traditional prone stereotactic biopsy table or upright with an add-on stereotactic biopsy unit that attaches to the standard mammography equipment. There are advantages and disadvantages to both systems. If a patient is wheelchair bound or obese, the traditional prone table may not be ideal; however, wheelchair bound patients may be elevated on a stretcher and rolled onto the table, if this can be safely performed. Otherwise, the biopsy must be performed with the add-on unit. Advantages of the prone position are less patient anxiety and there is more room for the physician and technologist to maneuver because they can work under the table. When an add-on unit is used, the patient can visualize the needle, which can result in more anxiety and motion. However, the advantage of the add-on unit is that the resolution and quality of the images acquired are similar to diagnostic mammography. At most facilities, a special examination table will allow the patient to lie face down with the breast hanging freely through an opening in the table.

Biopsy Needles

The standard for stereotactic biopsy is now the vacuum assisted biopsy needle devices. They offer a number of advantages over spring loaded biopsy devices. The vacuum-assisted devices can obtain multiple specimens in a 360 degree fashion, require only one needle insertion, and provide larger specimens. The needles are

BOX 1 Indications for Stereotactic Core Biopsy

- Certain probably benign lesions, BI-RADS 3, depending on clinical suspicion, patient or physician preference, or when short-term follow-up is not practical
- BI-RADS 4, suspicious lesions
- BI-RADS 5, highly suspicious lesions
- BI-RADS 6, known biopsy-proven malignancy
- New suspicious mass- or calcification-type abnormalities, or architectural distortions
- Nonpalpable asymmetry, focal asymmetry, or density on mammogram not seen on ultrasound
- Magnetic resonance imaging–only lesions, corresponding to suspicious areas of enhancement on magnetic resonance imaging
- New mass or area of previous surgery site
- Area of abnormal tissue change

BI-RADS, Breast Imaging Reporting and Data System.

BOX 2 Contraindications for Stereotactic Core Biopsy

- Patient unable to lie prone or cooperate
- Patient's excess weight
- Lesion location near chest wall, axilla, or inframammary fold position to chest wall, or too close to implant
- Lesion too small or not well seen
- Patient unable to move table or move from one machine to another
- Lack of adequate skin-to-lesion distance (e.g., lesion too superficial)
- Pregnancy

powered by a suction device and have a rotating cutter. The automated biopsy guns usually have 14- to 18-gauge needles, whereas the vacuum-assisted biopsy guns have 7- to 11-gauge needles allowing for up to 12 biopsies. A 9-gauge needle is very popular and allows almost 1 cm of tissue removed. Regardless of the number or size of core biopsy samples obtained, most important is ensuring adequate sampling of the intended target. The biopsy should demonstrate presence of targeted calcifications on specimen radiography with radiologic-pathologic correlation to ensure the pathologic diagnosis are concordant and explain the imaging findings. For patients with microcalcifications, stereotactic vacuum-assisted biopsy is the standard approach; however, if calcifications are associated with a solid mass, then ultrasound-guided biopsy may be used.

Technique and Lesion Targeting

In the late 1990s, vacuum-assisted core biopsy devices became available, allowing larger specimen samples to be obtained. The patient is positioned, the skin is cleansed, and local anesthetic is administered. A small nick is made in the skin and the vacuum-assisted device is inserted into the breast under image guidance placed either in the suspicious lesion or adjacent to it. The device is typically rotated and multiple biopsies are taken from the suspicious lesion. The ideal approach is the shortest distance from skin to a targeted lesion. A scout view is obtained and after the target is identified, two additional images are obtained 30 degrees apart, at +15 degrees and −15 degrees. The basis of stereotactic localization is the principle of parallax, which is used to locate the lesion in the three-dimensional breast from a pair of two-dimensional images. Scout view provides the *x* (horizontal) and *y* (vertical) coordinates of the lesion to be targeted in the breast. Two additional images are then used to determine depth (*z* coordinate). The distance from needle tip to image receptor plate should be 5 mm or more to avoid penetration of the opposite side of the patient's skin and penetration of the image receptor plate. Once the needle device is introduced into the breast, and preimages are obtained to confirm the position, the needle is fired and then postfire images are obtained to confirm position (Fig. 1).

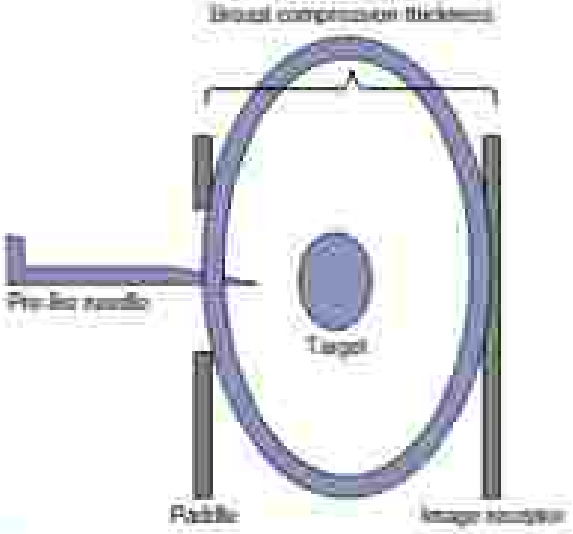

FIG. 1 This image demonstrates scenario of pre-fire positioning to target. (*See bottom, left.*) *x*, *y*, and *z* axes. (*See bottom, right.*)

When the vacuum-assisted biopsy device is used, tissue sampling is performed in a 360-degree fashion. Typically, 6 to 12 samples are obtained. The breast is compressed and held in position throughout the procedure.

Core Specimen Handling

To ensure adequate sampling, a specimen radiograph is obtained of the histologic samples collected during core biopsy to document targeted lesion retrieval (Fig. 2). After the specimen cores have been retrieved, a postbiopsy marker (clip) should be placed at the biopsy site. This marker facilitates mammographic surveillance and serves as a guide if surgical excision is required. If more than one lesion is biopsied, different types of clips are placed in the respective biopsy sites that will be visible on future mammograms and will show the physician which area has been biopsied. If the biopsy is being performed to evaluate calcifications, the specimens will be x-rayed to ensure that they do contain calcifications (Fig. 3). To ensure that the clip is deployed at the biopsy site, a postprocedure mammogram should be obtained. Clip migration can occur in up to 20% of cases.

Image-guided percutaneous biopsy is minimally invasive, causes minimal breast deformity and scarring, is faster than open surgical biopsy, and is well tolerated by the patient. The advantage of the vacuum-assisted biopsy device is that only one tube is inserted and the biopsies can be performed in a full degree fashion, with removal of the biopsy needle leaving the tube in place. Although overall accuracy is higher and false negative rates are low, these findings are heavily influenced by technique and experience of the physician performing the procedure.

Pathologic Correlation

Pathologic findings should correlate with imaging findings; however, when pathologic findings do not correlate with imaging, there is discordance, and excision is recommended. If the imaging has numerous calcifications, but the pathologic report lacks calcifications and indicates only benign breast tissue, the accuracy of the biopsy is suspect. If the calcifications were noted in the specimen radiograph, the pathologic blocks should be imaged to determine if calcifications remain unsampled in the block prompting additional levels being cut for pathology review.

Certain lesions require surgical excision to exclude a high-grade lesion malignancy (Box 3).

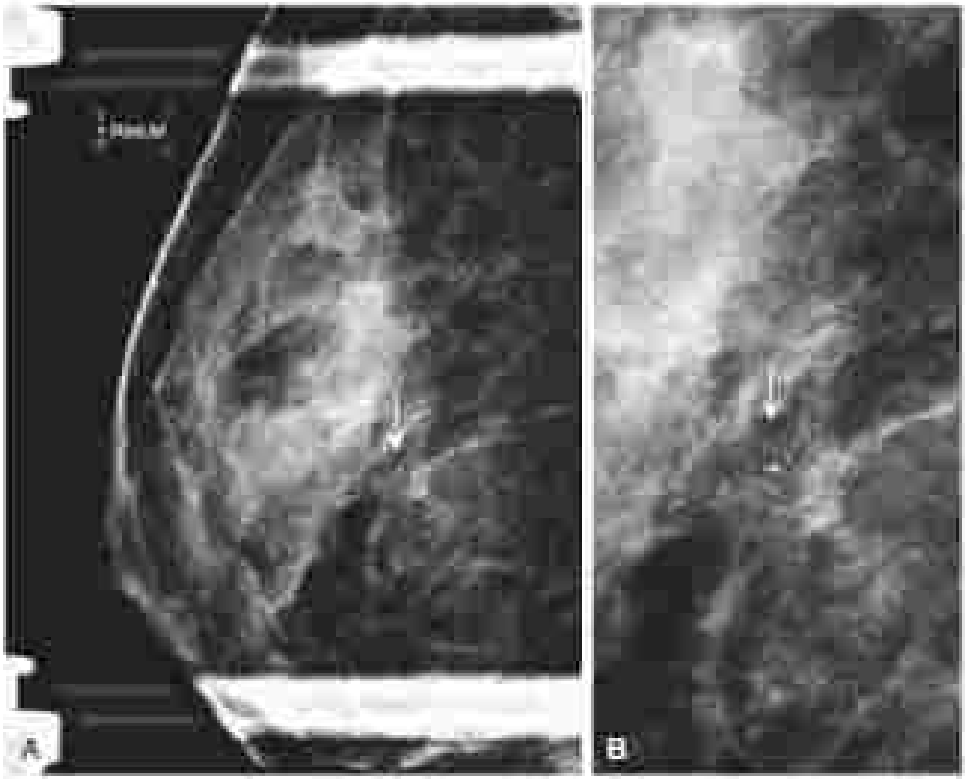

FIG. 2 (A) Mammographic images showing targeted stereotactic vacuum-assisted core biopsy of a pleomorphic microcalcification cluster (lateral view, (B) magnification mediolateral oblique view) in a patient undergoing stereotactic breast biopsy. (Courtesy of Carlos D'Alessio, MD.)

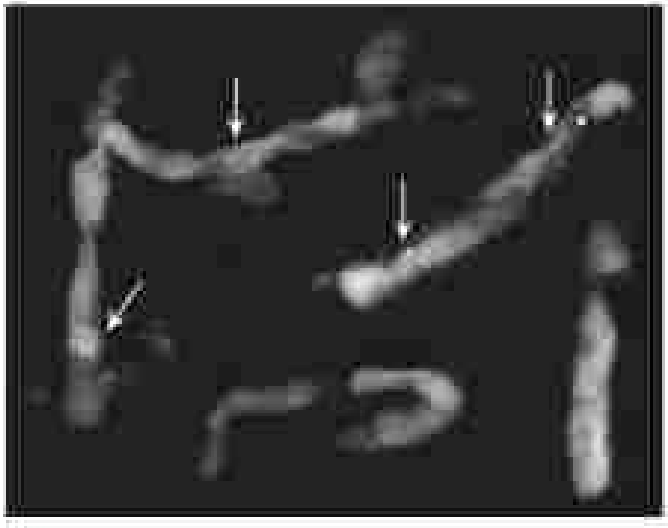

FIG. 3 Specimen radiograph demonstrating target microcalcifications contained within the tissue core. (Courtesy Carlos D'Alessio, MD.)

COMPLICATIONS

The incidence of severe complications is less than 1%. These include bleeding resulting in hematoma, infection, pneumothorax from biopsying lesions near to the chest wall, and vasovagal reactions. Core needle biopsies may obviate the need for open surgical procedures in about 72% of women.

The referring physician should stop anticoagulant therapy a few days before core biopsy. Core needle biopsy may still be performed safely in patients receiving anticoagulant therapy or aspirin, but the patient should be informed of increased risk of bleeding and hematoma formation.

BOX 3 Indications for Surgical Excision After Stereotactic Core Biopsy

- Imaging findings and pathologic findings do not correlate (discordance)
- Atypical ductal hyperplasia
- Atypical lobular hyperplasia
- Radial scar, complex sclerosing lesion
- Papillary lesions
- Cellular fibroepithelial lesions and Phyllodes tumors
- Lobular carcinoma in situ
- Mucocele-like lesions

For most patients with concordant radiologic pathologic findings after biopsy, a follow-up mammogram is suggested at approximately 6–12 months. Following excision of DCIS associated with larger areas of malignant calcifications, a postoperative mammogram is suggested to ensure completeness of resection beyond specimen radiography and pathologic margin assessment. A shorter imaging period may be indicated in certain situations. If the patient is older than 35 years, a unilateral diagnostic mammogram is generally obtained as a new baseline study within 6 to 6 months of the procedure.

WHAT'S NEW

Tomosynthesis

Digital breast tomosynthesis is rapidly replacing two-dimensional full field digital mammography as the preferred method of breast cancer screening. This technique acquires a series of 1-mm sections throughout the breast that can be viewed as a three-dimensional image set or individual slices. Although detection of microcalcifications is not improved, the ability to remove superposition artifacts allows the reviewer to better discern areas of architectural distortion, especially within dense breasts (Fig. 4A–C). These clinical utilities

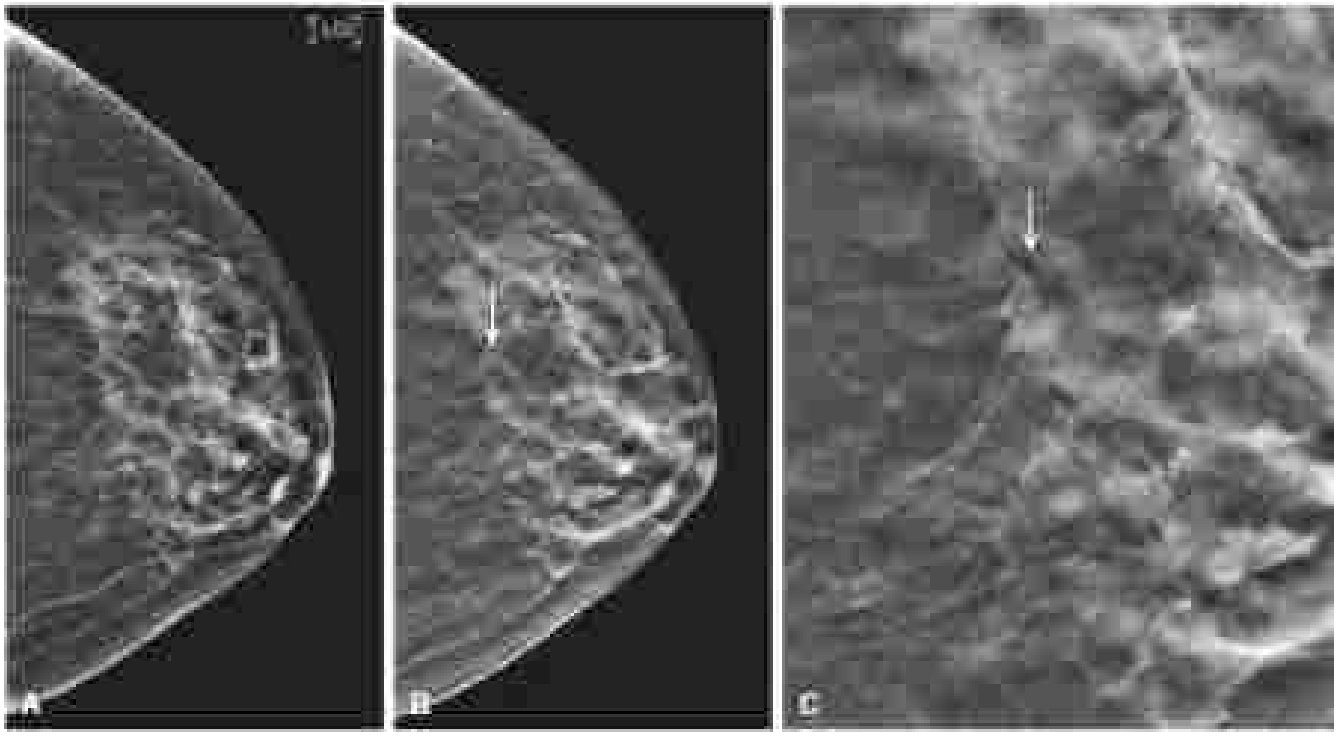

FIG. 4 (A) Two-dimensional digital craniocaudal mammogram and (B) tomographic image of the same view revealing suspicious area of architectural distortion (*arrow*) in a dense breast. (C) Magnification of the region depicts abnormal features. This lesion could not be localized sonographically and proved to be a low-grade invasive ductal and cribriform carcinoma on tomosynthesis-guided needle biopsy. (*Courtesy Northern Westchester Hospital, Mount Kisco, NY.*)

frequently require tissue sampling, but may not be able to be localized by additional sonographic or conventional two-dimensional radiographic techniques for percutaneous needle biopsy. Fortunately, an upright, add-on biopsy system is available that is attached directly to the three-dimensional mammography unit. This stereotactic tool can accurately localize these lesions for vacuum biopsy that may only be seen on one of the tomosynthesis sections.

SUMMARY

Stereotactic core needle biopsy is indicated in approximately 10% of biopsies and is safe with high specificity. It is the preferred method of diagnosis for nonpalpable lesions and microcalcifications. It is much more cost effective than surgical biopsy and results in shorter procedure time and return to normal activity. Newer technology is tomosynthesis screening and biopsy of architectural distortion.

MOLECULAR TARGETS IN BREAST CANCER

Meredith O. Wittke, MD, Helen Kourlaba, MD, Kirby L. Bland, MD, FACS, and Rachael B. Jacobstein, MD

Breast cancer, the most frequently diagnosed non-skin cancer in women is named based on a single tissue of origin, however, breast cancer is a heterogeneous disease with a multitude of presentations, prognoses, and treatments. Although most women with breast cancer have an excellent prognosis, many women will die from this disease. Breast cancer remains the second leading cause of death among women in the United States, reflecting the systemic aggressiveness of many of these tumors. Understanding tumor biology is critical to providing appropriate, personalized, and comprehensive cancer care. A thorough understanding of molecular profiling, breast cancer subtypes, and targeted drug therapies is both key to providing complete breast cancer care and clinically relevant to surgeons.

MOLECULAR PROFILING

Previously, breast cancer heterogeneity was defined in terms of anatomic staging (American Joint Committee on Cancer tumor node metastasis) and histologic appearance (ductal vs lobular, grade, lymphovascular invasion, etc.). These characteristics provided prognostic information on treatment response, risk of recurrence, and survival. However, molecular characteristics of tumors provide further and more specific characterization offering additional information regarding prognosis and tailored treatment options.

MOLECULAR TARGETS IN BREAST CANCER

Meredith O. Wittke, MD, Helen Krontiras, MD, Kirby I. Bland, MD, FACS, and Rachael R. Lancaster, MD

Breast cancer, the most frequently diagnosed non-skin cancer in women is named based on a single tissue of origin, however, breast cancer is a heterogeneous disease with a multitude of presentations, prognoses, and treatments. Although most women with breast cancer have an excellent prognosis, many women will die from this disease. Breast cancer remains the second leading cause of death among women in the United States, reflecting the systemic aggressiveness of many of these tumors. Understanding tumor biology is critical to providing appropriate, personalized, and comprehensive cancer care. A thorough understanding of molecular profiling, breast cancer subtypes, and targeted drug therapies is both key to providing complete breast cancer care and clinically relevant to surgeons.

MOLECULAR PROFILING

Previously, breast cancer heterogeneity was defined in terms of anatomic staging (American Joint Committee on Cancer tumor node metastasis) and histologic appearance (ductal vs lobular, grade, lymphovascular invasion, etc.). These characteristics provided prognostic information on treatment response, risk of recurrence, and survival. However, molecular characteristics of tumors provide further and more specific characterization offering additional information regarding prognosis and tailored treatment options.

TABLE 1 Breast Cancer Intrinsic Subtypes

Subtype	Characteristics	Markers
Luminal A	Low grade High ER ~80% of all breast cancer Good prognosis	ER+, PR+, HER2- Low Ki-67 (<14%)
Luminal B	Higher grade Lower ER ~20% of all breast cancer Poorer prognosis than luminal A	ER+, PR+/-, HER2 +/- High Ki-67 (>14%)
HER2 enriched	High grade Often node positive *TP53* mutations ~10%–15% of all breast cancer	ER-, PR-, HER2+
Basal like	High proliferation *BRCA* dysfunction ~15%–20% of all breast cancer Poor prognosis	ER-, PR-, HER2- CK5/6+ Or EGFR+

CK, Cytokeratin; EGFR, epidermal growth factor receptor; ER, estrogen receptor; HER2, human epidermal growth factor receptor-2; PR, progesterone receptor.

In 2000, Perou and colleagues first described intrinsic breast cancer portraits, or molecular classifications based on microarrays and hierarchal cluster analysis. These subtypes are essential to determining the surgeon's management and timing of surgical intervention of breast cancer. The four major molecular portraits are (1) estrogen receptor (ER)–positive, (2) basal like, (3) human epidermal growth factor receptor 2 (HER2) enriched, and (4) normal like. ER positive tumors are further divided into luminal A and luminal B subtypes. Complete molecular profiling is not feasible on individual patients; therefore, immunohistochemically defined surrogates were developed, and are generally comparable with the genomic profile (Table 1).

LUMINAL SUBTYPES

The majority of breast cancers are classified within the luminal subtypes are generally low grade with a favorable prognosis. The term *luminal* indicates a similar molecular expression of these tumors when compared with the epithelium of normal breast tissue. The two main ER positive subtypes are divided into luminal A and luminal B, which have different gene expressions, prognosis, and treatment responses.

Luminal A breast cancers express high levels of ER and demonstrate the best response rate to endocrine therapy. They represent the most common subtype (80%) and have the best prognosis compared with other breast cancer subtypes. Luminal B breast cancers are less common (20%) and, although they still have a good overall prognosis, they demonstrate more aggressiveness and a worse prognosis compared with luminal A tumors. Luminal B tumors display a higher grade, lower levels of ER positivity, and higher expression of the proliferation cluster (Ki-67) compared with luminal A tumors. In accordance with the lower ER expression, their response to endocrine therapy is lower than luminal A tumors; however, their response to traditional chemotherapy is superior to luminal A tumors. When compared with basal like and HER2 enriched tumors, luminal B tumors have a superior prognosis.

TABLE 2 Treatment According to Breast Cancer Subtype

Subtype	Treatment Response and Prognosis
Luminal A	Responds to endocrine therapy • Premenopausal: ER—Mx (amenorrhea) • Postmenopausal: AIs (exemestane, anastrozole, letrozole)
Luminal B	Response to endocrine therapy lower Response to chemotherapy greater than luminal A
HER2 enriched	Responds to anti-HER2 agents (trastuzumab, pertuzumab, lapatinib)
Basal like	No response to endocrine therapy or anti-HER2 agents Chemotherapy only treatment outside of a clinical trial

AI, Aromatase inhibitors; HER2, human epidermal growth factor receptor-2; SERMs, selective estrogen receptor modulators.

ER SIGNALING PATHWAYS

In 1896, Beatson first reported the regression of advanced breast cancer by removing the ovaries in premenopausal patients with this disease. Currently, it was noted, that oophorectomy only benefited approximately one third of women with breast cancer; for other women with breast tumors, there seemed to be no benefit to oophorectomy. In the 1970s, Jensen and colleagues described determining the presence of the ER within breast tumors and furthermore demonstrated that ER rich tumors were more likely to respond to endocrine modification than those with ER poor breast tumors.

The ER, a member of the steroid hormone receptor superfamily, is a ligand dependent transcription factor. The transcription factor is composed of two receptors, the ER alpha receptor and the estrogen beta receptor, both binding with high affinity to the ligand estrogen. When estrogen binds to the receptor, dimerization occurs and facilitates interaction of the receptor with promoter regions in the DNA.

In clinical practice, the assays used to define ER expression measure ER alpha levels, referred to as the classic ER. ER positivity is traditionally quantitatively with immunohistochemistry (IHC). Almost 65% of ER positive tumors are also progesterone receptor (PR) positive. The level of expression of ER is used to predict response to endocrine therapy. Approximately 70% of ER/PR positive breast cancers respond to endocrine therapy. A small percentage of breast cancers are ER negative/PR positive, and some of these tumors have shown a response with endocrine therapy, suggesting downstream endocrine pathway activation.

Endocrine therapy is administered with either selective estrogen receptor modulators (SERMs) or aromatase inhibitors (AIs) (Table 2). SERMs are competitive ER antagonists in breast tissue but act as partial agonists in other tissues. The most common and widely used SERM for breast cancer treatment, tamoxifen, was introduced in 1977. Tamoxifen competitively inhibits the binding of estradiol to estrogen receptors in the breast but has agonist activity in endometrial tissue.

Tamoxifen reduces the risk of breast cancer recurrence and death in premenopausal and postmenopausal women with ER positive tumors. A number of landmark trials have investigated the safety and efficacy of tamoxifen in the adjuvant setting. The Early Breast Cancer Trialists' Collaborative Group meta analysis included 18,445 patients from randomized trials and found that tamoxifen

reduced the 15-year probability of breast cancer recurrence and breast cancer mortality. These results led to establishing 5 years of adjuvant tamoxifen in premenopausal women with ER-positive breast cancers.

In 1982, the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 performed a randomized, double-blind, placebo-controlled trial in 2800 patients with primary operable, ER-positive, and lymph node–negative breast cancer to determine the effectiveness of adjuvant tamoxifen therapy. Disease-free survival was prolonged significantly through 10 years of follow-up in women treated with tamoxifen (69%) versus placebo (57%). There was also a 37% relative reduction in the cumulative incidence of a second primary breast cancer in the contralateral breast at 10 years of follow-up, 3.8% for tamoxifen-treated patients versus 6.1% for those on placebo ($P = .007$).

Tamoxifen is an oral drug taken daily (20 mg) with side effects commonly including hot flashes and vaginal dryness or discharge. The more severe side effects are rare and include thromboembolic events and development of endometrial cancer. The majority of the risk related to development of endometrial cancer is carried by postmenopausal women taking tamoxifen. With a risk of less than 1% per year, postmenopausal women taking tamoxifen should be monitored for symptoms of endometrial hyperplasia or cancer such as vaginal bleeding or spotting.

With a different mechanism of action than SERMs, AIs are the endocrine therapy of choice for postmenopausal patients with ER-positive tumors. The AIs currently approved in the clinical setting include exemestane, anastrozole, and letrozole. AIs block the conversion of adrenally synthesized androgens to estrogens, the final step in steroid conversion to the active form of the hormone. AIs do not alter the estrogen production from the ovary and are therefore contraindicated as single agent endocrine therapy in premenopausal women, but AIs can be administered to premenopausal women with ovarian function suppression (OFS) therapy. Reported in 2014, the combined results from the Tamoxifen and Exemestane Trial and the Suppression of Ovarian Function Trial demonstrated an improved disease-free survival in premenopausal women with ER-positive breast cancer who were treated with exemestane and OFS compared with tamoxifen and OFS. AIs are superior to tamoxifen for postmenopausal women displaying improved effectiveness and lower toxicity. Prospective randomized trials show the risk of local recurrence is reduced and disease-free survival is improved with AIs compared with tamoxifen. The Arimidex, Tamoxifen, Alone or in Combination trial studied ER-positive breast cancers in postmenopausal women by comparing anastrozole with tamoxifen, alone or in combination. The trial evaluated 9366 postmenopausal women with localized breast cancer. Anastrozole significantly prolonged disease-free survival and time to recurrence, in addition to reduced distant metastases and contralateral breast cancers. Almost all patients completed their scheduled treatment, with fewer withdrawals from anastrozole than tamoxifen. Anastrozole had fewer gynecologic and vascular events, but myalgia, arthralgia, and fractures were more common.

Extended Adjuvant Hormone Therapy

The typical ER-positive breast cancer recurrence occurs in a delayed fashion (15–20 years or more after diagnosis). Several studies investigated and showed value in extending endocrine therapy from 5 to 10 years. Ongoing trials are analyzing the impact of an initial 5 years of tamoxifen or an AI followed by another 5 years of an AI, as well as the concept of continuous versus intermittent extended AI therapy. In the Adjuvant Tamoxifen Longer Against Shorter trial, 6846 women with ER-positive breast cancer who had completed 5 years of tamoxifen were randomly assigned to either stop tamoxifen or continue tamoxifen for another 5 years. A reduction in breast cancer recurrence and mortality was observed in the group that took tamoxifen for an additional 5 years suggesting that 10 years of tamoxifen can reduce breast cancer mortality by one half in the second decade after diagnosis. The 20-year outcomes from the Adjuvant Tamoxifen Longer Against Shorter trial will be reported in 2018.

Endocrine Resistance

Although endocrine therapy is the most effective treatment for ER-positive breast cancers, the outcomes are limited by significant rates of both de novo resistance and resistance acquired during treatment. Methods of overcoming endocrine resistance include optimizing the schedule and dose of endocrine therapies, in addition to combining different agents. For example, the Southwestern Oncology Group (SWOG) S0226 trial showed anastrozole plus fulvestrant to be superior to anastrozole alone in terms of progression-free survival and overall survival. Endocrine resistance can also be addressed by understanding, identifying, and targeting crosstalk between ER and other signaling pathways, such as HER2, cyclin-dependent kinase, and phosphatidylinositol 3-kinase/mammalian target of rapamycin. This strategy becomes particularly important in the setting of stage IV disease. Largely because of results from the Evaluation in Combination With Exemestane in the Treatment of Postmenopausal Women With Estrogen Receptor Positive Locally Advanced or Metastatic Breast Cancer Who Are Refractory to Letrozole or Anastrozole II phase III clinical trial, the US Food and Drug Administration (FDA) has approved everolimus (mammalian target of rapamycin inhibitor) in combination with exemestane for the treatment of ER-positive/HER2-negative women who have recurrence or progression after anastrozole or letrozole therapy.

Targeted Treatment Through Gene Expression

With a greater understanding of tumor biology and molecular signatures, breast cancer treatments focus on characteristics of the individual tumor leading to appropriately administered chemotherapy in the high-risk ER-positive patient and avoidance of overtreatment in the low-risk ER-positive patient. Prognostic breast cancer tests based on gene expression profiling have been developed and are used in today's clinical setting to select patients that will obtain benefit from chemotherapy. Genetic expression profile analysis is covered by most insurance carriers. These assays are typically used in ER-positive/HER2-negative, node-negative breast cancers as an adjunct to other prognostic markers. Current National Comprehensive Cancer Network breast cancer guidelines recommend the use of gene expression profiles in patients with ER-positive, node-negative breast cancers to assess the benefits of additional therapy.

First described in 2004, Oncotype Dx (Genomic Health) is a multigene assay to predict recurrence of ER-positive breast cancers. Using reverse transcriptase polymerase chain reaction assay of 21 genes (5 reference genes and 16 cancer-related genes) in formalin-fixed, paraffin-embedded tumor tissue, Paik and colleagues used tissue samples collected from patients with node-negative, tamoxifen-treated breast cancer enrolled in NSABP B-14 to generate individual risk of recurrence. An individualized risk estimate or recurrence score (RS) of 0 to 100 is provided for each tumor sample: low risk, less than 18; intermediate risk, 18 to 30; and high risk, 31 or greater (Fig. 1). A low RS indicates that hormone therapy alone is adequate treatment. A high RS shows a high-risk patient who would benefit from chemotherapy followed by hormonal therapy. Studies have shown that associations of RS with survival are independent from standard clinicopathologic factors. Published in 2018, the Trial Assigning Individualized Options for Treatment (Rx) randomized 6711 patients with node-negative, ER-positive breast cancer with an RS of 11 to 25 randomly assigned to chemotherapy followed by endocrine therapy

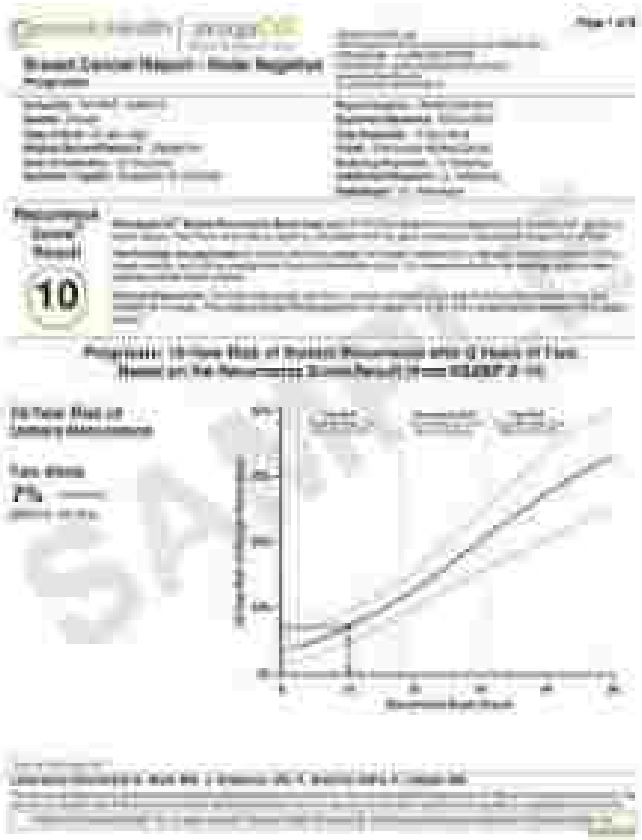

FIG. 1. Sample oncotype DX individual recurrence score (RS). The report shows an RS score on a scale of 1 to 100, which corresponds with a likelihood of distant recurrence at 10 years based on the average 10-year distant recurrence rate for that RS in the clinical trial population. Note that the clinical trial population was created with ... *(Oncotype DX and the genomic Score are in various trademarks of Genomic Health, Inc. Reproduced with permission.)*

versus endocrine therapy alone. Results showed that in women older than 50 years of age with RS 11 to 25 endocrine therapy alone was noninferior to combination of chemotherapy and endocrine therapy. Disease-free survival was similar between the two groups, and the overall survival was approximately 93% for both groups. Disease-free survival was affected with the combination of RS and age, however, with women younger than 50 years and an RS of 11 to 25 showing some benefit from chemotherapy. Investigators are also testing the value of the 21-gene assay in ER-positive, node-positive breast cancers. Retrospective studies such as the SWOG 8814 trial have investigated the prognostic utility of the 21-gene recurrence score in ER-positive, node-positive breast cancer. In this retrospective analysis, a low RS predicted little benefit from chemotherapy despite positive lymph nodes; high RS predicted significant benefit from chemotherapy. Studies have also shown this information has already changed clinical practice, with clinicians being influenced by the RS in node-positive patients before prospective data have been reported. Currently, the ongoing prospective SWOG RS for Positive Node, Endocrine Responsive Breast Cancer trial aims to answer the question regarding utility of RS in the setting of positive lymph nodes. Women with ER-positive/HER2-negative breast cancer with one to three positive nodes and an RS of 25 or lower are currently being enrolled and randomly assigned to chemotherapy followed by hormonal therapy versus hormonal therapy alone.

Other commercially available genomic assays include MammaPrint (Agendia) and PAM50 (Prosigna). MammaPrint is a 70-gene microarray assay performed originally only on freshly collected tissue, now also FDA-approved with formalin-fixed, paraffin-embedded tissue. Analysis of tumor generates a low-risk or high-risk result (without an intermediate group) to provide assistance with determining the benefit of adjuvant chemotherapy in selected patients with ER-positive or ER-negative disease. The Microarray in Node-Negative and 1 to 3 Positive Lymph Node Disease May Avoid Chemotherapy trial evaluated women with T1 to T2 operable disease and up to three positive lymph nodes. Total accrual of 6693 patients and patients with high clinical risk and high genomic risk went on to receive chemotherapy. Women with low clinical risk and low genomic risk received endocrine therapy alone; however, 1550 were deemed high clinical risk and low genetic risk. At 5 years, the rate of survival without metastatic disease in those who did not receive chemotherapy was 94.7%. The absolute difference between the two groups was 1.5 percentage points and was lower than the group receiving chemotherapy, indicating that 6% of women with breast cancer at high clinical risk may not require chemotherapy. PAM50 provides a Prosigna Score (0–100) with formalin-fixed, paraffin-embedded tissue. Prosigna is indicated for use in postmenopausal women with ER-positive, node-negative breast cancers.

HER2-Enriched

HER2-enriched tumors account for only 10% to 15% of all breast cancers. This subtype is characterized by high expression of HER2

TABLE 3 HER2 Immunohistochemistry (IHC) Result Interpretation

Staining Pattern	Score	Assessment
No observable staining, or membrane staining that is incomplete and is faint/barely perceptible in <10% of invasive tumor cells	0	Negative
Incomplete membrane staining that is faint/barely perceptible in >10% of invasive tumor cells	1+	Negative
Circumferential membrane staining that is incomplete and/or weak/ moderate in >10% of invasive tumor cells, or complete and circumferential intense membrane staining in <10% of invasive tumor cells	2+	Weakly positive (equivocal)
Homogeneous, dark, circumferential (chicken wire) pattern in >10% of invasive tumor cells	3+	Positive

HER2, Human epidermal growth factor receptor 2; IHC, immunohistochemistry.

TABLE 4 HER2 FISH Result Interpretation

	Copy Number	Ratio
Positive	>4.0	≥2.0
	<2.0	≥2.0
	≥6.0	<2.0
Negative	<4.0	<2.0
Equivocal	≥4.0 or <6.0	<2.0

HER2, Human epidermal growth factor receptor 2; FISH, fluorescence in situ hybridization.

and proliferation gene clusters but low expression of the luminal cluster; these tumors are typically HER2 positive and ER/PR negative. However some are also ER positive and included in the luminal B subtype. Before HER2 targeted therapy this subtype was associated with a short time to relapse, decreased overall survival, and carried a poor prognosis. HER2 overexpression is an independent poor prognostic indicator. HER2 should be tested on all invasive breast cancers because of its significant implications for prognosis and treatment. HER2 status can be determined through IHC testing or fluorescence in situ hybridization (FISH). In the United States, 80% to 90% of testing is done with IHC with confirmatory FISH testing for equivocal results (Tables 3 and 4).

HER2-Targeted Therapy

Four receptors make up the epidermal growth factor receptor (EGFR) family: HER1 (ERBB1/EGFR), HER2 (ERBB2), HER3 (ERBB3), and HER4 (ERBB4). These receptors are transmembrane proteins, and the best characterized of the EGFR family is HER2. The HER2 gene, also known as *HER2/neu* or *ERBB2*, is a proto-oncogene located on chromosome 17q21 and encodes a transmembrane protein composed of a ligand-binding extracellular domain and an intracellular tyrosine kinase domain. Normally, HER2 is expressed at a low level on the surface of epithelial cells and is necessary for the development of many tissues; however, the subset of breast cancer is characterized by an amplification or overexpression of the HER2 receptor on tumor cells.

Trastuzumab (Herceptin) is a recombinant humanized monoclonal antibody directed against the extracellular domain of the HER2 protein. Approved in 1998 for the treatment of metastatic breast cancer, trastuzumab significantly improved patients' outcomes and paved the way for developing targeted approaches in adjuvant breast cancer treatment. Several randomized controlled trials (NSABP B-31, North Central Cancer Treatment Group N9831, BCIRG 006, Finland Herceptin) using trastuzumab as adjuvant therapy have shown significantly improved disease-free and overall survival. As a result, current guidelines for patients with HER2 positive tumors include giving adjuvant trastuzumab with chemotherapy for tumors larger than 1 cm in diameter and node positive disease. In addition, trastuzumab should be considered for patients with tumors between 5 and 10 mm and micrometastatic nodal disease. The optimal duration of trastuzumab was determined through clinical trials to be 1 year of therapy.

Pertuzumab (monoclonal antibody directed at a different site of the HER2 extracellular domain) was approved in 2012 for use in metastatic HER2 positive breast cancers in combination with docetaxel and trastuzumab, based on results from the Neo*Sphere phase II study demonstrating that pertuzumab increased pathologic complete response rate; however, the FDA subsequently approved the use of pertuzumab in combination with trastuzumab and chemotherapy for early stage HER2 positive breast cancers in the neoadjuvant setting.

Overcoming HER2 Resistance

Primary or acquired resistance to trastuzumab is a major obstacle to the clinical management of HER2 positive breast cancers. Approximately 15% of patients relapse after therapy with trastuzumab. In understanding the mechanisms of trastuzumab resistance, new anti-HER2 agents are emerging as treatment alternatives. Antibody drug conjugates (T-DM1) consisting of the monoclonal antibody trastuzumab linked to the cytotoxic agent emtansine (DM1) are another emerging type of anti-HER2 targeted therapies. Lapatinib (oral, reversible, small molecule dual inhibitor of both HER1 [EGFR] and HER2 tyrosine kinases) for use in combination with capecitabine in trastuzumab refractory, HER2 positive, metastatic breast cancers was approved in 2007. However, thus far, randomized controlled trials have not shown any benefit in comparing trastuzumab plus capecitabine versus lapatinib plus capecitabine in patients with HER2 positive metastatic breast cancer previously treated with trastuzumab and taxanes. Current trials are investigating dual blockade and the potential synergistic effect of different combinations of both new and approved targeted HER pathway blockers to determine if chemotherapy may be avoided.

BASAL-LIKE

The basal-like subtype has a gene cluster profile similar to basal epithelial cells and is characterized by low expression of the luminal and HER2 gene clusters. Basal-like breast cancers have a high expression of EGFR and basal epithelial cytokeratins (CK) CK5/6, CK14, and CK17. Typically these tumors are ER, PR, and HER2 negative and are termed triple negative breast cancer (TNBC). The American Society of Clinical Oncology/College of American Pathologists guidelines used to define TNBC include lack of ER/PR (<1%) and HER2 expression (0 or 1+) by IHC and confirmation of HER2 status by FISH if indeterminate (2+) by IHC. The terms basal-like subtype and TNBC often are used interchangeably but they are not completely synonymous. For example, 20% of basal-like tumors

are not triple negative, and 23% of TNBCs are composed of other messenger RNA subtypes. TNBC is the clinical surrogate for the basal-like subtype.

TNBC accounts for about 10% to 20% of all breast cancers and is biologically the most aggressive. TNBC frequently affects younger patients (<40 years) and is more prevalent in African American women than in other demographic groups. These tumors tend to be larger, palpable, higher grade, and more often seen as interval cancers occurring between mammogram screenings; therefore, TNBC is associated with a higher relapse rate and a poorer survival rate than non-TNBC. Distant metastases typically occur at visceral sites rather than bone and often present within the first 3 years after diagnosis.

Triple-Negative Paradox

Triple-negative tumors lack estrogen and HER2 expression without current available targeted therapies. The standard of care for TNBC is anthracycline- and taxane-based combination chemotherapy (Table 2). Although patients with TNBC have a poor overall prognosis, their primary tumors are more sensitive to chemotherapy (higher pathologic complete response [pCR]) than luminal subtype breast cancers. This is termed the "triple-negative paradox." Although there is no overall survival advantage to receiving neoadjuvant versus adjuvant chemotherapy, it provides a surrogate marker for patients with TNBC who achieve pCR. Approximately 20% to 45% of TNBCs achieve pCR after anthracycline- or anthracycline/taxane-based treatments. Studies investigating the impact of pCR on overall survival in TNBC versus non-TNBC found that if pCR is achieved, patients with TNBC and non-TNBC have similar survival rates. However, TNBC patients with residual disease have a poor outcome, with a higher risk of relapse.

Triple-Negative Subtypes

Investigators recently have identified six different TNBC subtypes each displaying unique biology, and these subtypes have been found to be an independent predictor of pCR status. There are actually few overlapping gene mutations within the subtypes of TNBC with the exception of germline *BRCA1* mutations. The subtype genetic mutations differences are thought to drive the strikingly different responses to chemotherapy and progression of disease seen among these types of tumors. There are two basal-like subtypes, a mesenchymal subtype, a mesenchymal stem-like, an immunomodulatory type, and a luminal subtype driven by androgen signaling (luminal androgen receptor). Different cell types have different sensitivities to targeted therapeutic agents. Analysis of distinct gene expression signatures and the results of current clinical trials will assist in the selection of initial neoadjuvant chemotherapy regimens and ongoing treatment for those patients who do not achieve pCR.

Potential Targets for TNBC

There is ongoing research to identify potential targets within the subtypes of TNBC to deliver more targeted therapy. The Cancer Genome Atlas network discovered that basal-like breast cancers are more similar to high-grade serous ovarian cancer on the genomic level than to other subtypes of breast cancer. Approximately 20% of basal-like tumors had germline or somatic *BRCA1/BRCA2* mutations, suggesting shared driving events of basal-like breast cancer and serous ovarian cancer; therefore, TNBC lacking functional *BRCA1/BRCA2* might benefit from poly(ADP-ribose) polymerase inhibitors (olaparib, niraparib, rucaparib). Given the clinical similarities between sporadic TNBC and *BRCA1* mutation–associated breast cancer, it has been suggested that sporadic TNBC also may possess underlying DNA repair defects and demonstrate similar chemosensitivity, resulting in renewed interest in platinum agents. A subset of triple-negative breast cancers express androgen receptors. Enzalutamide, an androgen receptor inhibitor, has been studied and shown clinical activity and tolerability among patients with metastatic disease. Research and treatment recommendations regarding the androgen receptor and its role in triple-negative breast cancer is ongoing. Immune checkpoint inhibition is another potential future therapy for triple-negative breast cancer. The Study of Pembrolizumab (MK-3475) in Participants With Advanced Solid Tumors, a multicenter nonrandomized phase Ib trial of single-agent pembrolizumab given to patients with TNBC as well as gastric, urothelial, and head and neck cancers. Subsequent analysis of the TNBC subset showed that there was clinical activity with an acceptable safety profile.

FUTURE DIRECTION AND CONCLUSIONS

Through the discovery of cell receptors and molecular subtypes, there is a better understanding of tumor biology. Breast cancer subtypes provide prognostic information and direct therapeutic treatments. Gene expression profiling assays in the clinical setting provide personalized breast cancer care. Current investigations regarding immunotherapy in breast cancer are ongoing and will be an area of interest in the future. New therapies are needed to address resistance to current targeted drugs and lack of tailored therapy for TNBC. Surgeons caring for breast cancer patients should be well versed in the importance of tumor subtypes and their effect on treatment.

Breast Cancer: Surgical Therapy

Melissa S. Camp, MD, MPH

Surgery is a crucial element in the multidisciplinary treatment of breast cancer. The main benefits of surgery are to achieve locoregional control of the existing disease and to reduce the risk of locoregional recurrence. Surgery is most effective in achieving these goals when used in conjunction with systemic therapy and radiation. Since the era of the Halsted radical mastectomy, first performed in 1882 and the standard of care until the 1970s, the surgical management of breast cancer has changed dramatically. Over time, there has been a trend toward minimizing surgery in both the breast and axilla, with no detrimental effect on survival. This is due in large part to the significant advances in systemic therapy and radiation, both of which contribute to decreased rates of locoregional recurrence. Moreover, improvements in systemic therapy have led to enhanced long-term prognosis and survival. Thus, in the contemporary era, patients with breast cancer will often have an array of surgical options to choose from.

DIAGNOSIS OF BREAST CANCER

With screening mammography, many breast cancers are detected before they are palpable by the patient or by a physician on clinical examination. Imaging abnormalities, such as suspicious calcifications or a speculated mass, should undergo core needle biopsy for tissue diagnosis. If malignancy is identified, pathology from the core needle biopsy will provide information regarding in situ versus invasive cancer, the type of cancer such as ductal versus lobular, the grade of the cancer, and the receptor status (estrogen, progesterone, and human epidermal growth factor receptor 2 [HER2]). This information helps to guide decisions regarding surgery as well as other therapies.

Once a diagnosis of cancer is obtained, further imaging workup may be necessary to evaluate the extent of disease. In addition to mammography, other imaging modalities that could be used include ultrasound (US) of the breast, axillary US if there is a concern on clinical examination for axillary nodal involvement, and breast magnetic resonance imaging (MRI) if the extent of disease is difficult to define by mammography and US.

A clinical stage is assigned based on the size of the largest tumor in the breast and the clinical axillary nodal status. For patients with clinical stage III breast cancer and any patients with signs/symptoms of possible metastatic disease, a computed tomography (CT) scan of the chest/abdomen/pelvis plus a bone scan or a positron emission tomography (PET) should be performed to evaluate for distant metastatic disease.

DISCUSSION OF SURGICAL OPTIONS

For patients with early stage breast cancer (clinical stage I or II), surgery is typically the first step in treatment. The pathology results from surgery are then used to inform decisions regarding adjuvant systemic and/or radiation therapy. With respect to surgical management of the cancer in the breast, the two main options are breast conservation (lumpectomy plus radiation) versus mastectomy. National Surgical Adjuvant Breast and Bowel Project (NSABP) B-06 was a large, prospective randomized trial that demonstrated no difference in overall survival when comparing lumpectomy plus radiation versus mastectomy. The risk of local recurrence after lumpectomy plus radiation is a little higher than after mastectomy, but the risk of local recurrence after mastectomy is not zero. With modern systemic therapies and delivery of adjuvant radiation, the risk of local recurrence after lumpectomy and radiation is approximately 5% to 8%. The risk of local recurrence after mastectomy is approximately 2%.

Deciding between lumpectomy plus radiation versus mastectomy is often a very difficult choice for many patients. In some cases, mastectomy is necessary because of the presence of multicentric disease or due to prior radiation to the ipsilateral breast or chest wall. In other cases, the size of the tumor in relation to the size of the breast makes lumpectomy a less cosmetically desirable choice. But for many women with early stage breast cancer, they will have the option for either lumpectomy or mastectomy. It is the role of the surgeon to discuss both options in detail, with the associated pros and cons. It is important to emphasize that the long-term prognosis and overall survival are equivalent with lumpectomy plus radiation versus mastectomy, and that decisions about systemic therapy are completely independent of the type of surgery performed. Recommendations regarding chemotherapy, HER2 targeted therapy, and hormone blocking therapy are based on the characteristics of the tumor itself, and the type of surgery performed has no bearing on these recommendations. Adjuvant radiation therapy is recommended following lumpectomy but is sometimes omitted in women older than 70 with hormone sensitive tumors <2 cm in size. As demonstrated in the Cancer and Leukemia Group B (CALGB) 9343 trial, receiving radiation in addition to hormone blocking therapy does not improve overall survival, but adding radiation does contribute to a lower risk of local recurrence in this subset of patients (2% vs 9% at 10 years). Following mastectomy, radiation is indicated for women with tumors larger than 5 cm, positive margins, or evidence of axillary lymph node involvement.

Other factors that may affect surgical decision-making include a strong family history of breast cancer, a genetic predisposition to breast cancer (such as BRCA, p53, PTEN, or PALB2 mutation carrier), a personal history of prior chest wall radiation, or a history of lobular carcinoma in situ or atypia. A thorough family history should be obtained from the patient to determine eligibility for genetic testing. In general, any woman diagnosed with breast cancer before age of 50 (or with triple negative breast cancer before age of 60), woman diagnosed with breast cancer at any age who have a strong family history of breast and/or ovarian cancer, woman diagnosed with breast cancer who are of Ashkenazi Jewish descent, and any male diagnosed with breast cancer should be referred for genetic counseling and testing. Appropriate surgical management of the current breast cancer should be paramount, but it is also important to take into consideration the risk of development of a new primary breast cancer (either in the ipsilateral or contralateral breast). Women with a substantially elevated risk of developing another breast cancer in the future may opt for a more aggressive risk reducing surgical approach, such as bilateral mastectomy.

LUMPECTOMY

The goal with lumpectomy is to remove the area of malignancy with clear or negative margins. For nonpalpable lesions, preoperative localization is performed with a wire (Fig. 1), radioactive seed, or other device. Incision placement can vary according to the location of the lesion. If feasible, a periareolar incision may allow for a less noticeable scar and be more cosmetically appealing. If the location of the lesion dictates placement of the incision elsewhere on the breast, following the skin tension lines can guide the location and shape of the incision. This may result in a curvilinear incision in the upper outer and lower outer quadrants, horizontal incisions in the upper inner and lower inner quadrants, and radial incisions at the 3 and 9 o'clock positions. Confirmation of successful retrieval of the lesion is generally assessed with intraoperative specimen radiograph of the lumpectomy specimen. Recent American Society for Radiation Oncology (ASTRO) consensus guidelines for appropriate margins in the setting of lumpectomy are an inked surface of the lumpectomy specimen

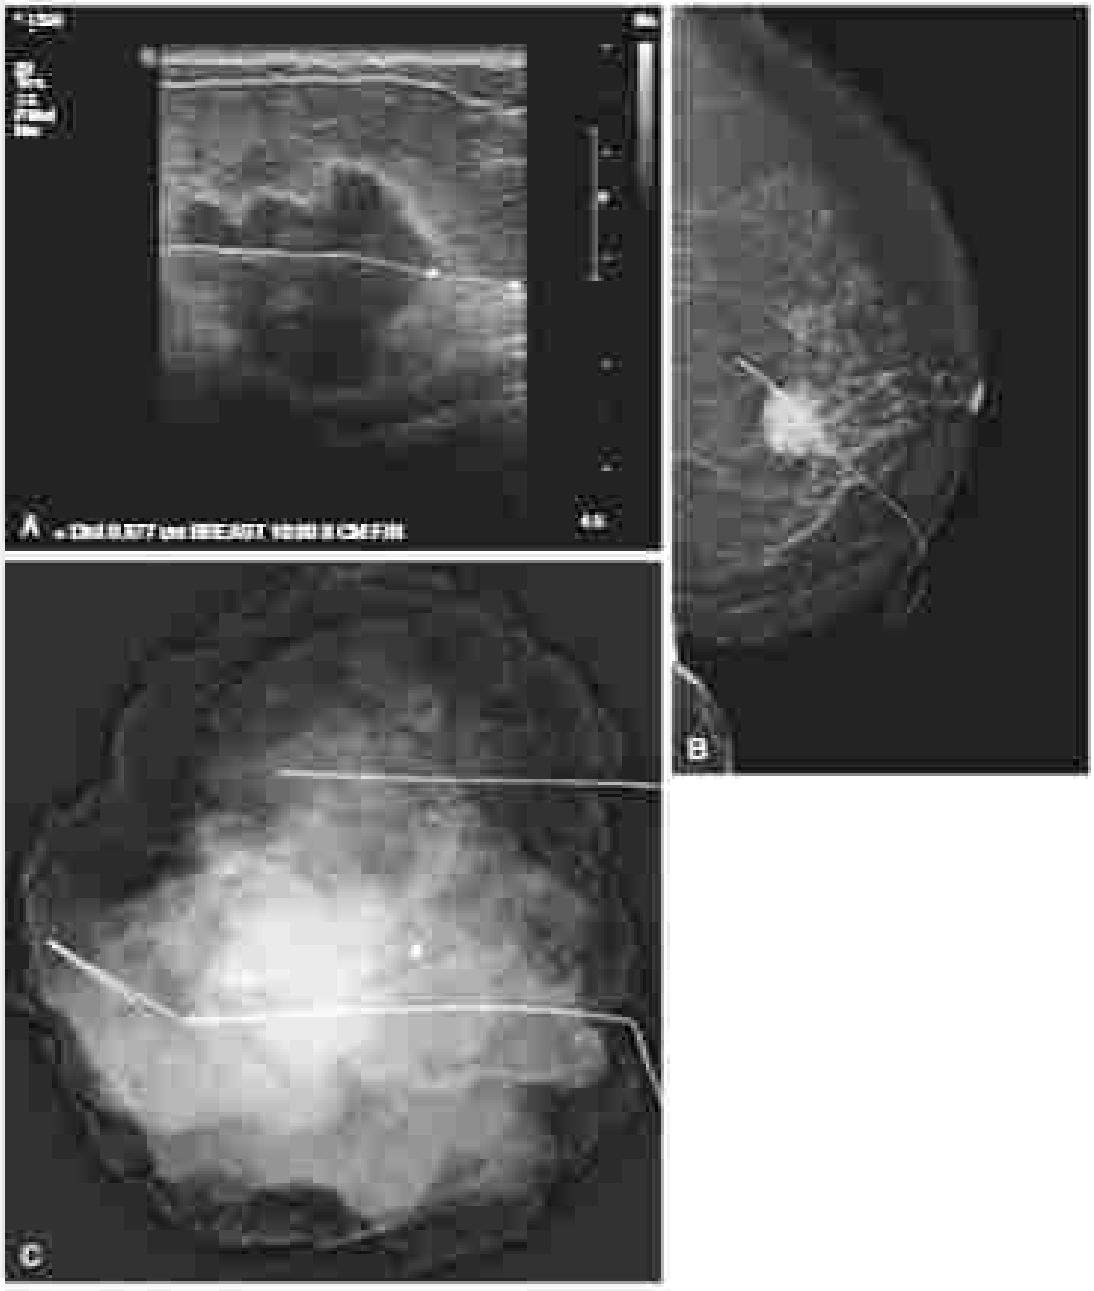

FIG. 1 W [illegible] Lumpectomy (A) A [illegible] with a guidewire [illegible] (B) [illegible] (C) [illegible]

for invasive cancer and a 2 mm margin for ductal carcinoma in situ. Wider margins have not been shown to reduce the risk of local recurrence, assuming appropriate adjuvant radiation and systemic therapies are delivered. If margins are positive following lumpectomy, then reexcision to achieve negative margins is indicated. The number of reexcisions that can be attempted if margins are persistently positive will depend on the volume of tissue already resected in relation to the breast size, as well as the number of positive margins requiring reexcision. If margins are persistently positive despite attempts at reexcision, then completion mastectomy is indicated.

Some surgeons will perform shave margins of the lumpectomy cavity after the lumpectomy specimen has been resected. Shave margins sample the six faces of the lumpectomy cavity and are considered to represent the final margins. Shave margins have been shown to reduce the risk of positive margins and need for reexcision by approximately 50%. Additional separate microscopic foci of disease are found in the shave margins about 12% of the time and may be indicative of a multifocal disease process that was not previously identified by imaging.

Oncoplastic techniques can be used in the setting of lumpectomy for rearrangement of the remaining tissue into the resultant defect, allowing for an improved cosmetic result. For women requiring a very large lumpectomy, or for women with large breasts who desire breast reduction, oncoplastic rearrangement of the affected breast can be performed in conjunction with reduction of the contralateral breast for symmetry.

MASTECTOMY

Mastectomy entails removal of all the breast tissue, which extends to the clavicle superiorly, to the sternum medially, to the inframammary fold inferiorly, and to the latissimus dorsi muscle laterally. Mastectomy can be performed either with or without reconstruction. For a simple mastectomy performed without reconstruction, a large elliptical incision is made encompassing the nipple areolar complex. Enough skin should be resected such that the remaining skin lies flat against the chest wall and the lateral portion of the incision may need to be tailored to resect any redundant skin. A flat chest wall surface following mastectomy without reconstruction aids in the fitting of a breast prosthesis postoperatively.

Mastectomy performed with reconstruction can be done in a skin sparing or nipple sparing fashion. A skin sparing mastectomy includes resection of the nipple and areola but preserves the majority of the skin overlying the breast to allow for reconstruction. A skin-sparing incision commonly consists of a small ellipse including the nipple areolar complex, but can be oriented obliquely or vertically (such as an inverted teardrop). Incision planning should take into account the location of the tumor if it is in close proximity to the skin, and the orientation of the incision should also be planned in concert with the plastic surgeon who will be performing the reconstruction.

Nipple sparing mastectomy is appropriate in some patients and preserves the entire skin envelope of the breast including the nipple and areola. The preferred options for incision placement are typically in the inframammary fold or along the mid-lateral border of the breast. A bi-lateral incision allows for access to the axillary lymph nodes to perform a sentinel lymph node biopsy or an axillary lymph node dissection. Other incisions, such as a lateral horizontal incision, can also be used for a nipple sparing approach. Eligibility for nipple-sparing mastectomy depends on the proximity of the cancer to the nipple, as well as risk factors for poor blood supply to the nipple such as large breast size, significant breast ptosis, current smoking status, and longstanding diabetes. Additional risks inherent to nipple sparing mastectomy include a positive subareolar margin and nipple necrosis, both of which could necessitate removal of the nipple areolar complex at a later date. The subareolar margin is the ductal tissue removed from directly underneath the nipple and sent to pathology for examination separately from the main mastectomy specimen. If there is evidence of malignancy in the subareolar margin, then the nipple should be resected to ensure no disease is left behind.

A modified radical mastectomy includes the removal of the level 1 and 2 axillary lymph nodes in addition to the breast and is indicated for clinically and biopsy proven positive lymph node involvement. A modified radical mastectomy can be performed with or without reconstruction. If immediate reconstruction is performed, a skin sparing or nipple sparing approach can be used. For patients undergoing modified radical mastectomy for inflammatory breast cancer, reconstruction should be performed in a delayed fashion. Radical mastectomies with resection of the entire pectoralis major and minor muscles are rarely performed in the current era, but limited resection of the pectoralis muscle is recommended if there is any evidence of pectoralis muscle invasion identified on preoperative imaging or the operative intraoperatively.

AXILLARY STAGING

The axillary nodal status is important in patients with breast cancer for staging and for decision making regarding adjuvant therapy. Moreover, it carries prognostic implications. For patients with clinically node negative disease, a sentinel lymph node biopsy is the standard of care. A sentinel lymph node biopsy can be performed in conjunction with a lumpectomy or a mastectomy, and sentinel node mapping can be accomplished using blue dye, radioactive tracer colloid radiotracer, or both. Patients who are found to have positive sentinel lymph nodes may or may not need to undergo a completion axillary lymph node dissection. According to the Z0011 trial, patients with T1 to T2 tumors who are clinically node negative and undergoing lumpectomy with sentinel lymph node biopsy do not require a completion axillary lymph node dissection if they are found to have one or two positive sentinel lymph nodes. There is no difference in overall survival or locoregional recurrence in this subset of patients if they undergo a completion axillary dissection versus no further axillary surgery. This suggests that adjuvant radiation and systemic therapies have a significant effect on any potential remaining positive nodes and contribute to effective local control without a completion axillary lymph node dissection.

Z0011 does not apply to patients with three or more positive sentinel lymph nodes, patients undergoing mastectomy, or patients who received neoadjuvant therapy. The After Mapping of the Axilla: Radiotherapy or Surgery? (AMAROS) trial included patients undergoing lumpectomy or mastectomy with positive sentinel lymph nodes, and randomized patients to completion axillary dissection versus axillary radiation. There was no statistically significant difference in overall survival or axillary recurrence, but the patients who underwent completion axillary dissection had a twofold increased risk of lymphedema compared with the patients who underwent axillary radiation (10% vs 22% at 1 year and 20% vs 14% at 5 years). The majority of patients in the AMAROS trial (82%) underwent lumpectomy, but 18% of patients did undergo mastectomy; therefore, postmastectomy radiation can be considered in place of completion axillary dissection for patients undergoing mastectomy with a limited number of positive sentinel lymph nodes.

For patients who present with clinically positive axillary lymph nodes, axillary US should be performed. US guided core needle biopsy or fine needle aspiration (FNA) should be performed of any lymph nodes with abnormal features. If malignancy is confirmed on pathology or cytology of needle biopsy of the lymph node, then a level 1 and 2 axillary lymph node dissection is indicated for patients undergoing surgery first. Biopsy proven lymph node involvement, however, warrants consideration of neoadjuvant therapy. Subsequent surgical management of the axilla will then depend on the response to neoadjuvant therapy.

LOCALLY ADVANCED BREAST CANCER

For patients who present with larger tumors and/or lymph node involvement at diagnosis, surgery may not be the first step in treatment. Systemic staging (with either a positron emission tomography CT or CT scan of the chest/abdomen/pelvis plus bone scan) should be performed to rule out the presence of distant metastatic disease. If disease is confirmed to be confined to a locoregional distribution, then neoadjuvant therapy should be considered to downstage the breast as well as the axilla. Repeating imaging with mammography, US and breast MRI following neoadjuvant therapy can assess response to treatment and determine eligibility for certain surgical options. MRI is typically the most sensitive imaging modality for evaluating response to neoadjuvant therapy. If breast conservation is planned, repeat mammography and US are very useful in preparation for localization of any residual imaging abnormality.

Management of the axilla following neoadjuvant therapy is dependent on the nodal status at diagnosis and the response to treatment in the axilla (Fig. 2). For patients eligible for neoadjuvant therapy who are clinically node negative at presentation, axillary US can be performed to confirm normal appearing axillary lymph nodes. In this subset of patients, a sentinel lymph node biopsy should be performed at the conclusion of neoadjuvant therapy. If any indeterminate or suspicious axillary lymph nodes are identified on axillary US, a US-guided FNA or core needle biopsy should be performed for tissue diagnosis. A biopsy clip, preferably a clip that is visible mammographically, should be placed into the lymph node at the time of biopsy. If needle biopsy is negative for malignancy, then a sentinel lymph node biopsy would be recommended at the conclusion of neoadjuvant therapy. As demonstrated in the Sentinel Neoadjuvant (SENTINA)

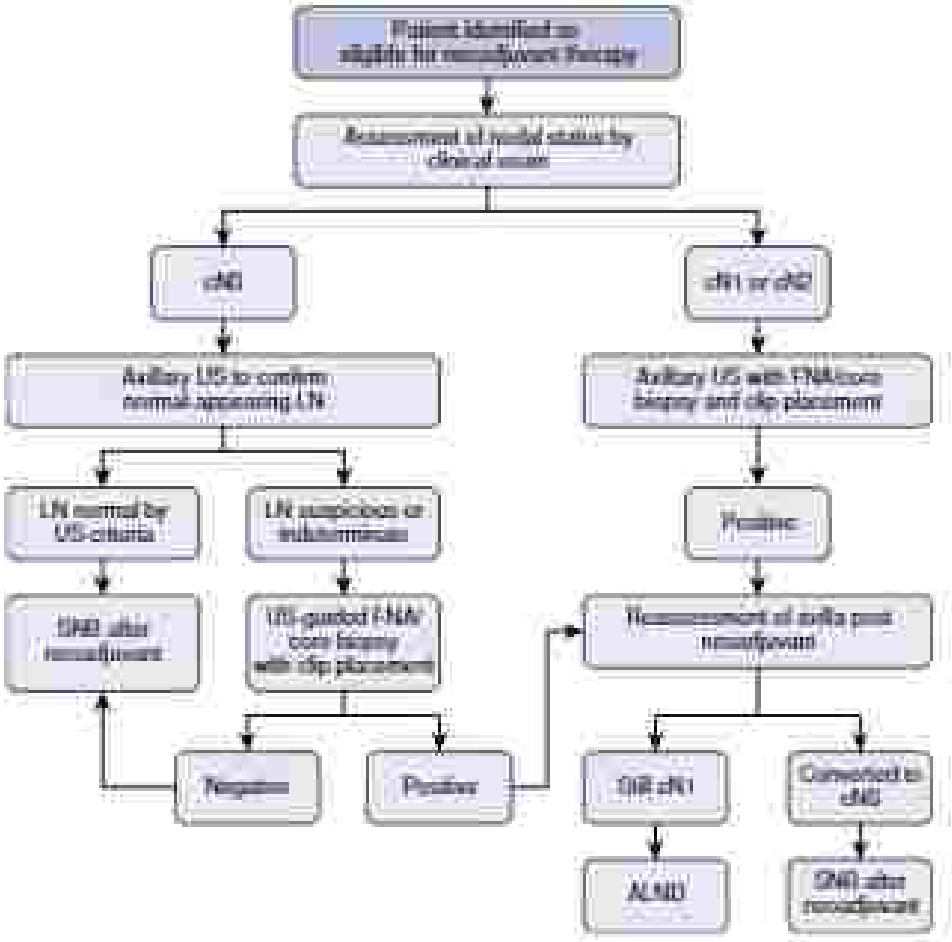

FIG. 2 Schematic diagram depicting management of the axilla for patients receiving neoadjuvant therapy. ALND, Axillary lymph node dissection; LN, lymph node; SNB, sentinel node biopsy.

trial, the false negative rate of a repeat sentinel lymph node biopsy (e.g., a sentinel lymph node biopsy performed before neoadjuvant therapy and then repeated again after neoadjuvant therapy) is unacceptably high. Thus, the preferred approach is to perform a sentinel lymph node biopsy following neoadjuvant therapy in patients who are clinically node negative at diagnosis. If a patient is clinically node negative on examination but needle biopsy of an indeterminate or suspicious axillary lymph node were on US to positive for malignancy, then the axilla should be reevaluated following neoadjuvant therapy to assess response to treatment.

For patients who present with clinically positive axillary lymph nodes at diagnosis, an axillary US followed by an US-guided FNA or core needle biopsy is indicated for tissue diagnosis. A xenographically visible clip should be placed into the lymph node at the time of biopsy. If pathology confirms evidence of lymph node involvement, then the axilla should be reassessed following neoadjuvant therapy. In the setting of persistently clinically positive nodes, an axillary lymph node dissection is recommended. If the axilla has converted to clinically node negative, then a sentinel lymph node biopsy may be appropriate to select patients. Important surgical considerations include the extent of nodal involvement at diagnosis (minimal vs extensive lymphadenopathy), the tumor biology (with respect to the likelihood of achieving a pathologic complete response in the axilla), as well as the clinical and imaging response following neoadjuvant therapy. The surgical technique used during the sentinel lymph node biopsy procedure is also critical to minimize the false negative rate to an acceptable level. As demonstrated by the ACOSOG Z0011 and SENTINA trials, the use of dual tracer (methylene blue dye and technetium sulfur colloid radiotracer), attempting to remove at least 3 sentinel lymph nodes, and successfully retrieving the previously biopsied clipped lymph node all contribute to a lower false negative rate. Approximately 25% of the time, the clipped lymph node is not one of the sentinel lymph nodes. The term "targeted axillary dissection" has been coined to refer to retrieval of the clipped lymph node in addition to the sentinel lymph nodes. Localization options to aid in successful retrieval of the clipped lymph node include use of intraoperative US to identify a sonographically visible biopsy clip, preoperative wire or radioactive seed localization of the clipped lymph node, and injection of tattoo ink into the clipped lymph node to assist in intraoperative visualization.

BREAST CANCER STAGING: AJCC 8TH EDITION

Breast cancer staging, according to the eighth edition of the American Joint Committee on Cancer (AJCC) staging guidelines released in late 2017, is now based on anatomic as well as biomarker information. The standard anatomic TNM criteria apply (T representing the size of the tumor, N representing the number of lymph nodes involved, and M representing the presence or absence of distant metastatic disease), but the new staging guidelines also incorporate biomarkers including the grade of the tumor and the estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2) receptor status. Oncotype Dx score, if applicable, is also included. If Oncotype Dx has been performed on a T1 or T2 N0, ER+, any PR status, HER2-negative tumor, and the score is less than 11, then the tumor is classified as Stage IA regardless of tumor size. If the Oncotype Dx score is 11 or greater, then the pathologic staging is based on TNM grade, ER, PR, and HER2 criteria. Oncotype Dx is currently the only multigene panel included in the staging system, but others may be added in the future.

TABLE 1 Anatomic Staging Groups, AJCC, 8th Edition, Staging

When T is...	And N is...	And M is...	Then Stage Group is:
Tis	N0	M0	0
T1	N0	M0	IA

T4	N1	M0	IIIB
T4	N2	M0	IIIB
Any T	N3	M0	IIIC
Any T	Any N	M1	IV

From Amin MB, Edge SB, Greene FL, et al, eds. AJCC Cancer Staging Manual. 8th ed. New York: Springer; 2017. Used with the permission of the American College of Surgeons.

The staging groups in the AJCC staging system are divided into anatomic and prognostic staging groups. The anatomic staging groups are based purely on TNM criteria and should only be used if biomarker information is unavailable (Table 1). The prognostic staging groups are based on TNM criteria and biomarker information, and are further subdivided into clinical prognostic and pathologic prognostic staging groups. Clinical prognostic staging can be used for all patients, regardless of neoadjuvant therapy, and is based on history, physical examination findings, biopsy results, and biomarker information (see example in Table 2). Pathologic prognostic staging is only applicable to patients who undergo definitive surgical resection as their initial treatment (see example in Table 3).

As depicted in Tables 2 and 3, the anatomic and clinical pathologic prognostic stages for a given tumor may differ because of the incorporation of biomarker information. The assigned stage based on clinical/pathologic prognostic staging groups reflects the biology of the tumor and expected prognosis based on treatment with appropriate therapies. Clinical/pathologic staging is therefore preferred, but anatomic staging can be performed in places where biomarker information is not readily available.

SURGERY IN PATIENTS WITH STAGE IV BREAST CANCER

For patients who present with distant metastatic disease at diagnosis, a prompt referral to medical oncology to discuss systemic therapy is indicated. Surgery may or may not be performed, depending on the extent of metastatic disease and the response to systemic therapy. In the setting of oligometastatic disease with an excellent response to systemic therapy, surgery to address the breast primary and locoregional lymph nodes may be contemplated. This approach should involve a multidisciplinary discussion with input from surgery, medical oncology, and radiation oncology. For patients with widespread metastatic disease and/or a poor response to systemic therapy, surgery is sometimes considered for palliation of locoregional progression.

TABLE 2 Clinical Prognostic Stage Groups, AJCC, 8th Edition, Staging

From Amin MB, Edge SB, Greene FL, et al, eds. *AJCC Cancer Staging Manual*. 8th ed. New York: Springer; 2017. Used with the permission of the American College of Surgeons.

By anatomic staging, all of these TNM categories would be classified as stage IIIA. With the addition of biomarker information, the Pathologic Prognostic Stage ranges from IB to IIIC.

CONCLUSIONS

Surgery is a key facet in the multidisciplinary treatment of patients diagnosed with breast cancer. Over time, the integration of surgical techniques with advances in radiation and systemic therapies has allowed for less invasive surgical procedures. This has resulted in decreased surgical morbidity for patients, yet overall improved outcomes and survival.

Ablative Techniques in the Treatment of Benign and Malignant Breast Disease

Mariusa Yasa, MD, MSc, and Fernando E. Gaviria, MD, FACS, FRCSEd

Extending the trend toward less invasive treatment, ablative techniques for benign tumors and small breast cancers have continued to progress. Ablative treatments are all image guided percutaneous techniques (using ultrasonography, mammography, magnetic resonance imaging [MRI], or computed tomography [CT]). Complete tumor ablation can be achieved using different types of energy instead of or in addition to immediate or delayed surgical excision. The goal of these ablative techniques is to reduce the complications, decrease morbidity, shorten hospitalization, and improve the cosmetic outcome and quality of life while not increasing recurrence rates. Ablation techniques include radiofrequency ablation (RFA), microwave, laser ablation, electromagnetic waves, cryoablation, and high intensity focused ultrasound.

RFA

RFA is a widely used ablative technique for various solid tumors at different sites, including liver, lung, kidney, and bone. RFA uses low-frequency electromagnetic waves to generate heat and ablate these tumors. To perform RFA, a needle is inserted percutaneously within the tumor, usually with ultrasound guidance, but CT or MRI guidance may be used. A generator creates a high-frequency alternating current, in response, ions attempt to follow the changing direction, causing agitation and frictional heating. This results in destruction of the tumor tissue through thermal coagulation and protein denaturation (Fig. 1).

In most studies, RFA is followed by immediate or delayed surgical excision of the tumor. Izzo et al. performed one of the first feasibility studies that included 26 breast cancer patients with a mean tumor size of 1.8 cm (range, 0.7–3.0 cm). Complete tumor ablation was obtained in 96% (25 of 26) of the patients. Since then, multiple RFA studies have been performed with success rates varying from 77% to 100%. Only a few studies performed RFA without surgical excision. Ohara et al. included 52 patients with a tumor size of 2 cm or less who underwent RFA alone. MRI after 1 to 3 months showed no evidence of residual disease. After a follow up of 71 months, none of the patients developed locoregional or distant recurrences. Cosmetic outcome was reported excellent in 83%, good in 11%, and fair in 6% of the patients.

Excision RFA (eRFA) consists of surgical excision of the tumor followed by RFA. The aim is to decrease the rate of reexcisions after breast-conserving surgery, to improve locoregional recurrence rates by extending the margins, and ablating possible residual disease. Klimberg et al. performed a study in 100 patients undergoing breast-conserving surgery followed by eRFA in which biopsy showed at least 1 cm circumferential ablation around the resection cavity. Of these 100 patients, 78 had negative margins (>2 mm) and 22 had margins 2 mm or less, of which 3 were locally positive. Recurrence after 5 years of follow up was seen in 3% of the patients treated with systemic hormonal therapy and in 10% without systemic hormonal therapy. Recently, results of the multicenter Radiofrequency Ablation After Breast Lumpectomy study were presented. A total of 267 T0 to T2 breast cancer patients treated with breast-conserving surgery followed by eRFA were included. Results showed a reexcision rate for positive margins of <5%. The rate of breast recurrence was 2.5% after 3 years of follow-up.

RFA appears to be limited to tumors with a maximum size of 2 cm. RFA treatment is not suitable for infiltrating lobular breast tumors, tumors with an extensive in situ component, and in patients treated with neoadjuvant systemic therapy. Complications from RFA are rare and generally mild, including skin or muscle burns and seromas.

MICROWAVE ABLATION

Thermal ablation can also be performed with the use of microwaves. Microwave ablation (MWA) uses electromagnetic waves at frequencies of at least 900 mHz. Localized heat caused by water molecules moving within tissue results in tissue destruction. Tissues with high water content, such as breast tumors, are heated and damaged more rapidly compared with tissues with lower water content, such as normal breast tissue with surrounding fat, which may remain unharmed. To perform MWA, the breast must be compressed between two plates. The electric field probe is inserted into the central portion of the tumor under ultrasound or CT guidance. A fiber optic temperature probe is placed in the tumor to guide and adjust the temperature. Skin temperature probes are applied to the skin to monitor the temperature to avoid skin burns. A cooling system can be used to provide air cooling, decreasing the risk of thermal injury to the skin.

The first pilot study of MWA was performed by Carbone et al. to assess the feasibility and safety of this technique. MWA was performed in 10 breast cancer patients with a mean tumor size of 4.3 cm (range, 1.0–8.0 cm). A reduction in tumor size was seen in 60% (6 of 10) of the patients. Dooley et al. performed a small trial that

CONCLUSIONS

Surgery is a key facet in the multidisciplinary treatment of patients diagnosed with breast cancer. Over time, the integration of surgical techniques with advances in radiation and systemic therapies has allowed for less invasive surgical procedures. This has resulted in decreased surgical morbidity for patients, yet overall improved outcomes and survival.

ABLATIVE TECHNIQUES IN THE TREATMENT OF BENIGN AND MALIGNANT BREAST DISEASE

Marissa Yassa, MD, MSc, and Armando E. Giuliano, MD, FACS, FRCSEd

Extending the trend toward less invasive treatment, ablative techniques for benign tumors and small breast cancers have continued to progress. Ablative treatments are all image guided percutaneous techniques (using ultrasonography, mammography, magnetic resonance imaging [MRI], or computed tomography [CT]). Complete tumor ablation can be achieved using different types of energy instead of or in addition to immediate or delayed surgical excision. The goal of these ablative techniques is to reduce the complications, decrease morbidity, shorten hospitalization, and improve the cosmetic outcome and quality of life while not increasing recurrence rates. Ablation techniques include radiofrequency ablation (RFA), microwave, laser ablation, electromagnetic waves, cryoablation, and high intensity focused ultrasound.

RFA

RFA is a widely used ablative technique for various solid tumors at different sites, including liver, lung, kidney, and bone. RFA uses low-frequency electromagnetic waves to generate heat and ablate these tumors. To perform RFA, a needle is inserted percutaneously within the tumor, usually with ultrasound guidance, but CT or MRI guidance may be used. A generator creates a high-frequency alternating current, in response, ions attempt to follow the changing direction, causing agitation and frictional heating. This results in destruction of the tumor tissue through thermal coagulation and protein denaturation (Fig. 1).

In most studies, RFA is followed by immediate or delayed surgical excision of the tumor. Izzo et al. performed one of the first feasibility studies that included 26 breast cancer patients with a mean tumor size of 1.8 cm (range, 0.7–3.0 cm). Complete tumor ablation was obtained in 96% (25 of 26) of the patients. Since then, multiple RFA studies have been performed with success rates varying from 77% to 100%. Only a few studies performed RFA without surgical excision. Ohara et al. included 52 patients with a tumor size of 2 cm or less who underwent RFA alone. MRI after 1 to 3 months showed no evidence of residual disease. After a follow-up of 71 months, none of the patients developed locoregional or distant recurrences. Cosmetic outcome was reported excellent in 83%, good in 11%, and fair in 6% of the patients.

Excision RFA (eRFA) consists of surgical excision of the tumor followed by RFA. The aim is to decrease the rate of reexcisions after breast-conserving surgery, to improve locoregional recurrence rates by extending the margins, and ablating possible residual disease. Klimberg et al. performed a study in 100 patients undergoing breast-conserving surgery followed by eRFA in which biopsy showed at least 1 cm circumferential ablation around the resection cavity. Of these 100 patients, 78 had negative margins (>2 mm) and 22 had margins 2 mm or less, of which 3 were locally positive. Recurrence after 5 years of follow-up was seen in 3% of the patients treated with systemic hormonal therapy and in 10% without systemic hormonal therapy. Recently, results of the multicenter Radiofrequency Ablation After Breast Lumpectomy study were presented. A total of 267 T0 to T2 breast cancer patients treated with breast-conserving surgery followed by eRFA were included. Results showed a reexcision rate for positive margins of <5%. The rate of breast recurrence was 2.5% after 3 years of follow-up.

RFA appears to be limited to tumors with a maximum size of 2 cm. RFA treatment is not suitable for infiltrating lobular breast tumors, tumors with an extensive in situ component, and in patients treated with neoadjuvant systemic therapy. Complications from RFA are rare and generally mild, including skin or muscle burns and seromas.

MICROWAVE ABLATION

Thermal ablation can also be performed with the use of microwaves. Microwave ablation (MWA) uses electromagnetic waves at frequencies of at least 900 mHz. Localized heat caused by water molecules moving within tissue results in tissue destruction. Tissues with high water content, such as breast tumors, are heated and damaged more rapidly compared with tissues with lower water content, such as normal breast tissue with surrounding fat, which may remain unharmed. To perform MWA, the breast must be compressed between two plates. The electric field probe is inserted into the central portion of the tumor under ultrasound or CT guidance. A fiber optic temperature probe is placed in the tumor to guide and adjust the temperature. Skin temperature probes are applied to the skin to monitor the temperature to avoid skin burns. A cooling system can be used to provide air cooling, decreasing the risk of thermal injury to the skin.

The first pilot study of MWA was performed by Carrafiello et al. to assess the feasibility and safety of this technique. MWA was performed in 10 breast cancer patients with a mean tumor size of 4.3 cm (range, 1.0–8.0 cm). A reduction in tumor size was seen in 60% (6 of 10) of the patients. Dooley et al. performed a small trial that

randomized patients to breast-conserving surgery followed by MWA versus breast-conserving surgery alone. This study found that patients with early breast cancer treated with breast-conserving surgery and MWA had 0% (0 of 34) positive tumor margins compared with 9.8% (4 of 41) for those with breast-conserving surgery only. More recently, Zhou et al. showed that complete tumor ablation using contrast-enhanced ultrasound was seen in 90% (37 of 41) of patients treated with MWA.

CRYOABLATION

Cryoablation is the only ablative technique using cold instead of heat to create tissue necrosis. It is accomplished percutaneously guided by ultrasound, MRI, or CT. Cryoablation involves two phases: freezing and thawing. Liquid nitrogen is inserted into the probe and results in a local freezing reaction; thereafter, a second gas (i.e., helium) is released through the probe to arrest the freezing process, allowing thawing to occur (Fig. 2A). Tumor cells are destroyed through direct intracellular and indirect vasculature injury. Intracellular ice formation results in shearing and irreversible rupture of cell membranes. Extracellular formation occurs, creating a hypertonic environment. Water flows out of the cells, resulting from osmosis, causing cellular dehydration and damage. When thawing occurs, water flows back into the cell, increasing intracellular volume and lysis occurs. Freezing and thawing is repeated. After at least two freeze–thaw cycles, an ice ball is created, which can be visualized with imaging. The tumor is left to remain in situ and is reabsorbed by the body (Fig. 2B).

Several studies have investigated the efficacy of cryotherapy in the treatment of fibroadenomas. The prospective Fibroadenoma Cryoablation Treatment Registry included 441 patients with fibroadenomas treated with cryotherapy. Two freeze–thaw cycles were used with a temperature of −160°C for the treatment of lesions with a median size of 1.8 cm. A reduction in size of 51% was seen after a follow-up of 6 months. Furthermore, palpability of the fibroadenomas reduced from 75% at pretreatment to 36% after 6 months and 15% after 12 months of follow-up. Recently, the role of cryoablation in the treatment for malignant breast tumors has been evaluated. The systematic review of Littrup et al. showed complete tumor ablation in 73% of included patients after a mean follow-up of 8 months. Cosmetic satisfaction was reached in 99% of the patients. In 2016, the American College of Surgeons Oncology Group undertook Z1072, a phase II trial exploring the effectiveness of cryoablation in the treatment of breast cancers, published their results. Patients with a malignant tumor size less than 2 cm with less than 5% intraductal component were included. There was a complete tumor ablation in 26% (26/87) of patients. If multifocal tumors were excluded, the success rate increased up to 92% (80/87). The Breast Journal of Resection of Small Breast Tumors trial is currently recruiting women with early stage invasive breast cancer to investigate whether cryoablation can achieve complete tumor ablation and adequate local control without surgical excision.

Criteria for cryoablation include tumor size smaller than 2 cm, location at least 1 cm from the skin surface, and lack of an extensive in situ component (<25% of carcinoma in situ). Advantages of cryoablation are patients' comfort and treatment of larger lesions with sparing of normal breast tissue. Disadvantages are potential risk of thermal

injury to the skin, biopsy staging information (e.g., tumor size and margin status), and timing of the sentinel lymph node biopsy.

HIGH-INTENSITY FOCUSED ULTRASOUND

High intensity focused ultrasound (HIFU) is a completely noninvasive thermal-based ablative technique using transcutaneously focused ultrasonic waves (Fig. 3). The focused ultrasound waves cause rapid (1–2 seconds) temperature elevation within the targeted tissue up to 50°C to 95°C. This causes melting of the lipid bilayer of the cellular membrane and protein denaturation, leading to tissue necrosis, whereas tissues outside the targeted area are spared. Because of the small (1.8 × 0.2 × 0.2 mm³) ablation zone, multiple overlapping applications are required to treat an entire lesion. Complete ablation can take up to 2 to 3 hours.

Peek et al. published a systematic review, including 9 HIFU studies and 367 breast cancer patients. No residual tumor after HIFU treatment was found in 86.2% (95 of 110) of the patients. The most reported complication was pain (81.5%), followed by edema (16.8%), skin burn (4.2%) and pectoralis major injury (3.6%). Symptomatic palpable fibroadenoma patients were included in a separate HIFU fibroadenoma trial. Twenty of the included patients were treated with HIFU, whereas the other 20 underwent an ultrasound after a months. Control group). Primary outcome was reduction in treatment time; secondary outcomes were reduction in volume on ultrasound after 12 months and the complication rate. Treatment time was reduced with 20.4% to circumferential ablation compared with whole lesion ablation. Reduction in volume was reported in 45.2% of the patients after 12 months of follow up.

HIFU is a completely noninvasive ablative technique. Cosmetic outcome is very good because there is no scarring at skin entry site. Disadvantages are patient discomfort, general or spinal anesthesia, and prolonged treatment times.

INTERSTITIAL LASER

Laser interstitial thermotherapy (LITT) is a hyperthermic ablative technique. Laser fibers are percutaneously inserted into the tumor, whereas a second probe is placed to measure the temperature (Fig. 4). A refraction of laser light is produced at the tumor, producing heat and causing coagulation necrosis and protein denaturation, resulting in irreversible tissue destruction. The level of necrosis depends on the temperature and ablation time. Three types of lasers are available: carbon dioxide, argon, and neodymium-doped yttrium aluminum garnet laser. The two latter lasers have the benefit of being able to treat larger volumes. Only a few studies have evaluated LITT followed by surgical excision. Dowlatshahi et al. performed a study in 64 breast cancer patients and showed complete tumor ablation of 70% in tumors with a mean diameter of 12 mm (range, 5–25 mm). Incomplete tumor ablation was attributed to technical issues, such as inadequate laser energy, patient motion, malfunctioning thermal probes and fluid pump, and suboptimal target visualization. LITT under MRI guidance showed a complete ablation in 76% of the tumors ranging from 1.8 to 8.0 cm. LITT performed in patients with fibroadenomas (n = 24) showed a reduction of 60% after 6 months of follow up.

The advantage of LITT is that it has a photocoagulative effect that reduces bleeding during the procedure. Disadvantage is that tumors larger than 2 cm or tumor with extension in skin component are not good candidates for laser therapy.

IRREVERSIBLE ELECTROPORATION

Irreversible electroporation is a nonthermal ablative technique that uses electrical fields to create permeable cell membranes and cause cell death. Electroporation occurs when short electric pulses (1000 V/cm field) are passed across the cell membranes, resulting in membrane permeabilization. This ablative technique only affects the cell membrane while sparing the extracellular matrix and other tissues (i.e., blood vessels). Permeabilization can be reversible or irreversible, depending on the number, duration, and time between electric pulses and electric field strength. Irreversible electroporation has been investigated for a short period and much of in vivo research involves animal models only. Disadvantages of this technique are the potential occurrence of cardiac arrhythmias and general anesthesia because the electric pulses cause muscle contractions.

SUMMARY

A meta-analysis showed that complete ablation rates of ablative techniques such as RFA, MWA, cryoablation, LITT, and HIFU vary and

have been highest in patients undergoing RSA (87.1%), followed by [illegible]

Lymphatic Mapping and Sentinel Lymphadenectomy

David L. [illegible], MD

The importance of the axilla in breast cancer management has been recognized for centuries. The German surgeon, Wilhelm Fabry (1560–1634), wrote, "I found in the right breast a hidden cancer, far larger than a [illegible], hard and pale. In the axilla there was also hidden three hard swellings, one of which was as big as an egg...I cut out all of these hard swellings and she became well again." By the late nineteenth century, William Halsted had published data suggesting that axillary dissection at the time of mastectomy may be associated with reduced breast cancer mortality. This approach was predicated on the belief that breast cancer cells initially spread through lymphatic channels to the axillary nodes and from there into the blood stream where they gained access to distant organs. The Halsted radical mastectomy remained the standard of care for more than 7[illegible] years. By the 19[illegible]s, however, available data suggested that axillary dissection did not improve survival. This was confirmed by the randomized, prospective National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 trial conducted by the American surgeon, Bernard Fisher. Breast cancer came to be viewed as metastatic, or not, at inception. Lymph node metastases became a marker of metastatic potential, not a step in the metastatic process.

Although spread to lymph nodes is not required for systemic dissemination, identification of lymph node metastases remains one of the strongest predictors of eventual distant metastases and death. Afferent lymphatic channels maintain connections with venules to ensure unrestricted lymphatic flow. Metastatic disease in an axillary node is strong evidence that the cancer cells have already gained access to the circulation and are capable of surviving outside of the breast. Survival is strongly inversely related to the number of positive lymph nodes, especially for estrogen receptor–negative breast cancer. Lymph node metastases provide prognostic information for estrogen receptor–positive disease as well, but genomic assays performed on the primary tumor can identify the subgroup of node-positive tumors with a good prognosis.

By 1977, it was known that, for clinically node-negative women, axillary dissection does not improve survival. Nevertheless, axillary dissection remained the standard of care for all breast cancer patients, largely because nodal stage strongly influenced adjuvant therapy decisions. Axillary dissection is a morbid procedure that can cause lifelong upper extremity symptoms including lymphedema. Sentinel node biopsy provides nearly as much staging information as axillary dissection with a fraction of the morbidity.

Development of Lymphatic Mapping and Sentinel Node Biopsy

The lymphatic drainage of the breast was well described by the 1930s. In 1953, Gray described the four levels of axillary lymphatic drainage of the breast, recognizing that blue dye injection in any part of the breast stained the same few axillary nodes and that accessory

have been highest in patients undergoing RFA (87.1%), followed by microwave ablation (83.2%), cryoablation (74.1%), laser ablation (62.2%), and HIFU (47.4%). Other important, but less investigated outcomes are recurrence and complication rates. No local recurrences have been reported using microwave ablation (0%). Other ablative techniques have small but measurable recurrence rates: cryoablation (1.4%), HIFU (2.9%), RFA (3.1%), and laser ablation (10.2%). Complications occur in about 10% of patients. Most commonly seen were skin burns followed by pectoralis major muscle damage. MWA is associated with the highest postoperative complication rate of 14.8%, followed by cryoablation (10.9%), RFA (10.3%), HIFU (6.9%), and laser ablation (6.3%). Excellent cosmetic outcome has been reported in patients treated with ablation. Cryoablation results in greater than 90% excellent cosmesis compared with 85.3% in patients treated with RFA and 66.3% in patients treated with HIFU. HIFU may ultimately have the best cosmetic outcome because this technique is completely noninvasive.

All ablative techniques show several benefits compared with breast conserving surgery; however, larger multicenter randomized controlled trials are required to confirm the efficacy of ablation compared with resection. Current problems are the lack of a predictive tool for assessing complete tumor ablation, determination of accurate tumor size, information on the timing of axillary surgery, and adequate patient and tumor inclusion criteria. Ablative treatment techniques may be most suitable for patients with contraindications to operation or patients with a preference to avoid breast conserving therapy. Furthermore, ablative treatment can only be used for small (T1) breast tumors (<2 cm), T can from the skin and pectoralis major, less than 25% carcinoma in situ component and, most important, tumors must be visible using imaging modalities. In addition, many techniques result in a palpable mass, disturbing to patient and surgeon. Intraoperative RFA after surgical excision may become a means to avoid radiation after breast conserving surgery for patients with favorable tumors.

Lymphatic Mapping and Sentinel Lymphadenectomy

David Euhus, MD

The importance of the axilla in breast cancer management has been recognized for centuries. The German surgeon, Wilhelm Fabry (1560–1634), wrote, "I found in the right breast a hidden cancer, far larger than a fist, hard and pale. In the axilla there was also hidden three hard swellings, one of which was as big as an egg...I cut out all of these hard swellings and the breast well again." By the late nineteenth century, William Halsted had published data suggesting that axillary dissection at the time of mastectomy may be associated with reduced breast cancer mortality. This approach was predicated on the belief that breast cancer cells initially spread through lymphatic channels to the axillary nodes and from there into the blood stream where they gained access to distant organs. The Halsted radical mastectomy remained the standard of care for more than 70 years. By the 1960s, however, available data suggested that axillary dissection did not improve survival. This was confirmed by the randomized, prospective National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 trial conducted by the American surgeon, Bernard Fisher. Breast cancer came to be viewed as metastatic, or not, at inception. Lymph node metastases became a marker of metastatic potential, not a step in the metastatic process.

Although spread to lymph nodes is not required for systemic dissemination, identification of lymph node metastases remains one of the strongest predictors of eventual distant metastases and death. Afferent lymphatic channels maintain connections with vessels to ensure unrestricted lymphatic flow. Metastatic disease in an axillary node is strong evidence that the cancer cells have already gained access to the circulation and are capable of surviving outside of the breast. Survival is strongly inversely related to the number of positive lymph nodes, especially for estrogen receptor–negative breast cancer. Lymph node metastases provide prognostic information for estrogen receptor–positive disease as well, but genomic assays performed on the primary tumor can identify the subgroup of node-positive tumors with a good prognosis.

By 1977, it was known that, for clinically node-negative tumors, axillary dissection does not improve survival. Nevertheless, axillary dissection remained the standard of care for all breast cancer patients, largely because nodal stage strongly influenced adjuvant therapy decisions. Axillary dissection is a morbid procedure that can cause lifelong upper extremity symptoms including lymphedema. Sentinel node biopsy provides nearly as much staging information as axillary dissection with a fraction of the morbidity.

DEVELOPMENT OF LYMPHATIC MAPPING AND SENTINEL NODE BIOPSY

The lymphatic drainage of the breast was well described by the 1930s. In 1953, Crane described the four levels of efferent lymphatic drainage of the breast, recognizing that blue dye injection to any part of the breast stained the same few axillary nodes and that accessory

EVALUATION OF [illegible] MATTER MAPPING AND SENTINEL NODE BIOPSY IN CLINICALLY NODE-NEGATIVE WOMEN

[illegible] and [illegible] were [illegible] an accuracy [illegible] biopsy to [illegible] axillary dissection and a subsequent meta-analysis reported that SLNs reflect the status of the axilla in 97% of clinically node-negative patients. Three randomized prospective trials comparing SLN biopsy alone to axillary dissection in clinically and pathologically node-negative patients all reported a low risk of axillary recurrence in the sentinel node only arm (<10%), similar disease-free and overall survival, and significantly lower morbidity (Table 118.1). On the strength of these trials, sentinel node biopsy became accepted as a safe and accurate procedure for nodal staging in clinically node-negative women.

The next question to answer was whether axillary dissection is required in clinically node-negative women with a positive sentinel node. The International Breast Cancer Study Group (IBCSG) 23-01 trial, the Aflac Mapping of the Axilla: Radiotherapy or Surgery trial (AMAROS) and the American College of Surgeons Oncology Group Z11 trial each took on this question in slightly different ways. The IBCSG trial showed that disease-free survival is the same with or without axillary dissection in patients with one or more micrometastases (<2 mm) in SLNs. The AMAROS trial found that survival and axillary recurrence rates were similar for SLN-positive patients who were treated with axillary dissection or comprehensive regional nodal radiation, whereas lymphedema rates were reduced by one-half in the radiation arm (14% vs. 28%). Z11 was designed to exclude any axillary treatment in women with one or two positive SLNs undergoing breast-conserving surgery, though ultimately 19% of patients in each arm received nodal treatment. Although 27% of patients in the axillary dissection group had additional positive, nonsentinel nodes, the axillary recurrence rate was only about 1% in the SLN-only group. It is important to recognize that 97% of the women in the SLN group received adjuvant systemic therapy. There is now little opposition to the notion that axillary dissection can be avoided in women with clinically negative lymph nodes, T1 to T2 tumors, and one or two positive SLNs as long as these women are treated with breast-conserving surgery followed by adjuvant systemic therapy and whole-breast radiation therapy.

As neoadjuvant chemotherapy gained in popularity, there were concerns that chemotherapy itself could affect lymphatic drainage, rendering SLN biopsy inaccurate. Numerous institutional studies existed and two meta-analyses reported that SLNs can be identified in 80% of patients after neoadjuvant chemotherapy with a false-negative rate of 8% to 12%. Data from the NSABP B-27 trial confirmed a similar 80% SLN identification rate, an 11% false-negative rate, and an accuracy of 89%. These performance metrics are similar to those reported from large multiinstitutional trials in women undergoing surgery before chemotherapy. Sentinel node biopsy is the preferred approach to axillary staging in clinically node-negative women after neoadjuvant chemotherapy.

OMITTING AXILLARY DISSECTION IN CLINICALLY NODE-NEGATIVE PATIENTS

Clinically node negative is defined as no suspicious adenopathy on clinical examination. Suspicious palpable nodes should undergo needle biopsy (Box 1). If metastatic breast cancer is detected, then the patient is classified as clinically node positive. Many patients are having axillary sonography as part of their initial imaging evaluation. This may be useful before neoadjuvant chemotherapy so that nodal response can be assessed. Patients with small metastases discovered through sonography are not clinically node positive and can undergo SLN biopsy as part of their primary surgical procedure. The biopsied node can be marked with a localizing device or India ink to ensure it is excised. Patients with negative SLNs do not require axillary dissection. Most patients with one or two positive sentinel nodes do not require axillary dissection if they have T1 to T2 tumors treated by breast-conserving surgery and will undergo whole-breast radiation and adjuvant systemic therapy. Patients with one or two positive sentinel nodes undergoing mastectomy do not require axillary dissection.

SLN, Sentinel lymph node.

if they receive regional nodal irradiation. Axillary dissection is still recommended for patients with positive SLNs after neoadjuvant chemotherapy, inflammatory cancer, or gross extracapsular extension. There is little experience with SLN biopsy in patients with T3 to T4 tumors. For these women, decisions about axillary staging should be individualized.

SENTINEL NODE BIOPSY IN CLINICALLY NODE-POSITIVE PATIENTS WHO CONVERT TO NODE NEGATIVE

Neoadjuvant chemotherapy, especially in hormone receptor–negative tumors, can eradicate all tumor cells in the breast and axillary lymph nodes (pathologic complete response). Current guidelines recommend axillary dissection for patients who were clinically node positive at diagnosis, regardless of the response to neoadjuvant chemotherapy. There is a trend, however, toward performing SLN biopsy in patients experiencing a complete clinical response to neoadjuvant chemotherapy and then foregoing axillary dissection if the SLNs are negative. The NSABP B-51/Radiation Therapy Oncology Group 1304 trial randomizes patients who have converted to SLN negative to regional nodal radiation or no axillary treatment at all. The Alliance A011202 trial is for patients who remain node positive after neoadjuvant chemotherapy. They are randomized to axillary dissection plus nodal radiation versus nodal radiation alone. Clinical trial participation is the best way to generate the data required to safely modify the guidelines, but a negative axillary dissection incurs morbidity without providing benefit. Most relevant are ~40% of breast cancer patients who are also estrogen receptor negative. Modern chemotherapy, combined with dual anti-HER2 targeting, induces pathological complete responses in as many as 72%. Many would forego axillary dissection in a patient like this with normalized posttreatment imaging and negative SLNs.

The American College of Surgeons Oncology Group (ACOSOG) Z1071 and Sentinel Neoadjuvant studies both reported that the false negative rate of SLN biopsy after neoadjuvant chemotherapy in initially clinical node positive patients is about 12%. The false negative rate can be reduced to about 9% if the following practices are observed: (1) dual tracer mapping with radiocolloid and blue dye, (2) resection of at least three lymph nodes, and (3) x-ray the nodes to verify that the previously clipped node has been removed. Because the previously biopsied and clipped lymph node is not recognized

as a SLN in about 25% of patients, it may be helpful to localize the node preoperatively using a localizing device (wire, radioactive seed, electronic tag…) or radiocolloid injection.

TECHNICAL CONSIDERATIONS

Sentinel lymph nodes are identified by injecting technetium 99m colloid (sulfur or albumin), visual dyes, or both into the breast where they are transported by afferent lymphatic channels to the first echelon lymph nodes responsible for the breast. As well illustrated by Grant in 1957 (Fig. 1), injections performed anywhere in the breast and at any depth will accumulate in the same axillary lymph nodes. Sappey's subareolar plexus is a particularly rich network and the preferred injection site for many. This is a subdermal lymphatic plexus that is not really subareolar at all. It is located in a ring just deep to the edge of the areola. If there is interest in identifying accessory drainage pathways (internal mammary or contralateral axilla, for instance) then the radiocolloid should be injected peritumoral (interlobar afferent lymphatics) and the patient imaged with a gamma camera. This is rarely done anymore because it has been recognized that it is very rare to find internal mammary metastases in patients with negative axillary sentinel nodes.

Using both technetium 99m colloid and a visual dye may increase SLN identification rate and reduce the false negative rate, but many surgeons are achieving adequate results using technetium 99m only. Technetium 99m is often filtered to achieve consistent particle sizes less than 50 nm and a dose of 0.1 to 1 mCi is used for injections on the same day as the surgery, whereas up to 3 mCi is used for the day before injections. A recent improvement to the radiocolloid is the addition of monose groups that bind to macrophages and dendritic cells in the lymph nodes targeting retention. The most common visual dyes are isosulfan blue, methylene blue, and indocyanine green. The latter is a fluorescent dye and requires specialized equipment for visualization. When methylene blue is used, it should be diluted 1:3 with injectable saline to reduce the risk of skin necrosis. One reason some surgeons have stopped using isosulfan blue routinely is the 1% incidence of anaphylaxis. A reasonable compromise is to interrogate the axilla with a gamma counter before prepping and then injecting blue dye only when there is no definite signal from the technetium. Anaphylaxis rates may be increased in patients who have previously been exposed to isosulfan blue. If isosulfan blue must be used again, the patient can be premedicated with antihistamines (H1 and H2) and steroids.

Sentinel nodes are defined as any lymph nodes that have accumulated the radiocolloid or visual dye and any lymph nodes that are suspicious by palpation. The primary SLN is usually located just deep to the midportion of the belly of the pectoralis muscle. Intercostal brachial cutaneous nerve symptoms often run just superior to the SLN. Bipolar cautery or sharp dissection may help to minimize intercostal brachial cutaneous symptoms that are common in the early postoperative period. There are at least two SLNs in most patients. The second SLN is often in close proximity to the first but is occasionally found in level 2. It is common to remove any lymph nodes with radioactive counts that are 10% or more of the most radioactive node.

Rarely (about 5%), the SLNs cannot be identified. This can happen if lymphatic channels are occluded with tumor cells but is also more common in obese patients. Practice guidelines recommend level 1 and 2 axillary dissection if an SLN cannot be identified. An alternative may be very careful axillary inspection and palpation followed by excision of a few lymph nodes from the vicinity of the underbelly of the pectoralis major muscle where the SLN usually resides. This decision can be individualized based on patient and tumor characteristics as they relate to the importance of pathologic axillary staging compared to the morbidity of axillary dissection.

HISTOLOGIC ASSESSMENT OF SENTINEL NODES

In the early days of axillary SLN biopsy for breast cancer, SLNs were serially sectioned and stained with cytokeratin immunohistochemical (IHC) stain. This significantly increased node-positive rates, but largely through the identification of very small tumor deposits. The ACOSOG Z10 and NSABP B-32 trials convincingly showed that detection of occult metastases using IHC contributed very little prognostic information. Routine IHC is no longer recommended for SLNs, but some pathologists use it in cases of invasive lobular carcinoma, where the metastatic cells can be diffuse and difficult to detect.

Historically, SLNs were assessed intraoperatively by frozen section so that node-positive patients could undergo axillary dissection under the same anesthetic. As clinical trial data have accumulated, decisions about axillary treatment have become more complex. Some patients with positive SLNs do not require any additional axillary treatment. For these who do require treatment, nodal radiation is finding broader use. It is a small minority of SLN-positive patients who will benefit from axillary dissection with or without adjuvant nodal radiation. Frozen section assessment of axillary SLNs is rarely useful in modern practice and many surgeons have abandoned it completely in favor of carefully considered multidisciplinary decisions about axillary dissection after all the information is available.

MORBIDITY OF AXILLARY SENTINEL NODE BIOPSY

The morbidity of SLN biopsy is a fraction of that incurred by axillary dissection but it is not negligible. The NSABP B-32 trial recorded a 10% or greater difference in arm volume for 7.5% at 36 months, shoulder abduction deficits of 10% or greater in 5.7% at 6 months, and arm numbness or tingling in about 8% at 36 months. The procedure should only be done when there is a reasonable probability that the results will influence treatment decisions.

A recent meta analysis that included 632 breast cancer patients who had undergone axillary surgery found that cellulitis, body mass index greater than 25, regional nodal radiation, and axillary dissection were all associated with increased lymphedema risk. Lymphedema risk was not increased by ipsilateral blood draws, blood pressure measurements, injections, or airline travel. Other than avoiding injury and infection, no special precautions are required after SLN biopsy.

LYMPHATIC MAPPING AND SLN BIOPSY IN SPECIAL SITUATIONS

Pregnancy

Lymphatic mapping using technetium 99m colloid can be performed in pregnant patients when the results will influence treatment decisions. Blue dyes should be avoided.

Male Breast Cancer

Lymphatic mapping is just as accurate in men with breast cancer as it is in women. Radiocolloid or visual dyes can be injected into Sappey's subareolar plexus.

Ductal Carcinoma in situ

About 15% of ductal carcinoma in situ (DCIS) lesions diagnosed on core needle biopsy will be upstaged to invasive cancer on excision. It seems reasonable to do SLN biopsy when mastectomy is being done for DCIS diagnosed on core needle biopsy. Sentinel node biopsy can also be considered in patients undergoing completion mastectomy after multiple failed attempts to achieve clear margins especially in cases of microinvasive DCIS. Some have advocated SLN biopsy for high grade, large (>2.5 cm), or palpable DCIS treated by breast conserving surgery because these features are associated with an even higher upstage rate. Lymphatic mapping is still possible after partial mastectomy as an alternative to re-do the SLN biopsy as a second procedure only in those who are found to have invasive cancer.

RISK-REDUCING MASTECTOMY

Occult invasive cancer is found in 2% to 4% of risk reducing mastectomies in high risk women. This poses a problem for axillary staging after the fact. Some have advocated routine SLN biopsy for all risk reducing mastectomies, but it has been estimated that more than 200 mastectomy procedures would need to be done to identify one patient with a positive SLN. It is reasonable to perform breast magnetic resonance imaging preoperatively and forego SLN biopsy in women with Breast Imaging Reporting and Data System 1 or 2 imaging. If an occult invasive cancer is identified on pathology, options would include axillary dissection, attempted lymphatic mapping and SLN biopsy postmastectomy, or ultrasound staging. Patient and tumor characteristics should guide this clinical decision.

AXILLARY RESTAGING FOR LOCAL RECURRENCE

Axillary assessment and management at the time of surgery for isolated local recurrence reduces axillary recurrence risk. Patients with local recurrence are likely to have already had SLN biopsy or axillary dissection as part of their initial treatment. This significantly reduces the SLN identification rate and increases the false negative rate. Nevertheless, lymphatic mapping can be attempted, even in patients who have had mastectomy, although this has not been systematically validated. Radiocolloid and blue dye can be injected subdermal. Imaging with a gamma camera is helpful in this setting as drainage may not be to the axilla. In any case, the axilla is opened and explored for radioactive, blue or suspicious palpable nodes.

AXILLARY REVERSE MAPPING

Axillary reverse mapping involves injection of blue dye into the upper arm and radiocolloid into the breast. Ideally, blue lymphatics and lymph nodes are preserved during sentinel node biopsy or axillary dissection. One institutional study that included 614 patients reported that arm nodes are also SLNs in 4% to 5%. The study found that 4.5% of axillary reverse mapping nodes harbored metastases. The data suggest that preservation of the arm nodes and lymphatics is associated with significantly reduced lymphedema risk (4.5% after axillary dissection) and a low rate of axillary recurrence (1%–2%).

AXILLARY STAGING IN THE ELDERLY

In general, breast cancer is treated less aggressively in elderly patients. Omission of radiation after breast conserving surgery in women over the age of 70 with small, node negative, estrogen receptor–positive tumors is common. Many surgeons are also beginning to omit SLN biopsy in patients older than age 70. There is no arbitrary age above which treatment guidelines can be modified. General health and anticipating remaining life should guide decisions. Sentinel node biopsy should be done if the results would influence decisions about adjuvant radiation or systemic therapies.

MANAGEMENT OF THE AXILLA IN BREAST CANCER

Tawakalitu O. Ozanne, MD, and Barbara L. Smith, MD, MPH

AXILLARY DISSECTION

Modern axillary dissection includes clearance of level I to II nodes with sparing of important vessels and nerves. Axillary dissection remains the treatment of choice for patients with locally advanced breast cancers including those with inflammatory carcinoma or palpable nodes at the time of surgery. Such patients often require regional nodal radiation to reduce the risk of recurrence in level III and supraclavicular nodes.

Sentinel Node Biopsy

In the 1990s, improved understanding of breast anatomy revealed that breast lymphatic drainage is to a specific sentinel node. The sentinel nodes are identified by injection of radioactive and/or blue dye particles in subareolar or peritumoral tissue and excision of nodes that accumulate dye particles. In contrast to axillary dissection, lymphedema, chronic pain, or shoulder dysfunction are rare after sentinel node biopsy (SNB).

Patients with clinically negative axillary exams and no signs of inflammatory cancer are eligible for SNB for axillary staging. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-32, American College of Surgeons Oncology Group (ACOSOG) Z0010, After Mapping of the Axilla: Radiotherapy or Surgery? (AMAROS), Axillary Lymphatic Mapping Against Nodal Axillary Clearance (ALMANAC) and Milan trials confirmed a 95% to 99% success rate for identifying sentinel nodes, an average of two sentinel nodes, and an acceptable 8% to 10% false negative rate. These trials showed that sentinel node mapping was as accurate as axillary dissection in identifying patients who are node positive and showed a less than 1% risk of axillary recurrence after a negative SNB. Axillary dissection has now been abandoned in patients whose sentinel nodes are negative.

Several randomized trials have now addressed management of patients with positive sentinel nodes. The ACOSOG Z0011 trial randomized clinically node negative lumpectomy patients with primary tumors less than 5 cm and 1 to 2 positive sentinel nodes to axillary dissection versus radiation without further axillary surgery. Axillary ultrasound was not routinely used for eligibility. Patients with three or more positive nodes or gross extranodal extension were excluded. All patients received standard tangent radiation and some systemic therapy. At 6.3 years median follow up, the risk of axillary relapse was 0.5% after axillary dissection and 3.5% after sentinel node biopsy

RISK-REDUCING MASTECTOMY

Occult invasive cancer is found in 2% to 4% of risk reducing mastectomies in high risk women. This poses a problem for axillary staging after the fact. Some have advocated routine SLN biopsy for all risk reducing mastectomies, but it has been estimated that more than 200 contemporary procedures would need to be done to identify one patient with a positive SLN. It is reasonable to perform breast magnetic resonance imaging preoperatively and forego SLN biopsy in women with Breast Imaging Reporting and Data System 1 or 2 imaging. If an occult invasive cancer is identified on pathology, options would include axillary dissection, attempted lymphatic mapping and SLN biopsy postmastectomy, or ultrasound staging. Patient and tumor characteristics should guide the clinical decision.

AXILLARY RESTAGING FOR LOCAL RECURRENCE

Axillary assessment and management at the time of surgery for isolated local recurrence reduces axillary recurrence risk. Patients with local recurrence are likely to have already had SLN biopsy or axillary dissection as part of their initial treatment. This significantly reduces the SLN identification rate and increases the false negative rate. Nevertheless, lymphatic mapping can be attempted, even in patients who have had mastectomy, although this has not been systematically validated. Radiocolloid and blue dye can be injected subdermal. Imaging with a gamma camera is helpful in this setting as drainage may not be to the axilla. In any case, the axilla is opened and explored for radioactive, blue or suspicious palpable nodes.

AXILLARY REVERSE MAPPING

Axillary reverse mapping involves injection of blue dye into the upper arm and radiocolloid into the breast. Ideally, blue lymphatics and lymph nodes are preserved during sentinel node biopsy or axillary dissection. One institutional study that included 614 patients reported that arm nodes are also SLNs in 4% to 6%. The study found that 4.5% of axillary reverse mapping nodes harbored metastases. The data suggest that preservation of the arm nodes and lymphatics is associated with significantly reduced lymphedema risk (4.5% after axillary dissection) and a low rate of axillary recurrence (1%–2%).

AXILLARY STAGING IN THE ELDERLY

In general, breast cancer is treated less aggressively in elderly patients. Omission of radiation after breast conserving surgery in women over the age of 70 with small, node negative, estrogen receptor–positive tumors is common. Many surgeons are also beginning to omit SLN biopsy in patients older than age 70. There is no arbitrary age above which treatment guidelines can be modified. General health and anticipating remaining life should guide decisions. Sentinel node biopsy should be done if the results would influence decisions about adjuvant radiation or systemic therapies.

Management of the Axilla in Breast Cancer

Tawakalitu O. Ozumi, MD, and Barbara L. Smith, MD, PhD

AXILLARY DISSECTION

Modern axillary dissection includes clearance of level I to II nodes with sparing of important vessels and nerves. Axillary dissection remains the treatment of choice for patients with locally advanced breast cancers including those with inflammatory carcinoma or palpable nodes at the time of surgery. Such patients often require regional nodal radiation to reduce the risk of recurrence in level III and supraclavicular nodes.

Sentinel Node Biopsy

In the 1990s, improved understanding of breast anatomy recognized that breast lymphatic drainage is to a specific sentinel node. The sentinel nodes are identified by injection of radioactive and/or blue dye particles in subareolar or peritumoral tissue and excision of nodes that accumulate dye particles. In contrast to axillary dissection, lymphedema, chronic pain, or shoulder dysfunction are rare after sentinel node biopsy (SNB).

Patients with clinically negative axillary exams and no signs of inflammatory cancer are eligible for SNB for axillary staging. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-32, American College of Surgeons Oncology Group (ACOSOG) Z0010, After Mapping of the Axilla: Radiotherapy or Surgery? (AMAROS), Axillary Lymphatic Mapping Against Nodal Axillary Clearance (ALMANAC) and Milan trials confirmed a 95% to 99% success rate for identifying sentinel nodes, an average of two sentinel nodes, and an acceptable 8% to 10% false negative rate. These trials showed that sentinel node mapping was as accurate as axillary dissection in identifying patients who are node positive and showed a less than 1% risk of axillary recurrence after a negative SNB. Axillary dissection has now been abandoned in patients whose sentinel nodes are negative.

Several randomized trials have now addressed management of patients with positive sentinel nodes. The ACOSOG Z0011 trial randomized clinically node negative lumpectomy patients with primary tumors less than 5 cm and 1 to 2 positive sentinel nodes to axillary dissection versus radiation without further axillary surgery. Axillary ultrasound was not routinely used for eligibility. Patients with three or more positive nodes or gross extranodal extension were excluded. All patients received standard tangent radiation and some systemic therapy. At 6.3 years median follow up, the risk of axillary relapse was 0.5% after axillary dissection and 2.3% after sentinel node biopsy

alone. Survival was no different in the omitted node versus axillary dissection arms. Of note, 27% of patients who underwent axillary dissection had additional positive nodes, suggesting that targeted radiation and systemic therapy was effective in controlling this extent of residual axillary node disease.

The AMAROS trial had a similar design and similar results. Patients undergoing lumpectomy or mastectomy for primary tumors less than 5 cm and 1 to 3 positive sentinel nodes were randomized to axillary dissection versus radiation that included regional and regional nodal radiation. Eighteen percent of patients underwent mastectomy and 7% of patients had 3 or more positive nodes. At 6.1 years median follow up, the risk of axillary recurrence was 0.4% after axillary dissection and 1.2% after SNB alone. Rates of lymphedema were measured at 13% for axillary dissection and 4% for SNB plus radiation. Like the ZO011 study, 33% of patients undergoing axillary dissection had additional positive nodes, again confirming the efficacy of radiation for controlling residual axillary node disease.

Histopathology Analysis of Excised Axillary Nodes

In patients undergoing axillary dissection, more often a single frozen section and stain stained slide is prepared from each node. More thorough analysis is generally performed on sentinel nodes, with each sentinel node sectioned at 2- to 3-mm intervals, and 1 slide made from each of these serial sections. Many centers use keratin immunohistochemistry (IHC) staining of sentinel nodes to identify small tumor deposits and to more easily identify invasive lobular cancer metastases.

These enhanced node pathology approaches have led to classification of nodal tumor deposits based on size. Tumor deposits greater than 0.2 cm are termed macrometastases, deposits greater than 0.02 to 0.2 cm are termed micrometastases, and deposits 0.02 cm or smaller are termed isolated tumor cells (ITCs). The ACOSOG Z0010 trial found no difference in survival in patients with ITCs identified only on IHC compared with patients without ITCs. In the current staging system, both nodes with macrometastases (N1) and micrometastases (N1mi[]) are classified as node positive, while nodes with ITCs are classified as node negative (N0(i+)).

AXILLARY IMAGING

Physical exam of the axilla may provide only limited information on node status because of patient habitus and anatomy. Ultrasound is the preferred imaging modality for assessment of axillary nodes. Suspicious node findings on ultrasound include a thickened or nodular cortex, loss of fatty hilum, a spherical shape and increased peripheral blood flow. Enlarged nodes may also be identified on breast magnetic resonance imaging (MRI) or computed tomography (CT) scans.

Axillary imaging has significant false positive and false negative rates, and clinical management should not be changed based on imaging alone. In the ACOSOG Z0011 trial, 641 breast cancer patients had axillary ultrasound after neoadjuvant chemotherapy and all had a complete axillary dissection. Only 21% of patients with suspicious axillary ultrasound were node positive on dissection and 57% of patients with a negative axillary ultrasound were node positive. Ultrasound-guided core- or fine needle biopsy may be used to perform diagnostic biopsy to confirm axillary metastasis. Placement of a marking clip during node biopsy can be used to guide excision of a positive node at the time of surgery.

It is important to note that axillary imaging is optional in patients with a negative clinical exam. Patients with nonpalpable nodes with suspicious findings on axillary imaging remain eligible for sentinel node biopsy and can safely be treated with axillary radiation rather than axillary dissection, as in the Z0011 and AMAROS trials.

MANAGEMENT OF THE AXILLA IN OLDER WOMEN

Several trials have shown that many older women with favorable, estrogen receptor (ER+) breast cancers do not require surgical staging of the axilla. Cancer and Leukemia Group B (CALGB) 9343 enrolled 636 women age 70 years and older with ER+ tumors of 2 cm or less. All received lumpectomy and 5 years of tamoxifen and were randomized to radiation or no radiation. Management of the axilla was at the discretion of the treating physician and 200 women in the radiation arm and 203 in the no radiation arm had no axillary surgery. At 12 years median follow up, the risk of axillary relapse was only 3% in women who had no axillary surgery and no radiation; there were no recurrences in women who received radiation. International Breast Cancer Study Group (IBCSG) 10-93 randomized 337 lumpectomy patients age 60 years and older who received tamoxifen and axillary dissection versus no axillary surgery. At 6.3 years median follow up, the risk of axillary recurrence was 1% after axillary dissection and 2% without axillary surgery.

The authors of these and other smaller studies concluded that axillary surgery did not contribute significantly to overall survival or to local control and could be omitted in older patients with favorable ER+ tumors who receive endocrine therapy.

Older patients with clinically palpable axillary nodes should undergo axillary dissection if they are fit enough for surgery. SNB should still be considered in older women with estrogen receptor negative (ER-) tumors if axillary node status will influence systemic therapy or radiation decisions. Frail elderly women may forego axillary surgery unless bulky disease requires excision for local control or symptom relief.

MANAGEMENT OF THE AXILLA IN PATIENTS WITH DUCTAL CARCINOMA IN SITU

Invasive cancer is found at definitive surgery in 10% to 20% of patients with an initial diagnosis of ductal carcinoma in situ (DCIS) on core biopsy. SNB can be performed as a second procedure after lumpectomy but is not possible immediately after mastectomy. As a result, SNB is recommended when mastectomy is performed for DCIS as it adds minimal morbidity and avoids the need for axillary dissection if invasive tumor is found on final pathology. SNB may be considered during lumpectomy for palpable DCIS or large areas of high grade DCIS, where an invasive component is more likely. SNB is routinely performed when core biopsy shows DCIS with any invasion.

When SNB is performed for DCIS or DCIS with microinvasion, micro- or macrometastases will be found in 1% to 2% of cases and ITCs will be present in approximately 10% of nodes examined with IHC. Micro- or macrometastases imply the presence of an occult invasive tumor and are managed as node positive disease. ITCs, however, are not associated with increased risk of local or distant recurrence in patients with DCIS and have no impact on prognosis.

MANAGEMENT OF THE AXILLA AFTER PREOPERATIVE NEOADJUVANT THERAPY

Neoadjuvant chemotherapy trials demonstrated that 35% to 43% of patients with documented positive nodes at diagnosis have no residual axillary disease when axillary dissection is performed after neoadjuvant therapy. A pathologic complete response (pCR) of axillary disease is more common in triple negative and human epidermal growth factor 2 (HER2) positive tumors. In all trials, women with ER+ disease were least likely to obtain a pCR with neoadjuvant chemotherapy or endocrine therapy. Residual disease in the axilla is an important predictor of locoregional and distant recurrence and guides decisions about subsequent systemic therapy and radiation.

For patients receiving neoadjuvant therapy, management algorithms are based on the patient's clinical exam and imaging results at presentation and are modified based on response to neoadjuvant therapy.

CLINICALLY NEGATIVE AXILLA

In the past, SNB was performed prior to neoadjuvant therapy due to concerns that response to therapy might alter lymphatic drainage patterns and reduce the accuracy of node mapping. However, multiple studies supported the use of sentinel node biopsy after neoadjuvant therapy in patients with no palpable axillary nodes at diagnosis. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B27 trial evaluated SNB after neoadjuvant chemotherapy in 428 patients, finding a 96.6% mapping success rate and a false negative rate of 10.2%, similar to that seen without neoadjuvant therapy. A meta-analysis summarizing 24 studies with a total of 1399 patients found an 89.6% sentinel node identification rate and an 8.4% false negative rate. These studies have confirmed that SNB after neoadjuvant therapy is feasible and accurate.

It is now standard practice to perform SNB after neoadjuvant therapy in patients who present with a clinically negative axilla and to base axillary management on the extent of residual disease. Axillary dissection is not required in patients who have no palpable axillary nodes at diagnosis and have a negative sentinel node after neoadjuvant therapy. Outside of a clinical trial, axillary dissection is performed for patients whose sentinel nodes are positive after neoadjuvant therapy, due to concerns that these positive nodes represent residual disease that benefits from complete surgical resection and radiation.

SNB is now only rarely performed before neoadjuvant therapy, as improved axillary ultrasound and needle biopsy techniques allow minimally invasive axillary node evaluation in patients where detailed pathology evaluation is required for treatment decisions.

Clinically Negative Axilla With Positive Axillary Imaging and Biopsy

Increasing use of axillary imaging at diagnosis identifies metastatic but imaging-negative axillary nodes. Needle biopsy can document that these nodes are pathologically positive, although nonpalpable. Although these patients previously would have undergone neoadjuvant therapy followed by SNB, imaging-based documentation of axillary tumor may lead to a recommendation for a complete axillary dissection that would otherwise have been avoided.

Three randomized controlled clinical trials addressed the question of axillary management in patients with documented positive nodes at diagnosis. The ACOSOG Z1071 evaluated the accuracy of SNB in women with stage II to IIIB disease. Positive axillary nodes were confirmed by fine needle aspiration or core needle biopsy prior to the initiation of therapy; the percentage of patients with palpable nodes at diagnosis was not reported. After neoadjuvant therapy the mapping success rate was 92.9% in patients with cN1 disease and 89.0% in patients with cN2 disease. The false negative rate was 12.6%. The SENTinel Neoadjuvant (SENTINA) trial found an 88.1% mapping success rate with a false negative rate of 14.2%. The Sentinel Node Biopsy Following Neoadjuvant Chemotherapy (SN FNAC) trial, which closed early when Z1071 results were published, had an 87.6% mapping success rate and a false negative rate of 8.9%.

In the Z1071 trial one third of patients had a clip placed in their positive sentinel node at the time of diagnostic biopsy. Retrieval of this clipped node during SNB resulted in a false negative rate of only 4.8%, compared with a false negative rate as high as 20% when the clipped node was not removed. Retrieval of a clipped node can be technically challenging but may be easier with seed-based localization techniques than with wire localization.

The Z1071 trial identified other factors that reduced false negative sentinel node results. Use of both radioisotope and blue dye mapping reduced the false negative rate, as did identification of at least three sentinel nodes.

These data support the use of SNB after neoadjuvant therapy for patients with no palpable nodes at diagnosis, where pretreatment axillary imaging identifies positive nodes. Dual tracer mapping should be used and positive nodes should be clipped and retrieved during SNB. Patients whose sentinel nodes are histologically negative after neoadjuvant therapy can be spared axillary dissection. Axillary dissection should be performed for patients whose nodes remain positive after neoadjuvant therapy.

These results are also being extended to include consideration of SNB in patients with palpable positive nodes at presentation whose nodes are no longer palpable after neoadjuvant therapy. Outside of a clinical trial, it may be reasonable to consider SNB in patients with only 1 to 2 positive nodes on initial imaging. The 2015 National Comprehensive Cancer Network (NCCN) guidelines acknowledge that SNB can be considered in patients with positive nodes if the axilla is clinically negative after neoadjuvant therapy.

Axillary dissection remains standard for patients with multiple positive nodes or bulky axillary disease at presentation, for patients with inflammatory cancer, and for patients with positive sentinel nodes after neoadjuvant therapy.

Ongoing Trials of Axillary Management After Neoadjuvant Therapy

Alliance Trial A11202 is evaluating the option of axillary radiation instead of axillary dissection in patients whose axillary nodes remain positive after neoadjuvant therapy. A11202 randomizes patients who become clinically node negative but whose sentinel nodes are positive after neoadjuvant therapy to axillary lymph node dissection (ALND) versus SNB plus axillary radiotherapy.

The NSABP B-51 trial is evaluating the extent of axillary radiotherapy required in women with stage II to III breast cancer whose nodes are negative after neoadjuvant therapy. Mastectomy patients are randomized to chest wall plus regional nodal irradiation versus no radiation, while lumpectomy patients are randomized to whole breast irradiation with or without nodal radiation. These studies will provide answers as to which patients are best suited for axillary dissection versus radiotherapy after neoadjuvant therapy. They will also provide information on whether treatment in the axilla should vary based on receptor subtype.

REPEAT SENTINEL NODE BIOPSY

Repeat sentinel node mapping and biopsy is possible in patients with a new ipsilateral primary cancer or a local recurrence after breast-conserving treatment. Mapping success rates are lower in such patients but if a sentinel node is identified, it is reliable for axillary staging. Several meta-analyses have found that mapping was successful in approximately 65% of patients, with success rates of 80% in patients with prior SNB but only 50% in patients with a prior axillary dissection. Dual tracer mapping should be used and a lymphoscintigram should be considered as up to a third of patients will have alternate drainage to internal mammary nodes or the contralateral axilla.

SENTINEL NODE BIOPSY IN PREGNANCY

Although the radiation dose administered for standard node mapping is low, approximately 1% of annual background exposure, sentinel lymph node biopsy during pregnancy remains controversial. NCCN guidelines state that radioisotope mapping can be used during pregnancy but the use of blue dye is contraindicated. American Society of Clinical Oncology (ASCO) guidelines still state that there is insufficient evidence to recommend SNB in pregnant patients. Generous hydration to facilitate urinary excretion of the isotope and use of a Foley catheter to reduce dwell time of isotope in the bladder may be useful in pregnant patients. Procedures should be discussed with the patient and her obstetrician.

TABLE 1 Patients Undergoing Primary Surgery

Ductal carcinoma in situ	• SNB with mastectomy • No axillary surgery during lumpectomy • Consider SNB during lumpectomy for palpable or large grade 3 DCIS lesions
Invasive breast cancer: node negative: lumpectomy	• SNB−: No further treatment • SNB+: Targeted radiation with systemic therapy • SNB+: 3 or more positive nodes, matted nodes, gross extracapsular extension perform axillary dissection
Invasive breast cancer: node negative: mastectomy	• SNB−: No further treatment • SNB+ • Post mastectomy chest wall and regional node radiation and/or ALND • ALND if results needed for decisions about post mastectomy radiation • ALND if more than 3 positive nodes, matted nodes, gross extracapsular extension
Invasive breast cancer: node positive: nodes, noisy or lumpectomy	• ALND for palpable nodes or multiple positive nodes at the time of surgery

ALND, Axillary lymph node dissection; +/−, ductal carcinoma in situ: −, negative; +, positive; SNB, sentinel node biopsy.

TABLE 2 Patients Undergoing Surgery After Neoadjuvant Systemic Therapy*

cN0 at presentation or cN0 with 1–2 positive nodes on imaging	• SNB after neoadjuvant therapy • No axillary treatment if SNB− • Axillary dissection if SNB+; or • Participation in a clinical trial of axillary management
cN1 at presentation with 1–2 palpable nodes, positive node biopsy	• Axillary dissection if still clinically node positive • Consider SNB if axilla becomes clinically node negative • SNB− then radiation • SNB+ then ALND; or • Participation in a clinical trial of axillary management
cN2 at presentation with 3 or more palpable or imaging positive nodes, positive node biopsy	• ALND; or • Participation in clinical trial of axillary management

*Treatment recommendations are changing for these patients, and participation in a clinical trial should be considered whenever possible.
ALND, Axillary lymph node dissection; −, negative; +, positive; SNB, sentinel node biopsy.

TABLE 3 Special Clinical Circumstances

Pregnant patient	Consider SNB with radiotherapy only
Elderly patient	No axillary surgery for women >70 years with ER+ tumor ≤2 cm who will receive endocrine therapy
Inflammatory breast cancer	ALND

ALND, Axillary lymph node dissection; ER+, estrogen receptor positive; SNB, sentinel node biopsy.

FUTURE DIRECTIONS

Genomic profiling of tumors increasingly informs decisions about the need for chemotherapy in ER+ breast cancer patients. Many ER+ patients with favorable genomic profiles are now treated with endocrine therapy alone, even if axillary nodes are positive. Axillary surgery may become unnecessary for patients with favorable ER+ tumors and clinically negative axillary exams if profiling of core biopsy specimens becomes routine. Surgical staging of the axilla still guides treatment decisions for ER− and HER2+ tumors. Improvements in axillary imaging will continue to influence axillary management.

SUMMARY: ALGORITHMS FOR MANAGEMENT OF THE AXILLA IN BREAST CANCER

Current management of the axilla in breast cancer aims to obtain staging information required for treatment decisions while minimizing interventions. Axillary dissection is avoided whenever possible but remains effective for treating bulky positive nodes (Tables 1 through 3).

Inflammatory Breast Cancer

Pridvi Kandagatla, MD, and Lisa A. Newman, MD, FACS

Inflammatory breast cancer (IBC) accounts for only 1% to 5% of all new breast cancer cases. Its hallmark clinical presentation features an edematous breast, with prominent skin thickening. This unusual pattern of disease is typically evaluated as a separate biologic entity when compared to non-IBC because of its substantially higher rates of locoregional as well as distant organ failure rates and correspondingly lower survival rates. Population-based data from the Surveillance, Epidemiology and End Results program have demonstrated increasing IBC incidence rates in the United States over the past few decades and it is more common among African American compared to white American women. Median age at diagnosis is 49 to 55 years, typically occurring 5 to 10 years younger than non-IBC patients. Because of its inherently aggressive nature, IBC is typically managed with a rigorous multidisciplinary approach in terms of initial diagnostic workup as well as treatment, which usually includes neoadjuvant chemotherapy followed by modified radical mastectomy and postmastectomy radiation. Individualized adjuvant therapies will depend on tumor biomarker expression, response to primary systemic therapy, and the patient's menopausal status.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

As its name implies, IBC presents as an inflamed-appearing breast with generalized edema and skin thickening, which is often referred to as peau d'orange. The spectrum of IBC symptoms is broad: some patients have diffuse breast involvement associated with skin dimpling and nipple retraction, others have more subtle findings, with only faint central skin erythema, and these symptoms can be particularly challenging to discern in women with darker skin tones.

IBC can be categorized as one of three different types: primary IBC, secondary IBC, and locally recurrent breast cancer presenting as IBC. International IBC experts have defined primary IBC as those cases where the breast symptoms had a rapid onset (within 3–6 months) and where at least one third of the breast skin is involved. Secondary IBC implies the presence of an untreated/neglected breast cancer that progressed into an inflammatory state. Sadly, some patients will experience an inflammatory recurrence following appropriate treatment for an early stage breast cancer. Regardless of the prior cancer history, the clinical management of all three IBC patients is the same.

The most common condition that can masquerade as IBC is mastitis, and if other clinical symptoms suggest an infectious etiology (e.g., fever, history of previous mastitis) then it may be reasonable to give the patient a trial of antibiotics as initial management. If symptoms do not respond promptly within a week, however, then continued workup to rule out IBC is indicated. Rarely, congestive heart failure can present with unilateral breast edema and skin thickening; these patients will usually have other symptoms of cardiac dysfunction but nevertheless should be monitored for resolution of their breast findings as the cardiac condition is treated. Granulomatous mastitis and breast lymphomas can also mimic IBC; these conditions will also require diagnostic biopsy workup.

The initial imaging workup for a patient presenting with IBC symptoms should include a mammogram and targeted breast ultrasound; axillary ultrasound should also be performed when local resources allow, to permit more definitive assessment of regional involvement. Mammographic imaging should be bilateral to evaluate for asymmetric skin thickening and/or occult contralateral pathology. The involved breast may reveal diffuse malignant microcalcifications or multiple satellite tumors; however, some IBC patients will have skin involvement but no discrete tumors within the breast itself.

Diagnostic biopsy for IBC can be performed as a percutaneous core needle biopsy (usually with a 14- or 16-gauge device and at least 3 to 4 passes to extract an adequate amount of tissue) or a full thickness skin punch biopsy (using a 4- or 6-mm-diameter device). The choice between these two options is based on clinical judgment—patients with an obvious and highly suspicious palpable mass can be successfully biopsied by a core needle, but a punch biopsy might be preferable in situations where the skin findings predominate. Alternatively, a combination of these biopsy approaches can be offered, in which case the skin punch biopsy site serves as the point of entry for the core needle device. An image-guided percutaneous core needle biopsy can also be considered when resources are available, either in the form of a stereotactic biopsy if the mammogram provides a readily accessible target or as an ultrasound-guided biopsy of a mass lesion or suspicious axillary lymph node. If the percutaneous biopsy approaches are nondiagnostic in the setting of a patient that has persistent clinical findings suspicious for IBC, then it is appropriate to pursue a surgical incisional biopsy to resect a sample of skin and underlying breast tissue.

The histopathologic features supporting an IBC diagnosis is the presence of cancer cells within the dermal lymphatic plexus, and these tumor emboli account for the clinical symptoms. Dermal lymphatic involvement, however, is not an essential diagnostic feature. Any biopsy confirming the presence of invasive breast cancer associated with the clinical impression of IBC is adequate for establishing a diagnosis of IBC. The majority of IBC cases are high-grade tumors with invasive ductal features, but invasive lobular and other histopathologic patterns have been reported.

Immunohistochemistry evaluation of the invasive component of the diagnostic biopsy material is essential; the pathologist should ensure that biomarkers are not inadvertently assessed on an associated in situ component instead. American Society of Clinical Oncology/College of American Pathologists (ASCO/CAP) guidelines define any expression (≥1%) of either estrogen receptor or progesterone receptor as being hormone receptor positive and these cases will be referred for endocrine therapy. HER2/neu expression scores of 0 or 1+ are considered negative and 3+ as positive; cases with an intermediate score (2+) are tested amplification of the HER2/neu gene by fluorescent in situ hybridization (FISH). Patients with HER2/neu overexpressing IBC are candidates for targeted anti-HER2 therapy. Cases that are negative for all three biomarkers are described as triple-negative breast cancer (TNBC). IBC can feature any combination of these markers, and systemic therapy is planned accordingly. While frequency distributions of the various phenotypes varies widely across different studies, approximately half of IBC cases will be hormone receptor positive, 20% to 30% will overexpress HER2/neu, and approximately one quarter are TNBC. Additional markers can be performed selectively, based on institutional pathology preferences. IBC usually overexpresses the cell adhesion protein E-cadherin and the markers of proliferative activity such as Ki-67.

The American Joint Committee on Cancer (AJCC) TNM staging system automatically designates any IBC case as T4d (regardless of whether any discrete measurable tumor mass is present), nodal and metastatic status are categorized on the basis of clinical and imaging findings. The AJCC eighth edition staging system accounts for tumor grade and biomarker expression as well in assigning an overall clinical and/or pathologic stage for nonmetastatic IBC; these features will determine between an overall stage of IIIA, IIIB, or IIIC.

INITIAL STAGING WORKUP AND SPECIAL REFERRAL CONSIDERATIONS

Approximately one third of IBC cases will have clinically evident distant organ metastatic disease at time of diagnosis, and body

imaging to evaluate extent of disease is therefore routinely recommended. Options include computed tomography (CT) scans of the chest, abdomen and pelvis in conjunction with bone scan or positron emission tomography (PET) CT scan. PET CT imaging may be more challenging to schedule because of preauthorization policies of the third party payer. Brain imaging may be considered in cases where symptoms suggest neurologic involvement. If body imaging reveals foci suspicious for metastatic disease, biopsy of at least one site is usually recommended as a confirmatory procedure, and to reevaluate biomarker expression. Baseline evaluation with either echocardiogram or multigated acquisition scan is often necessary as well to assess cardiac function prior to exposing the patient to cardiotoxic chemotherapy.

Supplemental breast imaging (beyond the initial diagnostic mammography and ultrasound) can be considered as well. Breast magnetic resonance imaging (MRI) may clarify the extent of disease on the chest wall as well as in the contralateral breast. MRI has also been recommended as a sensitive strategy for monitoring response to neoadjuvant chemotherapy. Photographs of the breast entered into the electronic medical record can serve as a valuable strategy for documenting the baseline clinical status and subsequent treatment response.

Referrals for genetic counselling and testing are made on the basis of standard criteria regardless of IBC versus non IBC status. Young age at diagnosis (any phenotype, up to age 50 years), TNBC diagnosed up to age 60 years, bilateral breast cancer, family history of breast and/or ovarian cancer, and male breast cancer are all considered indications for genetic risk evaluation by the National Comprehensive Cancer Network.

As with non IBC, premenopausal IBC patients should undergo counseling regarding contraception that is non hormonally active, as a pregnancy would complicate treatment recommendations. Fertility preservation counseling should also be offered. Premenopausal IBC patients with hormone receptor-positive disease will be candidates for ovarian suppression as a component of their endocrine systemic therapy.

MANAGEMENT

General Management Considerations

IBC is considered inoperable at presentation, and primary treatment is in the form of systemic therapy. Selection of initial systemic therapy will be influenced by patient age and comorbidities, extent of disease imaging, and biomarker expression, but combination chemotherapy is typically recommended whenever feasible, in order to obtain prompt control of both locoregional and distant disease (macrometastatic or micrometastatic). Despite the adverse prognostic significance of the IBC diagnosis, curative intent multimodality therapy (neoadjuvant chemotherapy followed by surgery and postmastectomy radiation) is usually recommended when the baseline imaging is negative for macrometastatic foci to distant organs (Fig. 1). Elderly patients with multiple comorbidities may be considered for primary endocrine therapy if initial immunohistochemistry shows strong hormone receptor expression.

Patients with overt macrometastatic disease detected on baseline body imaging (stage IV IBC) are considered as having incurable disease, and a palliative treatment plan will be designed. This may involve radiation therapy to control symptomatic brain or bone metastases. Systemic therapy will be determined by biomarker expression as well as the patient's ability to tolerate general poly drug chemotherapy. Control of locoregional symptoms remains important in these patients, if not achieved with primary systemic therapy, then chest wall radiation or a palliative mastectomy may be considered. Young and physically fit patients with minimal distant organ involvement (oligometastatic disease) may be approached initially with aggressive neoadjuvant chemotherapy, followed by transition to a "pseudo" curative intent multidisciplinary treatment plan based on extent of response to the primary systemic therapy.

Preoperative Management

If the baseline body imaging is negative for overt metastatic disease, then a curative intent IBC management plan is indicated. This includes neoadjuvant chemotherapy (to address micrometastases), followed by modified radical mastectomy, postmastectomy locoregional radiation, and additional endocrine and/or targeted anti-HER2/neu therapy based on biomarker expression.

Neoadjuvant chemotherapy for curative intent treatment will usually include several cycles of an anthracycline and a taxane; conventional schedules are infused every 3 weeks, to maintain adequate activity of platelets, red blood cells, and white blood cells (which have a lifespan of approximately 3 weeks). Dose-dense schedules can improve efficacy by delivering altered doses at shorter intervals (every 1–2 weeks). Advances in bone marrow supportive therapies can improve eligibility for dose dense schedules. Chemotherapy induced alopecia is another expected adverse effect of regimens that are used for breast cancer, but recent prospective randomized clinical trials have proven the safety of scalp cooling technologies to reduce the incidence of this toxicity. These devices are costly and not typically covered by public or private health insurance plans.

Patients with HER2/neu overexpressing IBC will receive targeted therapy with trastuzumab in conjunction with the combination chemotherapy regimen, given as an infusion every 3 to 4 weeks for 1 year. Anti-HER2 therapy can exacerbate the cardiotoxicity of anthracyclines, and cardiac function therefore must be monitored. Dual-agent targeted therapy with pertuzumab in addition to trastuzumab can synergistically improve response rates.

More than three-quarters of patients receiving neoadjuvant chemotherapy will have a response that renders operable disease. Post-treatment response should be assessed with a follow up mammogram and ultrasound; selected patients may undergo a breast MRI as well. IBC patients were typically excluded from participating in prospective randomized trials of breast conserving surgery and sentinel lymph node biopsy. The well documented substantially higher rates of locoregional failure related to the high burden of diffuse microscopic skin and nodal involvement associated with IBC has therefore resulted in modified radical mastectomy being the mainstay of surgical management, regardless of the apparent extent of clinical response to neoadjuvant chemotherapy.

Surgical Management

Surgery is scheduled to occur 3 to 4 weeks after infusion of the final neoadjuvant chemotherapy course, and preoperative blood work should confirm adequate platelet count (preferably more than 75,000 per μL) and absolute neutrophil count (preferably at least 1,000 per μL). Ideally, surgery should be performed sooner than 12 weeks after final chemotherapy infusion, to minimize risk of disease progression. Frozen section analysis of the superior and inferior mastectomy skin edges may be considered to facilitate margin control in cases where residual, indeterminate skin changes persist. A standard level 1 and 2 axillary lymph node dissection is performed, along with resection of any suspicious level 3 tissue.

Immediate breast reconstruction is generally discouraged in IBC patients because of concerns that the increased complication rates of the more extensive surgery could delay completion of any necessary postoperative treatment. Furthermore, the postmastectomy radiation therapy that is indicated for IBC patients can compromise the cosmetic results of immediate reconstruction. Similarly, contralateral prophylactic mastectomy is also discouraged, and patients are recommended to prioritize the necessary treatment for the cancer-at-risk. Consideration of surgery to reduce the risk of a new primary tumor. Contralateral prophylactic mastectomy or contralateral reduction mammoplasty may be considered in patients with large, pendulous breasts if a unilateral mastectomy is expected to cause substantial symptomatic chest wall imbalance and/or quality of life disruption.

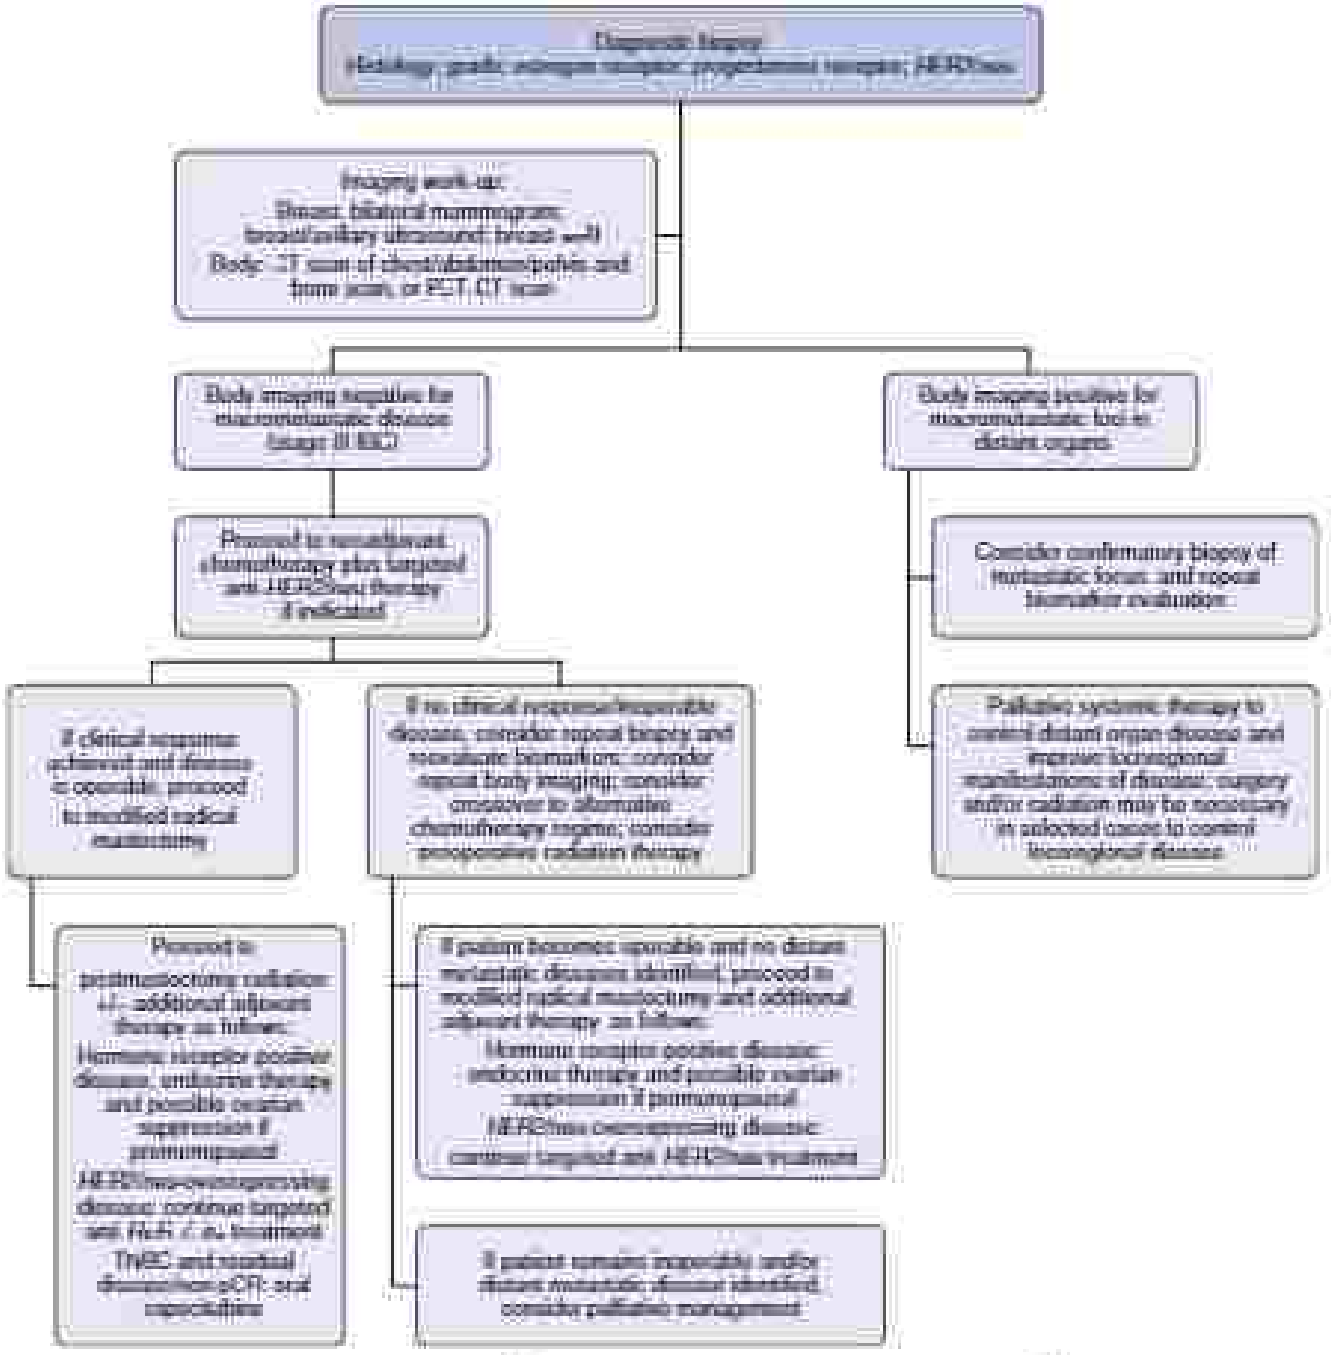

FIG. 1. Inflammatory breast cancer management algorithm. CT, Computed tomography; IC, inflammatory breast cancer; MR, magnetic resonance imaging; pCR, pathologic complete response; T/CT, positron emission tomography-computed tomography; TNBC, triple negative breast cancer.

Postoperative Considerations and Postoperative Management

The modified radical mastectomy surgical pathology specimen should be evaluated for extent of residual disease in the breast and lymph nodes. Immunohistochemistry to reevaluate hormone receptor and HER2/neu expression on residual malignant tissue is indicated. Evidence of treatment response (fibrosis, ghost cells) should also be documented. The presence of a pathologic complete response (pCR, no residual disease in the breast as well as axilla) is prognostically favorable but occurs in fewer than one third of cases. A complete response to neoadjuvant chemotherapy is more likely among tumors that are HER2 overexpressing and managed with targeted therapy, as well as cases of TNBC. Unfortunately, however, TNBC cases that do not achieve a pCR have a disproportionately worse outcome compared to non-TNBC cases with a non-pCR response; this is commonly described as the TNBC paradox. Recently, however, TNBC patients with a non-pCR following neoadjuvant chemotherapy were shown to benefit from receiving a 6 months of oral capecitabine as postoperative/adjuvant therapy, based on results from a prospective randomized trial conducted in Japan (Capecitabine for Residual Cancer as Adjuvant Therapy [CREATE]-X). This approach has been rapidly adopted elsewhere despite the fact that the number of IBC participants in this trial is unclear. Non-TNBC cases with complete biomarker driven adjuvant endocrine and/or targeted anti-HER2 therapy

Postmastectomy radiation is recommended for consolidation of locoregional management. These treatments typically begin 3 weeks after surgery, when the surgical drains have been removed and the patient is able to comfortably accommodate extremity positioning so that the arm is elevated up over the head. The radiation targets are designed with CT assistance to cover the soft tissue regions at highest risk for chest wall recurrence because of microscopic residual disease beyond the surgical resection field: the mastectomy skin flaps and underlying pectoralis musculature; the infraclavicular and supraclavicular regional nodes; the internal mammary chain is usually included as well. These treatments are usually delivered in daily fractions over 5 to 6 weeks to reach a cumulative dose of 5000 to 6000 rads. Left-sided postmastectomy radiation should include treatment planning that attempts to protect the heart, and clinical trials are underway to explore alternative imaging and radiation techniques to achieve this goal.

As noted previously, targeted anti-HER2/neu therapy is initiated during neoadjuvant chemotherapy for HER2 overexpressing cancers and continued to complete a 1 year course. Endocrine therapy is initiated after completion of neoadjuvant chemotherapy to avoid the risk of reducing chemotherapy effectiveness through its cytostatic effects. Tamoxifen (a selective estrogen receptor modifying agent) can be used in premenopausal or postmenopausal patients. Aromatase inhibitors can only be used in patients that have undergone natural menopause or in patients whose ovarian function has been ablated by surgical oophorectomy, pelvic radiation, or medical ovarian suppression. Advantages of medical ovarian suppression include its reversibility as well as its potential to protect fertility when administered during chemotherapy treatments. Tamoxifen is associated with an increased risk of venous thromboembolism, and so institution of this medication should be avoided until after surgery has been completed, or it should be withheld at least 2 weeks preoperatively to minimize postoperative deep vein thrombosis and pulmonary embolism complications.

Management of Chemoresistant Disease

IBC patients that appear to have clinically inoperable/unresectable disease following neoadjuvant chemotherapy can be considered for crossover to an alternative systemic therapy regimen. Repeating the body imaging may be useful in these patients to determine whether disease is progressing to distant organs; this information may influence the ultimate treatment goals and plans. Some patients will experience tumor necrosis that mimics chemoresistance, and follow up breast imaging may assist in distinguishing between these two situations. Repeat breast biopsies may also be indicated in these patients to confirm persistent disease and to reevaluate biomarker expression. Tumor heterogeneity may yield a phenotype that differs from the original biopsy and might influence choice of systemic therapy. Patients with definitively unresectable disease can be referred to receive preoperative radiation therapy in an attempt to improve resectability.

Mastectomy is occasionally indicated in IBC for palliative intent to control bulky or ulcerated disease that fails to respond to systemic therapy and/or radiation treatments. In these circumstances, assistance from the plastic surgery team may be necessary to provide latissimus dorsi flap or skin graft coverage of the resulting chest wall defect.

Prognosis

Contemporary multidisciplinary management of IBC has resulted in improved outcomes. For stage III IBC, rates of locoregional recurrence at 5 years range from 5% to 39% in patients receiving trimodality therapy (neoadjuvant chemotherapy, modified radical mastectomy, and postmastectomy radiation). Five year overall survival rates are 40% to 70%, and median survival times range from 2 to 4 years. Biomarker expression/phenotype and extent of response to neoadjuvant chemotherapy influence prognosis heavily. A recent series from the Mayo Clinic demonstrated that 5-year disease free survival was 36% for estrogen receptor–positive HER2/neu–negative IBC; 82% for HER2/neu–overexpressing disease; and 33% for triple-negative IBC. The prognosis of stage IV IBC remains particularly low, with fewer than 15% surviving 5 years.

SURVEILLANCE AND SURVIVORSHIP

IBC patients require long-term multidisciplinary follow-up. Clinical evaluation every 3 to 6 months is indicated to assess for any symptoms of chest wall, regional nodal, or distant organ failure. Contralateral mammography should be performed annually to screen for a new breast primary. Physical therapy is usually indicated to prevent and/or control lymphedema, which occurs in approximately 40% of patients undergoing an axillary lymph node dissection as well as postmastectomy radiation. Monitoring should also include assessments for impaired cognitive function, cardiac toxicity, and osteoporosis resulting from multidrug therapies.

FUTURE DIRECTIONS

Ongoing research seeks to identify additional biomarkers and technologies that may improve breast cancer outcomes. The role of these advances in IBC is uncertain, and warrants further study. Examples of such strategies include poly ADP ribose polymerase (PARP) inhibitors for patients with BRCA mutations; the addition of platinum agents to neoadjuvant chemotherapy regimens; and circulating tumor cells or cell free DNA as screening/surveillance tools. For locoregional management, lymphovascular bypass or alternative lymphatic grafting procedures can potentially reduce rates of lymphedema.

Ductal and Lobular Carcinoma in Situ of the Breast

Alastair M. Thompson, B.[illegible] (Hon), M. Ch.[illegible], MD, F.[illegible] La. d Carr Hon, FRCS, FACS

Ductal carcinoma in situ (DCIS) of the breast and lobular in situ neoplasia (LISN) represent neoplastic cells within the basement membrane of the terminal ductal lobular units of the breast. DCIS is a nonobligate precursor for progression to invasive disease. While the etiology and pathogenesis of in situ neoplasia remains uncertain, DCIS has become a frequently detected histologic feature of breast screening programs. Currently, 20% to 25% of "breast cancer" detected by mammography is DCIS alone. Standard of care for DCIS follows the established treatments for invasive breast cancer: complete excision of the DCIS with a clear margin (potentially followed by breast radiotherapy and endocrine therapy) or mastectomy. LISN, usually detected as an incidental finding also via breast screening, does not present the same risk of progression to invasive disease and, contrary to popular belief, is not usually bilateral at presentation (Maxwell 2016) only the rare, pleomorphic, variant should be considered equivalent to, and treated like, DCIS.

DIAGNOSIS

The diagnosis of DCIS is usually made as an impalpable lesion detected by breast screening mammography demonstrating microcalcifications and/or tissue distortion (Fig. 1). More extensive DCIS may demonstrate a mass effect visible on ultrasound or present as a palpable lump. Magnetic resonance imaging may also be utilized to demonstrate the extent of DCIS. Confirmation of DCIS is best made by core needle biopsy with radiologic confirmation of the presence of microcalcifications in the core (Fig. 2) and subsequent histopathology (Fig. 3). The inevitable selective sampling of areas of DCIS may miss invasive disease in 10% to 20% of lesions, although the risk of under-calling may be reduced by the use of wide bore (7–9 gauge) vacuum assisted stereotactic guided needle biopsy. At the time of diagnostic biopsy, placement of one or more radiologic markers (Fig. 4) will facilitate subsequent localization for surgery. The pathology diagnosis of DCIS may be challenging with a spectrum of neoplastic changes ranging from benign atypical ductal hyperplasia via DCIS, through micro invasive penetration of the basement membrane to overtly invasive disease. The natural history of DCIS has been little studied, but if not operated on may develop into invasive disease (Maxwell et al., 2018). The likelihood and timing of invasive progression varies from low grade through intermediate and to greatest in high grade DCIS (Table 1). The risk of progression may be reduced by endocrine therapy.

Given the uncertainty of progression from DCIS to invasive disease, there are currently trials in progress around the world studying the potential for nonoperative intervention for those women with low risk of DCIS progression to invasive disease. The active surveillance trial in the United States, COMET (Comparing an Operation to Monitoring With or Without Endocrine Therapy) trial is restricted to women with low risk DCIS for progression to invasive breast cancer (criteria including age 40 years or greater, low- or intermediate grade DCIS, no palpable mass, estrogen receptor–positive DCIS). However, for the majority of women with DCIS, surgical management as outlined below remains guideline concordant care.

Surgical planning for DCIS should consider breast conservation surgery (segmental mastectomy) versus mastectomy and only where appropriate (at the time of mastectomy, not breast conservation) sentinel node biopsy (Ansari et al., 2008). The aim of modern surgery for DCIS is to excise the DCIS with an adequate margin (Morrow et al., 2016) to reduce the likelihood for future development of invasive disease or further occurrence of DCIS.

BREAST SURGERY

Segmental mastectomy (breast conservation surgery) or mastectomy are the key surgical options for surgery for DCIS (or pleomorphic lobular carcinoma in situ). LISN, unless of the rare, pleomorphic, variety does not require resection; use of core biopsy (including wide gauge vacuum assisted core) should ensure lobular invasive breast cancer is excluded. The choice of operation is made in discussion between the patient and her surgeon considering the relative size and site(s) of the DCIS, in relation to the size, shape, and volume of the breast. It may be technically possible to locally excise more than one region of DCIS, potentially to a maximum of three or four lesions, although the balance between multiple excision(s) and the potential for mastectomy with or without reconstruction should be considered.

BREAST CONSERVATION

For breast conservation (segmental mastectomy or wide local excision) the principles of excision of the DCIS, which is often impalpable, are to use a localization technique to maximize the opportunity for complete excision at a single operation with a currently recommended margin of 2 mm (Morrow et al., 2016).

Localization

Localization of the DCIS may be by use of one or more wires, seeds, or alternative localization techniques. These techniques aim to delineate the DCIS either by placing one marker in the lesion or by bracketing with two or more markers the DCIS to guide surgical excision.

Wire localization has historically been the principle method of localization for DCIS. Placement of one or more hooked wires by image guidance shortly before surgery can be achieved using the ipsilateral (mammographic) placement or, if a marker has previously been placed in the DCIS at the time of diagnostic core biopsy, using ultrasound to place the wire in the correct region if visible on ultrasound. Following deployment of the hooked needle via image guidance, the end of the wire passing out of the skin of the breast needs to be protected as the wire itself has the potential for displacement or accidental removal.

Recently, one or more markers placed in or demarcating the volume of DCIS to be resected has been practiced, as the marker seed can be placed the day (or more) before surgery and is less likely to be dislodged than a wire. In general, three categories of marker seed are in common usage: the radioactive Iodine 125 seed (which can be readily detected percutaneously over several days and months), a ferrous seed (Magseed; detected by use of a magnet probe) (Fig. 4) or microscopic radar detected reflector (SAVI SCOUT). Each technology has its advocates and detractors: the Iodine seed requires key radioactivity processes, protections and procedures to be in place; the Magseed probe cannot be used adjacent to ferrous surgical instruments (titanium or plastic retractors and instruments can be used) and the SAVI SCOUT® may be deactivated by the inadvertent close use of diathermy. Most surgeons who have moved from the use of wire guidance to seed localization (of whichever type) seem to prefer the seed localization method.

Using the seed based approach, a detector for whichever seed is deployed is used to identify the localized lesion and guide the resection. Prior to commencing the incision, care should be taken to identify the position of the seed or seeds and mark the skin of the breast (Fig. 5). Post seed placement mammograms and sometimes

FIG. 1 Ductal carcinoma in situ detected on mammography with the microcalcifications and right mass distortion reflecting the extensive ductal pathology.

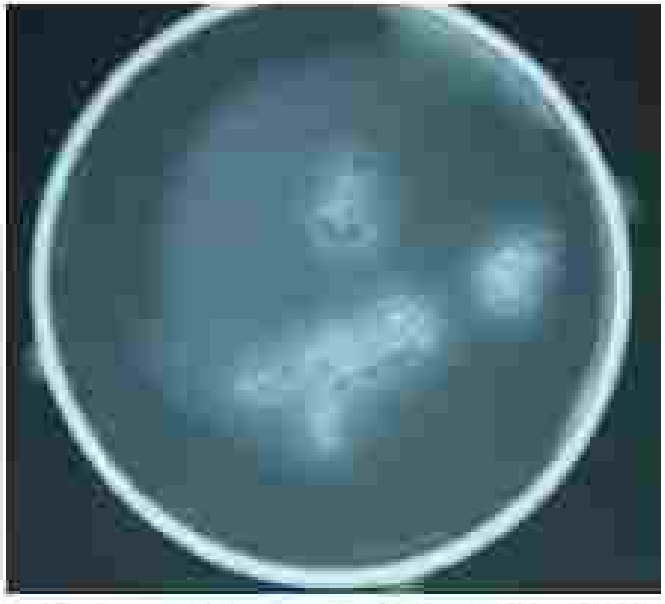

FIG. 2 Radiograph of cores demonstrating the microcalcifications and ductal carcinoma in situ.

FIG. 3 Example of the pathologic appearance of ductal carcinoma in situ on hematoxylin and eosin staining.

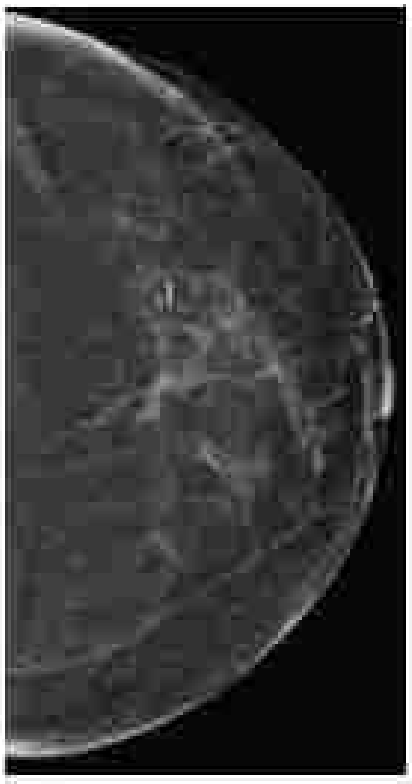

FIG. 4 Localized ductal carcinoma in situ with a marker clip and a negative seed (Pegseed).

the skin puncture wound from seed placement can be helpful to guide the approximate location of the seed or seeds and hence the tattoo for resection (see Fig. 5). The anticipated extent of the DCIS to be resected can then be outlined and thereafter the surgical incision placement determined (see Fig. 6).

Sentinel node biopsy should not be performed at the time of breast conservation in the setting of DCIS alone (Amant et al., 2008). Should there be an upgrade of the DCIS to identify invasive breast cancer, sentinel lymph node biopsy may be performed as a second procedure. This balances the low risk of upgrade (10%–20%) and need for a second procedure in such patients to perform a sentinel lymph node biopsy versus the unnecessary axillary surgery that would otherwise be conducted in the majority of women, with the risk of upper limb lymphedema of 4% to 10% even after sentinel lymph node biopsy.

Incision

In general, incisions can either be placed directly over the DCIS to be resected, preferably using skin lines (Fig. 6) (sometimes called Langer's lines or Dupuytren's lines), or placed distant from the lesion using the circumareolar junction between the areolar and breast skin (see Fig. 5 and Fig. 6). Rarely, however, they can be placed at the margin of the breast where it joins the chest wall laterally or inferiorly (see Fig. 6).

TABLE 1 Progression of Ductal Carcinoma in Situ (DCIS) to Invasive Disease (after Maxwell et al 2018)

Grade of DCIS	Cumulative incidence of invasion at 10 months	Cumulative incidence of invasion at 150 months
Low grade	10%	20%
Intermediate grade	20%	30%
High grade	40%	55%

Data from Maxwell AJ, Clements K, Hilton B, et al. Risk factors for the development of invasive cancer in unresected ductal carcinoma in situ. Eur J Surg Oncol. 2018;44:620–625.

FIG. 5 Markings prior to surgical lesion demonstrating the detectable mass (marked x); the false circular impression where the mass disappears under gentle applied pressure on the skin; the skin puncture (pinch) from mass placement; the circumareolar incision mark and the extent of the breast skin flap to be raised to excise the area of ductal carcinoma in situ excision.

Incision placement does not need to be directly over the DCIS to be resected, with techniques to raise skin flaps and thus tunnel to the lesion technically possible (see Fig. 5), as for invasive disease. Great care is required when raising the flap to ensure that the overlying skin is not damaged and good visualization with gentle tissue retraction (Fig. 7) needed to ensure the correct tissue is targeted and removed. Either sharp or diathermy dissection may be employed to raise the flap and thus allow subsequent dissection around the local, used DCIS. Frequent use of the appropriate probe (Fig. 8) to detect the needle and ensure sufficient tissue is taken should be a primary concern, while identifying and securing bleeding points. Particular care is required with the hollow needle technique not to use suction (as the tissue may be aspirated into the suction apparatus) for this foreign

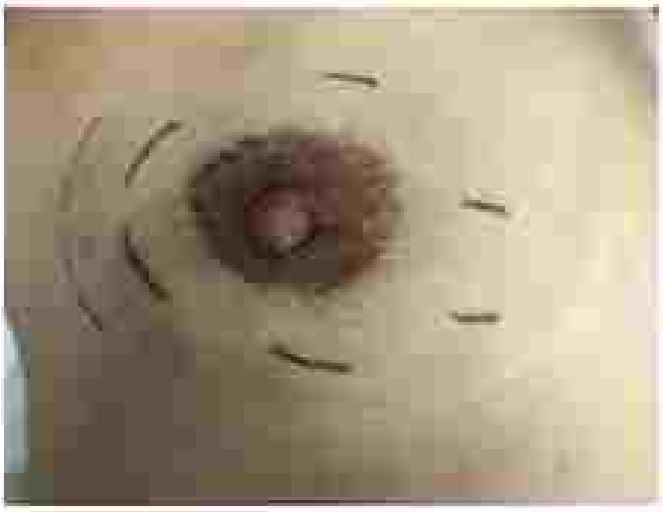

FIG. 6 Skin line markings around the breast. Note the direction of the final incision may be distinctly different from those secondly. Circumareolar and margin of lesion approaches are also marked.

FIG. 7 Patient from Fig. 5 with the skin flap raised and the ductal carcinoma in situ already removed. This image also illustrates two different types of retractor: the *curved retractor (blue)* to avoid transection of diathermy to the skin and a *gentle retractor (for use with the hollow wire probe)*.

need, to use nonmetallic instruments, for the radio transmitter technique, not to place the diathermy too close to, and hence inactivate, the wire.

The relationship between the excision/resection, whether conducted with scissors or diathermy and the lesion should aim to completely excise the DCIS with ultimately a technically adequate margin (2 mm or more circumferentially) (Morrow et al., 2016), recognizing that there will rarely be a palpable lesion or margin to guide the surgeon's fingers. It is unusual to take the skin overlying the DCIS lesion or the needle tract in modern approaches to breast surgery. There is a very low risk of DCIS seeding along the needle tract and the resection of skin may distort the final cosmetic appearance of the breast. The resection may go down as far as the pectoral fascia, which will not be transgressed by the DCIS, if the lesion is posteriorly located in the breast, and may need to take the superficial tissue up to the subcutaneous fat and dermis for superficially placed DCIS.

FIG. 8 Neoprobe seed detector which can detect iodine-125 seeds (left), and the Magseed detector (right), with the probe inside. ... Detector probe is used like pencil to detect seeds. The probe is placed into a plastic sheath to maintain sterility.

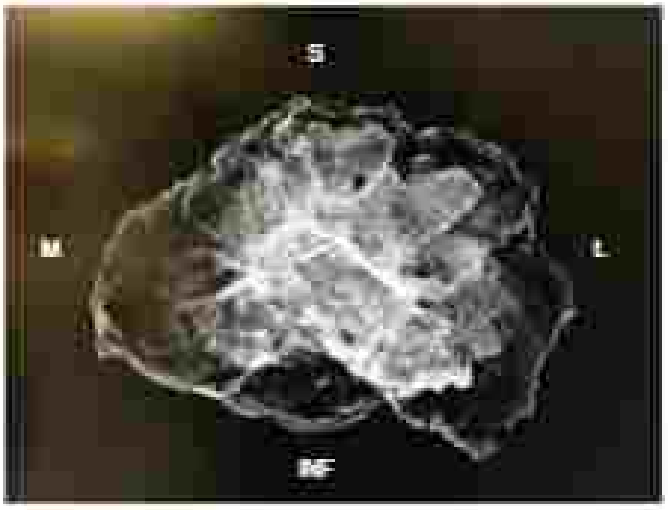

FIG. 10 Specimen radiograph of Fig. 9 demonstrating the centrally based steel and marker clip with wire margins. IN, inferior; L, lateral; M, medial; S, superior.

FIG. 9 Specimen oriented and marked with a short (superior) silk suture and long (lateral) suture for orientation.

Once removed, care is required to mark the orientation of the specimen for subsequent imaging and pathology orientation (Fig. 9). Some surgeons prefer to place the marking sutures or clips prior to finally removing the segment of breast to avoid errors of orientation as the tissue is removed from the breast. However, using the same markings and communicating to the pathology and imaging colleagues the markings used (e.g., short suture superior, long suture lateral), whether the lesion is from the left or right breast, and the position on a theoretical clock face on the breast are all helpful. The specimen should be imaged to ensure the model or wire is present in the specimen and for guidance for pathology (Fig. 10). It can be very helpful for the pathology team to section the resected mass and take further radiographs to demonstrate the likely resected margins, and whether any calcifications appear to be close to the margins. This may then guide the surgeon whether to take additional margins either guided by the imaging interpretation or possibly to perform cavity shavings if that is the practice of the surgeon operating.

Marking the site of the resection, once hemostasis has been established, is helpful if postoperative radiotherapy is to accurately target the resection bed. Either using several titanium based clips (e.g., Ingenuity clips) or a device inserted in place such as the Bmarq locator may facilitate such localization especially when the surgical skin incision is distant from the resection bed (see Fig. 5). These locators can usually be seen clearly on postoperative mammograms, CT planning for radiotherapy, and used to inform the design and delivery of postoperative radiotherapy if it is to be administered.

Tissue mobilization is often required to close the defect created by removal of the breast tissue harboring the DCIS. This can be achieved either by minor, local mobilization of the breast or by mobilization of the breast on the underlying chest wall and separating the breast from the overlying skin. Indeed, rotating breast tissue to fill the defect and using a few well placed absorbable sutures to maintain placement is usually effective in closing the defect while not creating skin tethering distortions. Alternatively, those who have undertaken experience to raise and place such a flap securely may deploy more advanced flap rotation techniques for larger defects, such as a lateral thoracoepigastric perforator flap.

Wound closure should employ dissolving sutures (e.g., 3.0 Vicryl) to appose the deeper tissues and the subcutaneous plane. Subcuticular sutures and/or skin glue (e.g., Dermabond) or paper adhesive strips complete wound closure. No drain should be necessary with this breast conservation approach and with support from a brassiere provided by the patient, normal upper limb movement and activities should be encouraged. By not using additional skin dressings, the patient may bathe as per normal from the next day.

Several experimental techniques are currently under investigation to provide intraoperative reassurance that resection margins around the DCIS are sufficient (at least 2 mm) (Morrow et al., 2016). These include preoperative injection of a "dye" that can be detected at the time of surgery to show involved margins; use of metabolomic profiling of the smoke plume from the diathermy; optical coherence tomography, either on the tissue bed or on the resected specimen to delineate up to 2 mm depth of clearance of the DCIS. All these techniques are under comparison with the gold standard of pathology of the resected margins, though the pathology examination may only actually consider some ~5% of the actual margin of resection. Some practitioners use touch preparation cytology of the resected margins or frozen section performed during the operative resection. This requires high quality, timely pathology support during the operative procedure.

Reoperation for a close margin (<2 mm) or positive margin (DCIS touching the surgical margin) is a relatively frequent occurrence reported in 10% to 60% of patients with DCIS who undergo breast

FIG. 11 Nipple-sparing mastectomy with intramammary incision and the blue dye in the breast skin ovoid from the sentinel lymph node biopsy technique. The sentinel node detected by blue dye and radioactive colloid is held by a suture for identification and subsequent excision.

FIG. 12 Prior to final closure of the circumareolar wound, a cannula has been placed deep into the wound through which 10 mL of 0.25% bupivacaine was subsequently injected after final wound closure with subcuticular sutures and Dermabond skin glue, additional bupivacaine was inserted into the subcutaneous tissues.

conversation. This may be attributed to a disparity between the images and ultimate pathology report (Thomas et al., 2014), the lack of tactile appreciation by the surgeon at the time of the original surgery and/or failure to examine the resected specimen. Reoperation should be guided by the pathology report and focused on which, if any, margins require further resection or whether the DCIS is sufficiently extensive that a mastectomy will be required to completely resect the DCIS.

Mastectomy

Mastectomy may be performed either at the request of the patient (who may opt for bilateral mastectomy for symmetry or who is a breast cancer gene carrier) or due to the extent of DCIS present relative to the volume of the breast. The mastectomy may be either a simple mastectomy, or, if undergoing immediate reconstruction, a skin sparing mastectomy or nipple sparing mastectomy. Reconstruction may be via autologous tissue, tissue expander, or direct to implant. For skin sparing mastectomy, clearance of the DCIS in the breast from the skin and for nipple sparing mastectomy, a 2 cm margin on imaging between the DCIS and the nipple is recommended.

Prior to commencing a mastectomy, a sentinel lymph node biopsy should be discussed with the patient and, typically, a dual technique of technetium-99 colloid and blue dye is used. With the two injections performed before the mastectomy incision (of whichever sort) is made, the sentinel nodes are usually detectable and resectable though the mastectomy incision (whether a simple mastectomy, skin sparing mastectomy, or nipple sparing mastectomy) (Fig. 11). Mastectomy is usually the only indication for sentinel node biopsy in the setting of DCIS (Monti et al., 2018).

For skin sparing mastectomy, most appropriate where the patient has opted for a mastectomy and the DCIS impinges close to the nipple areolar complex, a circumareolar incision may be enlarged to form an elliptical incision incorporating resection of the nipple and areolar complex. It is, however, worth noting that central excision of the nipple areolar complex for DCIS involving tissues deep to the nipple and areola, rather than mastectomy, may be a good option to conserve the breast if the patient prefers. A nipple sparing mastectomy may be considered if the DCIS is no closer than 2 cm from the nipple, and thus unlikely to be involving the nipple areolar complex. For a nipple-sparing mastectomy, an inframammary incision may be preferred (see Fig. 11) to other approaches and can be extended superiorly along the lateral border of the breast to allow ease of access to the axilla for the sentinel lymph node biopsy (see Fig. 11), obviating the need for a separate axillary incision for the node procedure. Whichever type of mastectomy approach is used, great care is needed to aim to remove all the breast tissue but not compromise the subcutaneous blood supply to the skin of the breast and, if remaining, the nipple areolar complex. Immediate specimen radiographs should indicate that a wide margin has been achieved around the DCIS at mastectomy. If, on final pathology, the margins adjacent to the nipple or areolar are compromised, these structures can be excised as a second procedure. Postoperative radiotherapy is not indicated after mastectomy.

Anesthesia and Analgesia Considerations

Many patients will undergo their surgery using general anesthesia, which may be enhanced by local anesthesia placed to and around the wound at the time of surgery. This may be extended by regional blockade, potentially a paravertebral block or local nerve block, which is particularly effective for pain relief if a mastectomy is performed.

However, local anesthesia is very effective for the breast conserving (no approach in place of general anesthesia (bupivacaine 0.5% with the potential addition of intravenous sedation). Local anesthesia using long-acting agents such as 0.25% bupivacaine plain or in liposomal formulation (Exparel) instilled into the wound via temporary placement of a cannula deep into the extent of the surgical cavity (Fig. 12), and injected around the wound, on completion of the surgery to provide excellent analgesia alongside the use of oral agents.

Postoperative analgesia in conjunction with the use of local anesthesia or regional blockade may include acetaminophen or non-steroidal antiinflammatory drugs such as ibuprofen. In reality, few patients require opiate analgesia after breast conservation procedures for DCIS and even postmastectomy, pain may be well managed with little, if any, opioid analgesia.

Subsequent Management

Radiotherapy reduces the recurrence of DCIS and development of invasive breast cancer in the ipsilateral breast and hence patients undergoing breast conservation for DCIS should be considered for radiotherapy postoperatively. At the present time, intraoperative radiotherapy for DCIS is not recommended outside clinical trials. Marking the DCIS resection site at initial surgery using metallic clips will guide the radiation oncologist to the tumor bed, particularly if a tumor bed boost is warranted.

Endocrine therapy may also reduce the reoccurrence of DCIS or development of invasive breast cancer in the same breast and/or the contralateral breast whether tamoxifen (for premenopausal women) or aromatase inhibitor (for postmenopausal women). It may be prescribed following detection of estrogen receptors in the DCIS.

Recurrence of DCIS in the same breast may be managed by further local, segmental excision if the patient prefers, or mastectomy. Annual mammography is likely to detect further development of DCIS at an early stage or the development of an invasive breast cancer in the breast.

The surgical management of DCIS broadly reflects that of invasive breast cancer although the technical demands of local excision and the need for localization of the often impalpable DCIS may be greater than for invasive disease. Individual decision making between the breast conservation and mastectomy approaches should reflect patient preference and the extent of the DCIS. A circumferential 2-mm margin of resection around DCIS is desirable in the setting of breast conservation and the surgical techniques deployed will be selected from the wide range of current approaches now possible.

Advances in Neoadjuvant and Adjuvant Therapy for Breast Cancer

Cesar A. Santa-Maria, MD, MSCI

SYSTEMIC THERAPY IN EARLY-STAGE BREAST CANCER

Systemic therapy for early stage breast cancer consists of cytotoxic chemotherapy and targeted therapies including endocrine and anti-human epidermal growth factor 2 (HER2) neu therapies. While surgery remains the cornerstone of therapy for early stage disease, advances in systemic therapy can decrease the risk of recurrence by eradicating micrometastatic disease. Adjuvant chemotherapy first demonstrated a benefit over surgery alone in the 1970s, opening a field that has seen numerous successes and failures. This experience solidified the appreciation and expectation that adjuvant therapies should be recommended based on high level data in carefully designed clinical trials. Large organizations such as the National Comprehensive Cancer Network provide guidance for practitioners in this ever changing field.

The goal of this chapter is to highlight key aspects of systemic therapy for early stage breast cancer with practical clinical implications based on the available level of evidence. It is not meant to be an in-depth analysis of each specific area, rather a comprehensive, clinically oriented account of modern systemic therapy for early stage breast cancer.

ADJUVANT VERSUS NEOADJUVANT APPROACHES

Advantages and Limitations

While systemic therapy can eradicate micrometastatic disease, it can also substantially decrease breast tumor size when appropriate selection of therapy for specific breast cancer subtype is made. Chemotherapy can be administered preoperatively (neoadjuvant) or postoperatively (adjuvant), and there is no difference in terms of risk of distance disease recurrence or death.

Indications for a neoadjuvant approach are based on surgical considerations but may also serve to risk stratify patients. If surgery is contraindicated at diagnosis, and neoadjuvant therapy is not, neoadjuvant therapy may allow patients to delay definitive surgery until they are a suitable surgical candidate. Locally advanced breast cancers that may not be operable, may become operable if systemic therapy can shrink the tumor. Inflammatory breast cancer is a specific clinical presentation that benefits from a neoadjuvant approach. Patients with large breast cancers who are not a candidate for a breast conservation approach and desire this may also be considered for neoadjuvant therapy. Patients with clinically positive lymph nodes, where the standard approach would involve axillary lymph node dissection may become candidates for the more limited sentinel lymph node biopsy and dissection, which carries less lymphedema risk, if they have a good response to neoadjuvant therapy.

Patients with HER2 positive breast cancer and triple negative breast cancer (TNBC) with stage II and III disease in particular may undergo risk stratification, with neoadjuvant therapy, which may impact treatment options if they are left with residual disease. This is particularly critical since prognosis for the individual patient is heavily influenced by residual disease. The KATHERINE study found that patients with residual disease after neoadjuvant anti-HER2 based chemotherapy had decreases in recurrence rates when treated with trastuzumab emtansine. The CREATE X study found that adjuvant capecitabine for patients with residual disease could improve outcomes; this was largely observed in TNBC. Other ongoing studies in the residual disease space are ongoing and may help further delineate effective therapies for patients with residual disease. Of course patients with stage I disease may potentially have chemotherapy regimens (discussed further), and upfront surgery may be more appropriate. Nonetheless, the neoadjuvant approach allows us to risk stratify patients with HER2 positive breast cancer and TNBC and should be considered strongly in these patients.

Neoadjuvant therapy may be considered in certain clinical scenarios as well. If true pathologic stage may potentially affect the recommended systemic therapy, it may be warranted to proceed with primary surgery first, such would be the case in small HER2 positive tumors for example (discussed later). The neoadjuvant setting is one that lends itself to translational and clinical research questions abundant from

Subsequent Management

Radiotherapy reduces the recurrence of DCIS and development of invasive breast cancer in the ipsilateral breast and hence patients undergoing breast conservation for DCIS should be considered for radiotherapy postoperatively. At the present time, intraoperative radiotherapy for DCIS is not recommended outside clinical trials. Marking the DCIS resection site at initial surgery using metallic clips will guide the radiation oncologist to the tumor bed, particularly if a tumor bed boost is warranted.

Endocrine therapy may also reduce the reoccurrence of DCIS or development of invasive breast cancer in the same breast and/or the contralateral breast whether tamoxifen (for premenopausal women) or aromatase inhibitor (for postmenopausal women). It may be prescribed following detection of estrogen receptors in the DCIS.

Recurrence of DCIS in the same breast may be managed by further local, segmental excision if the patient prefers, or mastectomy. Annual mammography is likely to detect further development of DCIS at an early stage or the development of an invasive breast cancer in the breast.

The surgical management of DCIS broadly reflects that of invasive breast cancer although the technical demands of local excision and the need for localization of the often impalpable DCIS may be greater than for invasive disease. Individual decision making between the breast conservation and mastectomy approaches should reflect patient preference and the extent of the DCIS. A circumferential 2-mm margin of resection around DCIS is desirable in the setting of breast conservation and the surgical techniques deployed will be selected from the wide range of current approaches now possible.

Advances in Neoadjuvant and Adjuvant Therapy for Breast Cancer

Cesar A. Santa-Maria, MD, MSCI

SYSTEMIC THERAPY IN EARLY-STAGE BREAST CANCER

Systemic therapy for early stage breast cancer consists of cytotoxic chemotherapy and targeted therapies including endocrine and anti-human epidermal growth factor 2 (HER2) neu therapies. While surgery remains the cornerstone of therapy for early stage disease, advances in systemic therapy can decrease the risk of recurrence by eradicating micrometastatic disease. Adjuvant chemotherapy first demonstrated a benefit over surgery alone in the 1970s, opening a field that has seen numerous successes and failures. This experience solidified the appreciation and expectation that adjuvant therapies should be recommended based on high level data in carefully designed clinical trials. Large organizations such as the National Comprehensive Cancer Network provide guidance for practitioners in this ever changing field.

The goal of this chapter is to highlight key aspects of systemic therapy for early stage breast cancer with practical clinical implications based on the available level of evidence. It is not meant to be an in-depth analysis of each specific area, rather a comprehensive, clinically oriented account of modern systemic therapy for early stage breast cancer.

ADJUVANT VERSUS NEOADJUVANT APPROACHES

Advantages and Limitations

While systemic therapy can eradicate micrometastatic disease, it can also substantially decrease breast tumor size when appropriate selection of therapy for specific breast cancer subtype is made. Chemotherapy can be administered preoperatively (neoadjuvant) or postoperatively (adjuvant), and there is no difference in terms of risk of distance disease recurrence or death.

Indications for a neoadjuvant approach are based on surgical considerations but may also serve to risk stratify patients. If surgery is contraindicated at diagnosis, and neoadjuvant therapy is not, neoadjuvant therapy may allow patients to delay definitive surgery until they are a suitable surgical candidate. Locally advanced breast cancers that may not be operable, may become operable if systemic therapy can shrink the tumor. Inflammatory breast cancer is a specific clinical presentation that benefits from a neoadjuvant approach. Patients with large breast cancers who are not a candidate for a breast conservative approach and desire this may also be considered for neoadjuvant therapy. Patients with clinically positive lymph nodes, where the standard approach would involve axillary lymph node dissection may become candidates for the more limited sentinel lymph node biopsy and dissection, which carries less lymphedema risk, if they have a good response to neoadjuvant therapy.

Patients with HER2 positive breast cancer and triple negative breast cancer (TNBC) with stage II and III disease in particular may undergo risk stratification, with neoadjuvant therapy, which may impact treatment options if they are left with residual disease. This is particularly critical since prognosis for the individual patient is heavily influenced by residual disease. The KATHERINE study found that patients with residual disease after neoadjuvant anti-HER2 based chemotherapy had decreases in recurrence rates when treated with trastuzumab emtansine. The CREATE X study found that adjuvant capecitabine for patients with residual disease could improve outcomes; this was largely observed in TNBC. Other ongoing studies in the residual disease space are ongoing and may help further delineate effective therapies for patients with residual disease. Of course patients with stage I disease may potentially have downstaging options (discussed further), and upfront surgery may be more appropriate. Nonetheless, the neoadjuvant approach allows us to risk stratify patients with HER2 positive breast cancer and TNBC and should be considered strongly in these patients.

Neoadjuvant therapy may be considered in certain clinical scenarios as well. If true pathologic stage may potentially affect the recommended systemic therapy, it may be warranted to proceed with primary surgery first, such would be the case in small HER2 positive tumors for example (discussed later). The neoadjuvant setting is one that lends itself to translational and clinical research questions abundant from

before and after therapy, and pathologic complete response (pCR) rate is a clinical endpoint with possible survival implications. Therefore, when neoadjuvant clinical trials are available, oncologists should discuss with patients these options and see if this would be an appropriate avenue.

Neoadjuvant therapy should be avoided when there is unlikely to be a significant response to systemic therapy, such as the use of chemotherapy for luminal A–like hormone positive, and/or classical lobular carcinoma.

Pathologic Complete Response

After neoadjuvant therapy, some patients may achieve a pCR. For those with HER2 positive or TNBC, this may provide favorable prognostic information, as the risk of recurrence is significantly lower for the individual achieving a pCR. Indeed, this has served as a surrogate endpoint for neoadjuvant studies, and even accelerated Food and Drug Administration (FDA) approval. However, it is crucial to understand the difference between the individual achieving a pCR, and the ability of a drug in the setting of a clinical trial to improve the pCR rate; the latter does not always translate to better survival and recurrence endpoints. Examples are bevacizumab and lapatinib, where numerous studies demonstrated improvements in pCR, but when the confirmatory adjuvant studies were completed recurrence rates and survival endpoints were no better.

Neoadjuvant Endocrine Therapy

Neoadjuvant therapy may be an option for patients with estrogen receptor (ER) positive breast cancer, where there exists an indication to intent of improving surgical options and outcomes. There are, however, a few caveats. While adjuvant endocrine therapy is almost a universal recommendation for patients with ER positive breast cancer, there are phenotypes that are more endocrine sensitive than others, such as luminal A–like breast cancers. Treating a patient with a more aggressive phenotype ER positive breast cancer with neoadjuvant endocrine therapy should generally be avoided since these phenotypes are less endocrine sensitive. It is also important to consider that clinical response to endocrine therapy occur typically after many weeks, and regimens of at least 4 to 6 months are required to fully maximize clinical response. Pathologic complete response rates are exceedingly low with either chemotherapy or endocrine therapy, and indeed, the relevance of pCR in ER positive breast cancer is less well defined. Most patients with endocrine sensitive disease present with lower stage disease where upfront surgery is feasible, and more locally advanced disease where neoadjuvant approaches are typically considered, are usually associated with more aggressive, less endocrine sensitive phenotypes where chemotherapy may be more effective.

SYSTEMIC THERAPY ACCORDING TO BREAST CANCER SUBTYPE

Breast cancer is a heterogeneous group of diseases that arise in the breast. These can be classified into many subtypes based on molecular testing; however, clinically the ER, progesterone receptor (PR), and HER2 receptors are used to classify them. While there is some correlation between clinical and molecular subtypes, there is significant overlap. Therapy is based on clinical subtypes and may include chemotherapy and targeted therapy such as endocrine or anti-HER2 therapy.

Triple-Negative Breast Cancer

Cytotoxic chemotherapy was initially found to have anti-cancer effects over 100 years ago, and some of the earliest agents used were nitrogen mustards and anti folates. The first combination regimen evaluated in early stage breast cancer was cyclophosphamide with methotrexate and 5-fluorouracil, typically referred to as a first generation regimen. Substituting the methotrexate for an anthracycline was found to have better outcomes, and the FEC (5-fluorouracil, epirubicin, and cyclophosphamide) and FAC (5-fluorouracil, doxorubicin, and cyclophosphamide) regimens were developed. These were found to be equivalent to doxorubicin and cyclophosphamide (AC), although AC is generally better tolerated. The addition of a taxane to AC was found to improve disease free survival (DFS) (hazard ratio [HR], 0.83; 95% CI, 0.79–0.87; $P < .00001$) and overall survival (OS) (HR, 0.85; 95% CI, 0.79–0.91; $P < .00001$), with an absolute improvement of 5% in DFS and 3% in OS. Dose density of the AC (every 2 week dosing with growth factor support), and taxane (either weekly or every 2 weeks) was found to be superior as well, which brings us to the current standard of care, dose dense AC/T. As there are no targeted agents currently approved in TNBC, dose dense AC/T is the standard of care for stages I to III (Table 1). Typically, patients with T1a/b do not have a significant benefit from chemotherapy, as the small size of their tumor portends a relatively favorable prognosis that chemotherapy is unlikely to substantially affect.

TABLE 1 Systemic Therapy for Early-Stage Triple-Negative Breast Cancer (TNBC)

Chemotherapy	Considerations
Anthracycline taxane regimens	• Anthracycline taxane regimens are standard of care for most patients with early stage TNBC • Dose dense A → paclitaxel weekly or dose dense (every 2 weeks) most common regimen in the United States
TC	• Not noninferior to anthracycline taxane regimens • May be considered when anthracyclines are contraindicated
Capecitabine	• May be considered in patients with residual disease after neoadjuvant chemotherapy
Carboplatin	• Typically added to the paclitaxel portion of AC/T • Can improve pCR, but effect on recurrence rates unknown • May have more activity in patients with BRCA mutations • Adds significant toxicity which may affect ability to complete standard therapy

AC, Doxorubicin and cyclophosphamide; AC/T, all standard chemotherapy (doxorubicin, cyclophosphamide, paclitaxel); pCR, pathologic complete response; TC, docetaxel with cyclophosphamide.

Because of the potential for serious toxicity from anthracyclines, including cardiomyopathies and secondary marrow neoplasms, anthracycline sparing regimens have been developed. Docetaxel with cyclophosphamide (TC) was compared to AC (not dose dense) and DFS rates favored TC, and OS was the same. A combined analysis of two trials evaluating TC versus an anthracycline and taxane regimen in HER2 negative early stage breast cancer found that 8 year DFS was 88.2% for TC and 90.7% for anthracycline and taxane regimen ($P = .08$) in the overall cohort. However, the benefit was especially noted in TNBC, where at all stages (stage I–III) anthracycline and taxanes was favored over TC. Only in the node negative ER positive subgroup did TC seem to do better.

Considering Carboplatin

Carboplatin has demonstrated efficacy in the metastatic setting, especially among patients with TNBC, in particular among patients with germline *BRCA* mutations. There have been numerous studies in the neoadjuvant setting that have confirmed that the addition of carboplatin to chemotherapy can improve pCR rates. The GeparSixto study evaluated the addition of carboplatin to neoadjuvant chemotherapy and found that overall it could improve the pCR rate; however, in those with BRCA mutations, the addition of carboplatin did not improve the pCR. Ongoing studies will confirm if there is a survival benefit. The addition of carboplatin does add toxicity and many patients are unable to complete all standard chemotherapy (AC/T) due to this toxicity.

Thus, in the meantime consideration of carboplatin should be on an individual basis, weighing the pros and cons of therapy (Table 1).

Capecitabine for Residual Disease

Although capecitabine has not been found to be a very active agent against TNBC in the metastatic setting, the CREATE X (Capecitabine for Residual Cancer as Adjuvant Therapy) study found it may improve outcomes in patients with residual disease after neoadjuvant chemotherapy. The CREATE X study included both TNBC and ER positive breast cancer, and randomized patients to 6 months of capecitabine or not and found there was benefit to DFS (HR, 0.70; 95% CI, 0.53–0.92; $P = .01$) and OS (HR, 0.68; 95% CI, 0.46–0.86; $P = .01$); however, this was mostly observed in the TNBC group. Although this was a relatively small phase III study and included heterogeneous disease (TNBC and ER positive); these data provide rationale to consider capecitabine in high risk patients (see Table 1). Ongoing studies are evaluating other agents in those with residual disease including carboplatin and immune checkpoint inhibitors.

Promise of Immunotherapy

Immune checkpoint blockade, especially against programmed cell death 1 or its ligand (PD1 or PD-L1, respectively) has shown modest benefits in the metastatic setting; however, early data in the neoadjuvant setting suggest significant activity. The IMPT2 study randomized patients to receive anthracycline taxane-based chemotherapy with or without the PD1 inhibitor pembrolizumab (during the taxane portion of therapy). Investigators found an unprecedented tripling of pCR rates with the addition of immunotherapy, and estimated pCR rate increased from 20% to 60%. A significant benefit was even observed in the ER positive subgroup. While other neoadjuvant studies adding immunotherapy to chemotherapy have not found the same degree of benefit (e.g., GeparSixtwo), a recent press release of KEYNOTE-522 (anthracycline/taxane study of chemotherapy with or without pembrolizumab) has claimed meeting its primary endpoint of pCR. We still need to await further data to evaluate the increase in anticancer benefit with toxicity.

Hormone Receptor–Positive Breast Cancer

Risk Stratification to Identify Need for Adjuvant Chemotherapy

While some ER positive breast cancers may benefit from adjuvant chemotherapy, many do not. Factors that can determine the net benefit from adjuvant chemotherapy include clinical and biologic characteristics. Clinically, age, comorbidities, and performance status are important factors to consider when considering the net benefit of adjuvant chemotherapy. Pathologically assessment of the primary (HR/PR, HER2 status, Ki-67, and grade can determine chemosensitivity. Gene expression platforms have been developed to determine the benefit of chemotherapy in ER positive breast cancer (Table 2).

Oncotype Dx (ODx) is a 21 gene expression panel that can provide a recurrence score (RS) between 0 and 100. This assay has been validated as a predictive and prognostic biomarker in numerous studies and is currently approved for use in ER positive lymph node–negative breast cancer. A score of 10 or less portends an excellent prognosis with endocrine therapy alone, and these patients should not be treated with chemotherapy. A score above 25 has been demonstrated to benefit from chemotherapy. Recently, the main results from the TAILORx (Trial Assigning Individualized Options for Treatment [Rx]) study were published where patients with scores between 11 and 25 were randomized to chemotherapy or not, followed by endocrine therapy. The primary endpoint of this noninferiority study demonstrated that in patients with an RS between 11 and 25, endocrine therapy alone was noninferior to chemoendocrine therapy. A subset analysis, however, suggested that women younger than 50 years derived benefit if they had an RS between 16 and 25; approximately a 6.8% decrease in distant recurrence between 11 and 25, and 1.8% with scores 16 to 20. The RxPONDER study is evaluating the benefit of chemotherapy in patients with ER positive lymph node positive disease.

The Mammaprint platform is a 70 gene expression panel that has also been prospectively validated; a score of high or low risk is generated. In the MINDACT (Microarray In Node-Negative Disease May Avoid Chemotherapy) study, investigators randomized patients with early stage breast cancer (any subtype and node status) with clinical high risk disease and molecular low risk disease to chemotherapy or not, finding that there was no significant benefit of chemotherapy in these patients. Strengths of this study were that it studied molecular risk in clinical risk, which included standard pathologic factors; it was also the only study where we have some prospective data in node positive disease. However, there are numerous limitations with the study including use of nonstandard chemotherapy (docetaxel with capecitabine), and a heterogeneous cohort (HER2 positive and TNBC included; lymph node positive disease included). Nevertheless, while ODx may have a higher level of evidence in ER positive node negative breast cancer, Mammaprint does provide prospective data, albeit limited, in ER positive node positive disease. Since HER2 positive and TNBC were a small subset of patients, there is currently insufficient data to apply to those patients.

However, the MINDACT study does provide additional information regarding the power of standard pathology in predicting benefit to adjuvant chemotherapy. Patients with clinical low risk disease did well whether or not their molecular risk was high, suggesting that these patients may not need genomic testing. While gene expression profiling can be valuable in assessing benefit from chemotherapy, it should be ordered with care, considering clinical and available pathologic information.

Optimizing Endocrine Therapy

Tamoxifen Versus Aromatase Inhibitors

Tamoxifen is a selective estrogen receptor modulator, which acts as an antagonist in breast cells. Studies have found that 5 years of adjuvant tamoxifen compared to no tamoxifen or shorter regimens can improve DFS. Tamoxifen can be administered to premenopausal women (see Table 2) and has also been studied in men with breast cancer.

TABLE 1 Systemic Therapy Options for Early Stage Hormone Receptor–Positive Breast Cancer

Treatment Type	Treatment Option	Considerations
Chemotherapy	• TC, e.g., (in node negative) • Anthracycline/taxane containing	• Standard pathology (ER/PR, HER2, grade, Ki-67) • Gene expression profiling (Oncotype Dx for ER positive, Mammaprint for low nodal burden)
Endocrine therapy	• Tamoxifen • Aromatase inhibitor	• Duration (5 vs. 10 years) • Addition of ovarian suppression (in high risk premenopausal)
Weight management	• None standard	• Universal recommendation for all breast cancer survivors • Includes diet and physical activity to achieve and maintain ideal body weight
Bisphosphonates	• Zoledronic acid • Clodronic acid	• No confirmatory studies • No standard schedule/duration

ER, estrogen receptor; LN, lymph node; PR, progesterone receptor; TC, docetaxel with cyclophosphamide.

Aromatase inhibitors (AI) can decrease circulating estrogens, thus "starving" cells that are dependent on estrogen. In postmenopausal women, 5 years of AI therapy is superior to tamoxifen (lower 10-year breast cancer mortality [HR, 0.85; 95% CI, 0.75–0.96]), and is generally the preferred agent for postmenopausal ER-positive breast cancer. There are three FDA-approved AIs: anastrozole, letrozole, and exemestane. While they are thought to be equally efficacious in terms of survival endpoints, due to differences in individual metabolism, patients may experience different side-effect profiles with the different drugs, especially AI-associated musculoskeletal symptoms. AI therapy alone may be inferior to tamoxifen in men with breast cancer; however, when a contraindication exists to tamoxifen, AIs may be used in conjunction with a gonadotropin-releasing hormone (GnRH) agonist.

Duration of Endocrine Therapy

A 10-year course of tamoxifen has been compared to a 5-year course in several studies. Two large randomized studies, the ATLAS and aTTOM studies, have found that a 10-year course may offer modest benefit compared to a 5-year course. In the ATLAS study 10 years of treatment compared to 5 years improved risk of recurrence (20.8% and 19% vs 18% and 20.8%, respectively; RR, 0.84; 95% CI, 0.76–0.90), breast cancer mortality (10.7% and 11.5% vs 9.7% and 11.5%, respectively; $P = .03$), and OS (Rs vs 21.1%, respectively; $P = .01$). The MA17 study evaluated 5 years of an AI after 5 years of tamoxifen, and found a benefit to the sequential approach (improved DFS locally/contralaterally [HR, 0.58; 95% CI, 0.45–0.76; $P < .001$], and risk of distant metastasis [HR, 0.68; 95% CI, 0.53–0.84; $P = .001$]). The study went on to have a second randomization (MA17R) to continue AI therapy for an additional 5 years versus placebo and found modest benefits in DFS with the 10 year AI course compared with placebo (90% vs 91%, respectively; HR, 0.66; $P = .01$), mostly in terms of contralateral prevention. Other extended AI studies have not demonstrated a benefit.

Adding Ovarian Suppression

Observations that chemotherapy-associated amenorrhea was associated with better outcomes in ER-positive early-stage breast cancer led to studies evaluating the role of medical ovarian suppression to addition to adjuvant endocrine therapy. The SOFT (Suppression of Ovarian Function) study randomized premenopausal women with early stage breast cancer to 5 years of tamoxifen, tamoxifen with ovarian suppression, or exemestane with ovarian suppression. Although initial reports did not find a difference in DFS between the tamoxifen alone versus with ovarian suppression arms, a recent update demonstrated a modest benefit with longer follow up; at 8 years, DFS was 78.9% with tamoxifen alone, 83.2% with tamoxifen plus ovarian suppression, and 85.9% with AI plus ovarian suppression ($P = .006$). Subgroup analysis demonstrated the majority of the benefit was seen in patients who were treated with chemotherapy. Indeed, authors presented a subpopulation Treatment Effect Pattern Plot (STEPP) analysis demonstrating benefit was mainly observed in high risk patients (see Table 2). It is important to note that the addition of ovarian suppression did come at the cost with higher toxicity, and long-term studies assessing effects on quality of life and bone health (AIs and ovarian suppression can both decrease bone density) are required.

Additional Adjuvant Considerations

Weight Management

Obesity and low physical activity are associated with a higher risk of breast cancer, and weight gain after diagnosis of breast cancer is associated with a higher risk of recurrence. The mechanisms between "energy excess" states and breast cancer is likely multifactorial including inflammatory cytokines and immune cells, adipocytokines, and excess hormones. The Women's Intervention Nutrition Study (WINS) found that a dietary intervention associated with weight loss could decrease the risk of breast cancer recurrence by 24% at 5 years. The Breast Cancer Weight Loss (BWEL) study is now confirming if weight loss can improve outcomes in patients with breast cancer. At the minimum, oncologists should recommend a healthy lifestyle including a balanced diet, physical activity, and attainment of an ideal body weight.

Benefit of Bisphosphonates

Bisphosphonates are a class of drugs approved for osteoporosis indications including osteopenia, hypercalcemia of malignancy, and decreasing fractures in patients with bone metastases. Numerous studies have been conducted using various different bisphosphonates and various schedules inconsistently finding possible benefit in terms of breast cancer recurrence. A large meta-analysis was conducted and found, especially in patients who were post-menopausal, bisphosphonates could improve rates of recurrence (RR, 0.86; 95% CI, 0.78–0.94; $2P = .002$), distant recurrence (RR, 0.82; 95% CI, 0.73–0.92; $2P = .0003$), especially bone metastases (RR, 0.72; 95% CI, 0.60–0.86; $2P = .0002$). Limitations with this study included use of various bisphosphonates, dosing regimens and schedule, as well as varied adjuvant chemotherapy and endocrine therapy treatment. The most well studied bisphosphonates are zoledronic acid and clodronic acid. Since definitive data from adequately powered and designed confirmatory trials are unlikely to occur in this class of mostly generic medications, oncologists may consider bisphosphonate therapy in close consultation with their patients, reviewing the pros and cons of therapy. Of note, postmenopausal women with ER-positive breast cancer are often prescribed AI therapy, which can decrease bone density, and many patients end up being prescribed bisphosphonates for bone density–related indications.

HER2-POSITIVE BREAST CANCER

Trastuzumab in HER2-Positive Breast Cancer

The development of trastuzumab, a monoclonal antibody targeting HER2, changed the treatment landscape of HER2-positive breast cancer. The Neoadjuvant Herceptin trial demonstrated that adding trastuzumab to chemotherapy increased pCR rates from 30% to 65% (OR for pCR 2.97; 95% CI, 1.41–5.03; $P = .0002$), and decreased relapse rate from 20% to 12% (RR for relapse 0.67; 95% CI, 0.48–0.94). Indeed, numerous large randomized studies have consistently demonstrated the addition of trastuzumab to chemotherapy improved not only DFS but overall survival as well. The Breast Cancer International Research Group (BCIRG) conducted one of these studies, where patients with HER2-positive early-stage breast cancer were randomized to AC/T, AC/T with trastuzumab, or docetaxel with carboplatin and trastuzumab (TCH). With 10 years of follow up, both trastuzumab-containing arms have shown DFS and OS benefit compared to the AC/T arm; however, outcomes between AC/T with trastuzumab were not significantly different than with TCH (AC/TCH HR, 0.78; 95% CI, 0.61–0.85; $P < .001$; TCH HR, 0.76; 95% CI, 0.65–0.89; $P < .001$). This is a particularly interesting observation, given the potential serious toxicity of doxorubicin (cardiomyopathy and secondary marrow neoplasms).

Duration of Trastuzumab

Initial studies with trastuzumab prescribed 1 year of trastuzumab, somewhat arbitrarily. Therefore, it was unclear if longer durations would improve outcomes. The Herceptin Adjuvant (HERA) trial randomized patients to 1 versus 2 years of trastuzumab and found no difference in DFS (HR, 0.99; 95% CI, 0.82–1.16). Various studies have looked at shorter durations of trastuzumab therapy, as may be more cost effective and possibly limit trastuzumab-related cardiotoxicity. Shorter 9-week regimens have been studied but have either not shown noninferiority or have not been reported yet. Three studies have examined 6 month regimens were noninferior to 12 month regimens; however, only one (PERSEPHONE) has reported that 6 months may be noninferior to 12 months. The PERSEPHONE study was a noninferiority study designed to allow a 5% margin in DFS benefit and found that indeed 6 months was noninferior to 12 months of trastuzumab (HR, 1.05; 95% CI, 0.88–1.25; 95th percentile, 1.22; noninferiority HR, < 1.30). In the current age, where trastuzumab-related cardiotoxicity has not been found to be as clinically relevant long term, the noninferiority margin may not be congruent with overall best outcomes. In addition, subgroup analysis demonstrated that

TABLE 3 Anti-HER2 Therapy for HER2-Positive Breast Cancer

Clinical Risk Stratification	Treatment Considerations
Small HER2-positive	• TH
Intermediate risk	• TCH • ACT with trastuzumab has equivalent DFS but more toxicity
High-risk HER2-positive	• TCHP or ACTHP • Strongly consider neoadjuvant trastuzumab emtansine for residual disease • May consider neratinib, especially if no pertuzumab or trastuzumab-emtansine given, and HR positive

ACT, doxorubicin, cyclophosphamide, paclitaxel; ACTHP, as addition to ACT plus trastuzumab and pertuzumab; DFS, disease-free survival; ER, estrogen receptor; H, H, docetaxel, carboplatin, trastuzumab; HCP, TCH plus pertuzumab; TH, paclitaxel and trastuzumab.

those with HR-negative disease, who underwent neoadjuvant therapy or who were treated with anthracycline-sparing regimens (as most patients commonly are now) tended to do better with the 12 month regimen. Thus, 12 months of trastuzumab remains the standard of care (Table 3).

Pertuzumab in High-Risk HER2-Positive Breast Cancer

Crosstalk between HER2 and HER3 as a resistance mechanism for anti-HER2 therapy led to the development of a monoclonal antibody targeting HER3, pertuzumab. The NeoSPHERE and TRYPHENA studies demonstrated that the addition of pertuzumab to trastuzumab-based chemotherapy regimens in early HER2-positive breast cancer could improve pCR rates significantly. The APHINITY study, a large phase III study randomizing patients to trastuzumab-based chemotherapy with or without pertuzumab, sought to assess if there was a DFS benefit. While the results of the intention-to-treat analysis demonstrated a very modest, albeit statistically significant, benefit in terms of DFS (94.8% in pertuzumab, 93.2% in placebo), a more pertuzumab benefit was seen in node-positive disease (HR, 0.77; 95% CI, 0.62–0.96; $P = .02$). Therefore, pertuzumab and trastuzumab-based chemotherapy is considered a standard approach for high-risk HER2-positive early breast cancer (see Table 3).

Trastuzumab-Emtansine for Residual Disease

Patients with HER2-positive breast cancer who do not achieve a pCR are at a higher risk of recurrence. The KATHERINE study found that invasive disease-free survival was significantly higher in patients receiving trastuzumab emtansine than trastuzumab alone (HR, 0.50; 95% CI, 0.39 to 0.64; $P < .001$). Even though the presented results are only the initial interim analysis, overall survival was trending positive, and the FDA granted approval as this has quickly become a standard of care.

Integration of Tyrosine Kinase Inhibitors

While trastuzumab and pertuzumab demonstrated that an improvement in pCR could lead to better survival outcomes, not all agents necessarily validate this relationship. Lapatinib, a small molecule tyrosine kinase inhibitor (TKI) against the intracellular domain of HER2, was found to improved pCR rates across multiple studies; however, the confirmatory Adjuvant Lapatinib And/Or Trastuzumab Treatment Optimization (ALTTO) study did not demonstrate a DFS benefit in patients treated with lapatinib.

Although lapatinib did not result in DFS benefit in confirmatory studies, neratinib, a next-generation oral HER2 TKI, has been shown to provide DFS benefit. The ExteNET study randomized patients with early-stage HER2-positive breast cancer to receive neratinib for 1 year after the completion of trastuzumab-based chemotherapy. Investigators found that treatment with neratinib resulted in better DFS in the intention-to-treat analysis (HR, 0.73; 95% CI, 0.57–0.92; $P = .0083$), although this was mostly in ER-positive HER2-positive disease (HR, 0.66; 95% CI, 0.49–0.88; $P = .0043$). A major limitation of this study was that it did not include patients treated with pertuzumab, thus we do not know if neratinib would have the same benefit in patients who received pertuzumab. Furthermore, 40% of patients experienced grade 3 diarrhea (defined as ≥7 bowel movements by a day and/or incontinence, and/or requirement of intravenous fluids for at least 24 hours, and/or hospitalization). Although subsequent studies found that prophylaxis with antidiarrheals could improve rates of severe diarrhea, the toxicity limits integration into practice.

Deescalating Strategies in Small HER2-Positive Breast Cancers

Given the excellent prognosis that anti-HER2 therapy can provide patients with HER2-positive breast cancer, deescalation studies have been conducted to determine if less therapy can still provide excellent outcomes. A single-arm phase two study evaluating paclitaxel with trastuzumab found that patients with small (≤3 cm) HER2-positive breast cancer can experience very low rates of recurrence (at 3 years, 98.2% free from invasive disease; 95% CI, 97.6–98.8). Longer follow-up demonstrated continued excellent prognosis. Although this has not been confirmed in a randomized phase three study, it has been widely adopted given the very low recurrence rates observed and lower toxicity (see Table 3).

Management of Recurrent and Metastatic Breast Cancer

Mufaro Lazar, MD, Sawsri Bhattacharya, DO, and Theodore N. Tsangaris, MD, MBA

Nothing challenges the surgeon and the multidisciplinary breast care team more than recurrent breast cancer. Today, recurrent breast cancer is treated by a team of physicians including a surgical oncologist, plastic surgeon, medical oncologist, and radiation oncologist. The advancements in breast imaging, surgical technique, systemic treatment and radiation therapy contribute to improved local, regional, and systemic control of recurrent or metastatic breast cancer. Recurrent and/or metastatic breast cancer presents in the following three scenarios: (1) local recurrence after breast conservation or mastectomy, (2) regional recurrence to regional lymph node basins, and (3) systemic metastatic disease.

LOCAL RECURRENCE AFTER LUMPECTOMY OR MASTECTOMY

Recurrence in the ipsilateral breast or to the chest wall after mastectomy is classified as local recurrence. Ipsilateral breast tumor recurrence (IBTR) after breast conservation today has an incidence of 4% to 9%. The majority of local recurrences happen at the original lumpectomy site or close to the site.

In contrast, 1% to 3% of patients undergoing a mastectomy will have a chest wall or nodal recurrence 10 years after surgery. Locoregional recurrence isolated to the chest wall occurs in 50% to 70% of these patients and only one third of these patients have synchronous distant disease. However, chest wall recurrences can represent a significant source of morbidity for breast cancer patients causing bleeding, ulceration, and pain.

Needless to say, local recurrence is disappointing and often disheartening to both patient and surgeon. However, local recurrence should not be considered the instigator of a patient's demise but an indicator of potential systemic disease. Here a pragmatic approach is wise. It is essential to perform re-staging scans with a computed tomography (CT) scan/bone scan or a positron emission tomography/CT (PET/CT) scan. Systemic disease in combination with local recurrence is common and represents a different scenario than local recurrence alone.

REGIONAL RECURRENCE

Tumor occurring in the axillary, infraclavicular, supraclavicular, or internal mammary lymph node basins is considered regional recurrence.

METASTATIC RECURRENCE

The treatment of metastatic breast cancer is tailored by the expression of the estrogen receptor, progesterone receptor, HER2/neu protein, PD-L1 status on the tumoric cell, and germline BRCA1 or 2 status. Other factors affecting prognosis include location of metastases, age, performance status, and values of the patient. The treatment of metastatic breast cancer is palliative, and it is essential that the goals of care are addressed from the beginning. The treatment of metastatic breast cancer includes treatment with oral chemotherapy agents (CDK4/6 inhibitors, Lapatinib, Xeloda, PARP [poly(ADP-ribose) polymerase] inhibitors), cytotoxic intravenous (IV) chemotherapy, antibody-directed therapy (e.g., ado-trastuzumab or trastuzumab), endocrine therapy, and immunotherapy agents (atezolizumab). Only 22% of metastatic breast cancer patients are alive at 5 years, underscoring the importance of developing novel therapies to improve survival.

Regardless of the type of recurrence (local, regional, or metastatic), the approach to the patient and the disease remains similar. Recurrence should be considered a systemic issue and the whole patient should be attended to. The two most important principles to consider when dealing with recurrent breast cancer are (1) fully understanding the implications of recurrent breast cancer for that individual and (2) carefully, thoughtfully, and realistically formulating a treatment plan. A one-size treatment for recurrent local, regional, or systemic disease does not fit all.

DIAGNOSIS AND STAGING

When a patient presents with signs and symptoms of a local, regional, or metastatic recurrence it should initiate a compulsive and complete diagnostic workup cascade. Included in this workup are the following elements:

- Complete history and physical examination
- Breast imaging (mammography, ultrasound, breast magnetic resonance imaging [MRI])
- Metastatic workup (CT of the chest, abdomen, and pelvis, bone scan; PET/CT scan)
- Core biopsy for tissue diagnosis
- Bloodwork to assess anemia, renal insufficiency, and synthetic liver function

MANAGEMENT OF LOCAL RECURRENCE AFTER BREAST CONSERVATION

Local Excision

The standard textbook answer of "mastectomy for all local recurrences after breast conservation" may no longer be appropriate. In fact, the surgeon's role may be to only provide material for pathologic diagnosis and tumor markers. Usually, however, some form of surgical therapy is appropriate. Factors that would influence local excision versus completion mastectomy include:

- Size of the recurrence
- Location of the recurrence
- Single versus multicentric disease in the breast
- Tumor prognostic and predictive markers including estrogen receptor, progesterone receptor, and HER2 status
- Time interval between initial treatment to the recurrence
- Age of patient
- Comorbidities
- Cosmetic considerations
- Presence or absence of metastatic disease
- Prior radiation
- Patient preference

For small recurrences, after many years, near the *old* tumor site, with favorable prognostic markers and no evidence of metastatic disease, a lumpectomy with or without additional radiation therapy may be perfectly appropriate. Based on the results of the NRG Oncology Radiation Therapy Oncology Group (RTOG) 1014 contradictions may be feasible in some cases. RTOG 1014 was a prospective phase II study of 30 conformal external beam partial radiation following repeat lumpectomy in patients with an IBTR following prior breast conserving therapy (BCT) (lumpectomy and whole breast radiation). Skin, fibrosis, and breast pain toxicity was acceptable at the 1 year follow up.

Mastectomy

If a mastectomy is necessary or the patient's preference, it can be a challenge after prior surgery and radiation therapy (Fig. 1). Care must be taken when creating the skin flaps as radiation can result in a diminished blood supply leading to skin necrosis. Also, radiation changes can make it difficult to identify the plane between the breast tissue and subcutaneous fat. It is important to achieve negative margins in the area of the recurrence. This may require excision of skin or a portion of muscle in the area of the tumor. If the patient desires breast reconstruction, this is also challenging in the face of prior surgery and radiation. An autologous tissue flap, such as deep inferior epigastric, transverse rectus abdominis myocutaneous, or a latissimus dorsi myocutaneous flap, is usually recommended. Implant based reconstruction can be performed but it has a higher complication and failure rate. The involvement and contributions of the plastic surgeon in this case should not be understated.

TECHNICAL POINTS FOR MASTECTOMY FOLLOWING BREAST-CONSERVING THERAPY

After a lumpectomy and radiation therapy, a mastectomy with or without reconstruction for IBTR recurrence can be challenging. Our institutional experience finds us using a modified radiation mastectomy incision instead of the more traditional horizontal ellipse for patients who require mastectomy after IBTR recurrence (Fig. 2).

Advantages

- The skin closure after mastectomy is usually under less tension.
- This incision provides excellent exposure.
- This approach is committally superior as it eliminates the dog ears and redundant skin and soft tissue at the edges.
- The inferior flap can be deepithelialized and be used as an autologous covering and protection over the tissue expander.
- Extremely versatile for the plastic surgeon and the patient's reconstructive options.
- This incision is cosmetically in harmony with a contralateral breast reduction mammoplasty that many women undergo at the time of definitive reconstruction to achieve symmetry.

Disadvantages

- Corners of the incision on the superior flaps are susceptible to vascular compromise.
- Technical learning curve.

MANAGEMENT OF LOCAL RECURRENCE AFTER MASTECTOMY

Local recurrence following a mastectomy is less common, about 1% to 5%, and is associated with a higher rate of distant disease as well as a worse prognosis. Core needle biopsy or skin punch biopsy can be used to confirm tissue diagnosis and test receptor status. The patient should undergo staging studies to rule out distance metastatic disease. Resectability can be assessed by physical exam, ultrasound, CT chest, or MRI. A simple local resection may be all that is necessary. Consideration should be given to neoadjuvant chemotherapy or hormonal therapy if the size of the recurrence would make surgical resection difficult. Plastic surgery may be helpful in helping to close or cover a defect. Following surgery, the patient should be referred to radiation oncology.

MANAGEMENT OF THE AXILLA

With the wide acceptance of the sentinel lymph node (SLN) biopsy as the standard of care versus axillary dissection in staging breast cancer patients, a completely new class of patients with local recurrences is emerging. This begs the question, what do we do with the ipsilateral axilla in the patient who recurs locally? The answer to the question may lie in the very reason SLN biopsy is now standard of care. The axilla provides prognostic and staging information with some therapeutic benefit. If one accepts that local recurrence is prognostic in and of itself, then excessive surgical attention to the axilla is superfluous and carries unnecessary morbidity. With MRIs and high definition ultrasound the status of the axilla may be well known to the surgeon and multidisciplinary team. However, there may be a time when another SLN biopsy or axillary dissection is appropriate. If a prior SLN procedure yielded 10 or fewer lymph nodes there is a good chance (70%–75%) that another SLN procedure would identify a SLN. Other factors that affect the ability to identify a SLN biopsy include prior surgery, radiation, location of prior tumor, and recurrent tumor location. Preoperative lymphoscintigraphy should be performed to understand the patient's current lymphatic drainage. Regardless, the need for axillary sampling should be carefully discussed so that unnecessary morbidity can be avoided. If not to control known regional disease or to direct systemic therapy, then the axilla should be left alone.

FIG. 1 Locally advanced recurrence in a patient with a history of prior breast conservation.

METASTATIC DISEASE

The aim in treatment of metastatic breast cancer is not cure, but prolonging survival, alleviating symptoms, and maintaining quality of life.

PRINCIPLES OF TREATMENT FOR METASTATIC BREAST CANCER

The estrogen receptor, progesterone receptor, human epidermal growth factor receptor 2 (HER2), programmed death ligand 1 (PD-L1), and germline *BRCA* status are important in determining a treatment plan. A treatment plan is tailored to the individual patient and the medical oncologist must weigh the risks and benefits of oral chemotherapy agents, cytotoxic chemotherapy, endocrine therapy, immunotherapy, and biologic agents. Factors such as symptoms, medical comorbidities, performance status, previous exposure to chemotherapy, menopausal status, and disease location are carefully considered before a regimen is chosen.

The average metastatic breast cancer patient is richer with decades of life and often has many medical comorbidities. It is important to assess each patient's medical problems and assess the patient's performance status before embarking on chemotherapy. Also, many patients with metastatic breast cancer are heavily pre-treated with adjuvant chemotherapy often with an anthracycline. The lifetime dose of an anthracycline is

FIG. 2 (A) Preoperative marking for mastectomy via Wise pattern reduction technique. (B) Operative photo of mastectomy via Wise pattern reduction technique. (C) One week postoperative photo. (D) After tissue expanders are changed to permanent silicone implants.

about 300 mg/m², thus limiting the ability to further treat with this regimen. Additionally, patients may have had coronary artery disease, thus limiting the use of an anthracycline. Liposomal doxorubicin or eribulin is often a suitable alternative. If a patient has HER2 positive disease, it is important to perform an echocardiogram prior to starting trastuzumab or ado-trastuzumab regimens. Many females also have concurrent type 2 diabetes with concurrent neuropathy, which further limits the ability to treat with a taxane-based regimen.

The location of metastatic disease can affect survival. Patients with metastatic lesions in the chest wall, liver, or lymph nodes may have prolonged progression free survival in comparison to those with hepatic and or lymphangitic pulmonary disease, who tend to have shorter progression free survival and overall survival. The term visceral crisis is used to describe patients with lymphangitic lung metastases, bone marrow replacement, cardiomyopathy, meningitis, or significant liver metastases. In these cases, cytotoxic chemotherapy is preferred as it will lead to rapid disease control. Patients with liver dysfunction have a very poor prognosis, with limited treatment options due to synthetic dysfunction. In these situations, low dose taxanes, eribulin, carboplatin/cisplatin, and gemcitabine are often used for disease control.

CDK4/6 Inhibitors

The interaction of cyclin D with CDK4 and CDK6 facilitates hyperphosphorylation of the retinoblastoma (Rb) gene, which leads to progression through the G1 checkpoint to the S phase of the cell cycle. Alterations in the cyclin D-CDK4/6-Rb pathway have been described in many malignancies and are associated with endocrine resistance in breast cancer. Treatment with a CDK4/6 inhibitor (ribociclib, palbociclib, and abemaciclib) is now considered first line therapy for patients with metastatic hormone receptor positive breast cancer and has resulted in a significant improvement in quality of life, progression free survival, and overall survival. Multiple key trials showing this in combination with hormonal therapy include the PALOMA 2, PALOMA 3, MONALEESA 2, MONALEESA 7, MONARCH 2, and MONARCH 3 trials.

PARP Inhibitors

For patients with a germline BRCA1 or 2 mutation, PARP inhibitors including olaparib and talazoparib were recently approved for the treatment of metastatic breast in patients with germline BRCA1/2 mutations, based on the results of the OlympiAD trial and more recently the EMBRACA trial. The initial study that led to olaparib approval demonstrated that olaparib given at 300 mg by mouth twice a day improves progression free survival in patients with metastatic breast cancer with a BRCA1/2 mutation with a response rate of 59.9% in the olaparib group and 28.8% in the standard therapy group (single agent chemotherapy with capecitabine, eribulin or vinorelbine in 21-day cycles). The median progression free survival was significantly longer in the olaparib group than in the standard therapy group (7.0

months vs. 4.2 months; hazards ratio [HR] for disease progression or death, 0.56; 95% confidence interval [CI], 0.43–0.80; $P < .001$). Olaparib is an effective treatment for patients with metastatic breast cancer with a BRCA1/2 mutation.

Cytotoxic Chemotherapy

Treatment with single agent or combination based cytotoxic regimens can lead to improved disease control. Single agent chemotherapy regimens are reserved for patients with a low burden of disease. Combination based regimens are given to patients with symptomatic disease with need for rapid disease control. Agents often used include taxanes (paclitaxel and docetaxel), platinums (cisplatin and carboplatin), anthracyclines (erlotinib, doxorubicin, or liposomal doxorubicin), and anti metabolites (capecitabine and gemcitabine). When choosing a suitable cytotoxic chemotherapy option, a patient's comorbidities must be carefully examined including renal function, liver function, residual neuropathy, and anemia. Patient preferences such as frequency of therapy and side effect profile must also be considered.

Immunotherapy

For patients with triple negative breast cancer, immunotherapy in combination with cytotoxic chemotherapy has potential to provide durable treatment. By harnessing the immune system's ability to recognize cancer related antigens, immunotherapy can induce targeted immune responses against cancer cells. Recently, the IMpassion130 trial showed that treatment with atezolizumab, an immunotherapy agent that is a PD-L1 inhibitor, in combination with cytotoxic chemotherapy with nab-paclitaxel (Abraxane) resulted in meaningful progression free survival for patients with metastatic triple negative breast cancer with tumor infiltrating lymphocytes expressing PD-L1 greater than 1% (Schmid et al., 2018). Among the PD-L1 positive tumors, the median overall survival was 25.0 months with the combination of cytotoxic chemotherapy and immunotherapy versus 15.5 months with nab-paclitaxel alone (HR, 0.62; 95% CI, 0.45–0.86). This trial recently led to Food and Drug Administration approval of the first immunotherapy drug in combination with cytotoxic chemotherapy in the treatment of patients with metastatic triple negative breast cancer.

CONCLUSION

Recurrent and metastatic breast cancer patients are a heterogeneous group of patients for whom the experienced breast surgeon seeks the support of his or her multidisciplinary team. Today there is no one size fits all treatment. Advanced diagnostic surgical techniques and medicines have greatly impacted this special group of patients. Improved quality of life as well as longevity should be the goal.

Management of Male Breast Cancer

Samuel Sarmiento, MD, MPH, MBA, Michael McCall, BS, and Mahran Habibi, MD, MBA

Male breast cancer (MBC) is a rare disease. In 2018, the number of men with breast cancer was around 2550 compared to 266,120 in females, slightly less than 1%. The lifetime risk of developing MBC is about 1 in 1000. There is some evidence that the incidence has been increasing since the 1980s. This may be due to the increasing prevalence of associated risk factors. The risk of MBC is increased by those conditions that increase the effects of estrogen (cirrhosis, obesity, exogenous estrogens) or decrease the effects of testosterone (testicular malignancy, infection, trauma, 5α-reductase inhibitors, or Klinefelter's syndrome [XXY]) and is especially increased for genetic predisposition. The estimated proportion of MBC associated with BRCA mutations varies widely (4%–40%), but for men with BRCA mutations the cumulative absolute risk of MBC by age 70 years is estimated to be 1.2% for *BRCA1* (a relative risk 12 times that of non-mutation carriers) and 6.8% for *BRCA2* (a relative risk 42 times that of noncarriers). The evidence linking MBC to other gene mutations (CHEK2, AR, CYP17, PTEN) is suggestive but inconclusive. Most MBCs are ductal in origin; 75% of cases in the National Cancer Database were infiltrating ductal carcinomas. Most tumors are invasive but about 2% are in situ, and more than 90% are hormone receptor (HR) positive.

The prognosis of MBC appears to be worse than for female breast cancer but is comparable when corrected for stage of disease (most MBC is detected as a mass, not by mammography). Data from the 31,995 MBC diagnoses between 2004 and 2014 revealed a 5-year survival of 75% (95% confidence interval [CI], 0.74–0.76). Unfortunately, more than half of MBCs were seen as advanced disease (Stages III–IV), but with a trend toward earlier diagnosis in the more recent series, about 80% of MBCs have been seen with local or regional disease. MBC inhabits a unique diagnostic and treatment landscape as its rarity precludes most randomized controlled trials; however, it has a very common corollary to female breast cancer that provides a large source of related data to extrapolate from and apply. Historically, much of the diagnosis and treatment of MBC stems from what we know about female breast cancer. In recent years some investigative efforts have begun to establish MBC as its own entity.

DIAGNOSIS

MBC most commonly presents as a painless, unilateral breast mass. The tumorous onset contributes to the advanced stages of disease at diagnosis that is typical of MBC. Some men may experience bloody nipple discharge, skin changes in the nipple and areola, or suspicious axillary adenopathy, which often brings them to care earlier. The differential must include gynecomastia, as it is a fairly more common cause of breast masses in men. However, these masses will typically be tender and transient. Mammography and ultrasound should be used to investigate a potential mass. If these suggest a benign diagnosis, observation alone is sufficient, as most masses will resolve spontaneously in 2 to 3 months. A core biopsy is not necessary unless the mass persists or has particularly suspicious physical findings. In the case that mammography and ultrasound suggest a more pathologic lesion, a core biopsy of the breast lesion, punch biopsy of the nipple and areola, or ultrasound (US) guided fine-needle aspiration of axillary nodes is appropriate. Excisional biopsy is required for no more than 5% to 10% of patients, mainly those in whom the core biopsy is nondiagnostic or discordant with imaging

months vs. 4.2 months; hazards ratio [HR] for disease progression or death, 0.56; 95% confidence interval [CI], 0.43–0.80; $P < .001$). Olaparib is an effective treatment for patients with metastatic breast cancer with a BRCA1/2 mutation.

Cytotoxic Chemotherapy

Treatment with single agent or combination based cytotoxic regimens can lead to improved disease control. Single agent chemotherapy regimens are reserved for patients with a low burden of disease. Combination based regimens are given to patients with symptomatic disease with need for rapid disease control. Agents often used include taxanes (paclitaxel and docetaxel), platinums (cisplatin and carboplatin), anthracyclines (erlotinib, doxorubicin, or liposomal doxorubicin), and anti metabolites (capecitabine and gemcitabine). When choosing a suitable cytotoxic chemotherapy option, a patient's comorbidities must be carefully examined including renal function, liver function, residual neuropathy, and anemia. Management of Male Breast Cancer

Samuel Sarmiento, MD, MPH, MBA, Michael McCall, BS, and Mahran Habibi, MD, MBA

Male breast cancer (MBC) is a rare disease. In 2018, the number of men with breast cancer was around 2550 compared to 266,120 in females, slightly less than 1%. The lifetime risk of developing MBC is about 1 in 1000. There is some evidence that the incidence has been increasing since the 1980s. This may be due to the increasing prevalence of associated risk factors. The risk of MBC is increased by those conditions that increase the effects of estrogen (cirrhosis, obesity, exogenous estrogens) or decrease the effects of testosterone (testicular malignancy, infection, trauma, 5α-reductase inhibitors, or Klinefelter's syndrome [XXY]) and is especially increased for genetic predisposition. The estimated proportion of MBC associated with BRCA mutations varies widely (4%–40%), but for men with BRCA mutations the cumulative absolute risk of MBC by age 70 years is estimated to be 1.2% for *BRCA1* (a relative risk 12 times that of non-mutation carriers) and 6.8% for *BRCA2* (a relative risk 42 times that of noncarriers). The evidence linking MBC to other gene mutations (CHEK2, AR, CYP17, PTEN) is suggestive but inconclusive. Most MBCs are ductal in origin; 75% of cases in the National Cancer Database were infiltrating ductal carcinomas. Most tumors are invasive but about 2% are in situ, and more than 90% are hormone receptor (HR) positive.

The prognosis of MBC appears to be worse than for female breast cancer but is comparable when corrected for stage of disease (most MBC is detected as a mass, not by mammography). Data from the 31,995 MBC diagnoses between 2004 and 2014 revealed a 5-year survival of 75% (95% confidence interval [CI], 0.74–0.76). Unfortunately, more than half of MBCs were seen as advanced disease (Stages III–IV), but with a trend toward earlier diagnosis in the more recent series, about 80% of MBCs have been seen with local or regional disease. MBC inhabits a unique diagnostic and treatment landscape as its rarity precludes most randomized controlled trials; however, it has a very common corollary to female breast cancer that provides a large source of related data to extrapolate from and apply. Historically, much of the diagnosis and treatment of MBC stems from what we know about female breast cancer. In recent years some investigative efforts have begun to establish MBC as its own entity.

DIAGNOSIS

MBC most commonly presents as a painless, unilateral breast mass. The tumorous onset contributes to the advanced stages of disease at diagnosis that is typical of MBC. Some men may experience bloody nipple discharge, skin changes in the nipple and areola, or suspicious axillary adenopathy, which often brings them to care earlier. The differential must include gynecomastia, as it is a fairly more common cause of breast masses in men. However, these masses will typically be tender and transient. Mammography and ultrasound should be used to investigate a potential mass. If these suggest a benign diagnosis, observation alone is sufficient, as most masses will resolve spontaneously in 2 to 3 months. A core biopsy is not necessary unless the mass persists or has particularly suspicious physical findings. In the case that mammography and ultrasound suggest a more pathologic lesion, a core biopsy of the breast lesion, punch biopsy of the nipple and areola, or ultrasound (US) guided fine-needle aspiration of axillary nodes is appropriate. Excisional biopsy is required for no more than 5% to 10% of patients, mainly those in whom the core biopsy is nondiagnostic or discordant with imaging

characteristics. All biopsy diagnoses of MBC should include determination of estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor–2 (HER2). As with female breast cancer, a preoperative workup for distant metastases (by positron emission tomography/computed tomography [PET/CT] or CT and bone scan) is indicated only for locally advanced disease (stage III) or suspicious symptoms.

TREATMENT

Preoperative Considerations

Although surgery is the appropriate initial treatment for most MBC, neoadjuvant chemotherapy or hormonal therapy should be considered. The indications for neoadjuvant chemotherapy are the same as for women: advanced T or N stage (T3 to T4 tumors, including inflammatory cancer, or N2 to N3 nodes). The main limitation of neoadjuvant chemotherapy is that almost all MBC is ER positive, and this tumor subtype is not particularly responsive to neoadjuvant chemotherapy, with rates of pathologic complete response of 10% or less. For the same reason, neoadjuvant hormonal therapy makes sense for locally advanced MBC, especially in the setting of advanced age or significant comorbidities. Most patients respond to hormonal treatment with tamoxifen or aromatase inhibitors; the typical duration of response is in the range of 1 to 2 years, and those who progress often will respond to a change in hormonal agent.

Breast Conservation

Although historically, mastectomy was the method of choice in managing MBC, in a select group of patients, partial mastectomy can be done with similar outcomes.

The rationale for mastectomy for MBC has been the paucity of data in breast conserving surgery (BCS). The extent of excision required to obtain negative margins for BCS in women is significant and for most men could easily approach the volume of the entire breast. Further, the delivery of tangential field radiotherapy (RT) to the much smaller male breast raises concerns about exposure to the chest wall, lung, and heart, although these concerns are substantially reduced by contemporary techniques of CT guided treatment planning, they are eliminated altogether by the performance of mastectomy, after which RT is required only for locally advanced disease. Finally, even for men who wish to preserve the nipple as part of a nipple sparing mastectomy, the proximity of most MBC to the nipple and areola renders this approach unsound from both a cosmetic and an oncologic perspective. Despite these, a 2010 National Surgical Quality Improvement Program (NSQIP) study showed 15.9% of men had BCS, which suggests significant progress in surgical technique for MBC.

Mastectomy

Mastectomy remains the most common surgical technique for patients with MBC. The incision is dependent on body habitus. For most men, separate breast and axillary incisions are not needed and especially for those with a laterally placed nipple and areola, a single oblique elliptical incision encompassing both breast and axilla is reasonable (Fig. 1). For certain bulky or locally advanced cancers, a single incision will allow en bloc resection of the breast in continuity with the intervening soft tissues, lymphatics, and axillary nodes, but because these patients will all receive postmastectomy RT (PMRT), the benefit of this approach in local control is debatable. The mastectomy is done through a transversely oriented elliptical incision sufficient to encompass all of the breast and tumor tissue. The incision should widely encompass any areas of skin, nipple, or areolar involvement. For men with marked obesity or gynecomastia, the incision will be comparable to that required for a female mastectomy, whereas for those who are thin, the incision rarely needs to encompass the nipple and areola but should be long enough to avoid dog ears at the time of skin closure. Skin flaps are elevated peripherally sufficient to remove all breast tissue and any gynecomastia. The extent of this dissection again varies widely and is highly dependent on body habitus, but in general, the skin flaps in MBC do not need to be as thin as for women. In obese patients, as one nears the edges of the breast the skin flaps should be thickened gradually to avoid a sharp drop off differently at the periphery of the operative defect. The breast is dissected from the underlying pectoralis major muscle, removing the pectoral fascia and, if muscle invasion is found, the adherent portion of the pectoral muscle. The surgical specimen is oriented with sutures for noting of the margins by the surgical pathologist and handed off. Resection of the entire pectoralis major (i.e., radical mastectomy) is almost never required in the current era, but partial muscle resection is indicated for all patients with muscle invasion.

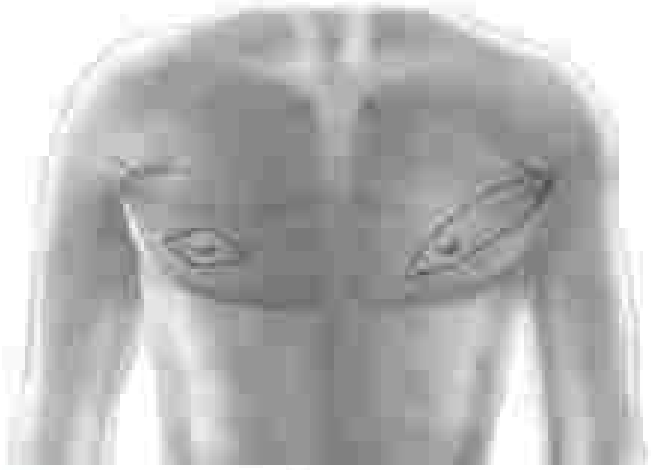

FIG. 1 Suggested incision (dotted line) for mastectomy with axillary staging in male breast cancer.

Axillary Management

Management of the axilla in MBC is comparable to that in female breast cancer. Sentinel lymph node (SLN) biopsy is appropriate for all operable invasive MBC with clinically negative axillary nodes (cT1-3N0). Because most men with a core biopsy diagnosis of ductal carcinoma in situ also have a palpable mass, invasion cannot be ruled out and SLN biopsy makes sense for them as well. Because patients with MBC do not fall within the eligibility of the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial (which showed that patients with one or two positive SLNs having BCS with whole breast RT do not require axillary lymph node dissection [ALND]), we recommend intraoperative pathologic assessment of the SLN and ALND for patients who are SLN positive. For patients who are clinically node positive we recommend a stepwise approach. First, if metastasis is confirmed preoperatively by fine needle aspiration or core biopsy, we recommend ALND. Second, if metastasis cannot be confirmed by preoperative needle biopsy, we recommend SLN biopsy with intraoperative assessment and, if positive, ALND. Finally, when metastasis cannot be confirmed at the time of SLN biopsy, surgical judgment prevails, and it is reasonable to proceed to ALND on the basis of intraoperative suspicion alone, recognizing that the possibility of a false positive clinical and intraoperative lymph node examination must be balanced against the consequences of leaving gross axillary disease behind. For men who will receive neoadjuvant chemotherapy for locally advanced disease, we recommend axillary staging upfront by US guided fine needle aspiration, not SLN biopsy. Because about 40% of patients with positive axillary nodes will convert to node negative, we recommend SLN biopsy with intraoperative assessment after chemotherapy at the time of definitive surgery and ALND for those with positive SLN.

Perioperative Management

Wound closure is straightforward. Even for tumors that have required an extensive skin excision, primary wound closure is virtually always possible by elevating the skin flaps superiorly toward the clavicle and inferiorly onto the abdomen. We recommend closed suction drainage for mastectomy, and we instruct all patients in shoulder exercises to maintain or restore range of motion. There is no evidence to support any of the "standard" recommendations for the avoidance of lymphedema, and patients are encouraged to use their arms as normally as possible.

Postoperative Management

Postoperative consultations should include referral to genetic counseling (BRCA testing is appropriate for all patients with MBC and especially appropriate if there is a family history of breast or ovarian cancer), to medical oncology (the criteria for adjuvant hormonal therapy and chemotherapy in MBC are the same as with female breast cancer), and to radiation oncology (for patients with more locally advanced disease requiring PMRT). Plastic surgical consultation is also reasonable for the small minority of men who are bothered by loss of the nipple; nipple reconstruction by a local skin flap and tattooing gives excellent results in appropriate patients. It is vital to recognize that cosmetics are important to some male patients. NSQIP data shows 8% of men opted for immediate reconstruction and another 13.9% chose BCS even in the setting of the challenges with the procedure discussed previously.

Postoperative follow up for MBC, as for female breast cancer, should also include regular physical examination. Unlike female breast cancer, contralateral MBC is very rare and there are no data to support screening of the contralateral breast by mammography; however, patients may be unconvinced of this (in fact, NSQIP data shows 6.7% of men choosing contralateral prophylactic mastectomy) and mammography every 2 to 3 years is a reasonable compromise. As with female breast cancer, there are no data to support routine screening for distant metastases, but further workup is indicated for all new and persistent complaints suspicious for metastatic disease. ER positive breast cancers in women have a long natural history, with as many breast cancer events in years 5 to 10 as in years 0 to 5, and relapses beyond 10 years are not rare. The same is probably true for men, and because 90% of MBC are ER positive there is a strong rationale for lifelong surveillance of all MBC.

A Surgeon's Practical Guide to Breast Imaging

Ashley L. Hoppe, MD, Christine E. Taul, MD, and Rachel F. Brem, MD, FACR, FSBI

Breast imaging is a constantly evolving, technology-driven specialty that is often in the spotlight due to the impact of breast imaging on mortality reduction, cost, and direct patient care. Additionally, breast imaging is the only subspecialty in radiology that is regulated by the federal government. This results in breast imagers undergoing annual evaluation with regard to image quality and radiation dose, as well as requiring an annual practice audit that allows physicians to objectively evaluate their practice against established benchmarks. The interaction of the breast radiologist and breast surgeon plays an integral role in the optimal diagnosis and treatment of the breast cancer patient as well as the identification and surveillance of patients at elevated risk for breast cancer. This chapter is a guide for the surgeon to better understand the wide array of imaging modalities utilized by the radiologist and their indications; the terminology of the standardized lexicon and the techniques of percutaneous, image-guided procedures as well as known localization prior to surgery. A discussion of breast cancer screening will also be provided, as screening has become controversial and thus relevant to any provider caring for women.

Breast Cancer Screening

Current Recommendations and Controversy

Breast cancer is the second leading cause of cancer-related death in women and was the cause of death in an estimated 40,610 women in the United States in 2017. It is well established that breast cancer is a treatable disease when detected early, with a vast amount of data demonstrating up to 45% reduction in mortality over the last 30 years—a laudable accomplishment achieved by both improved screening and improved therapies. While there are many factors that can increase a woman's risk for breast cancer, approximately 75% of breast cancers occur in women who have no risk factor other than being a woman. Despite the indisputable evidence supporting screening mammography, there remains significant controversy stemming from the interpretation of the data, varying opinions on risk versus benefit, and the potential harms of mammography (false positives, patient anxiety, overdiagnosis, and radiation exposure).

There are numerous organizations that have released recommendations and guidelines for breast cancer screening, among them the American College of Radiology (ACR), Society of Breast Imaging (SBI), the American Cancer Society (ACS), and the United States Preventive Services Task Force (USPSTF), all of whom agreed until about 10 years ago that all women over the age of 40 should be routinely screened with annual mammography. Since then, the ACR, SBI and American College of Obstetrics and Gynecology (ACOG) have continued to support this screening schedule, maintaining that this is not only the most effective method to save the most lives, but also has the additional benefit of reducing aggressive surgery and chemotherapy treatments by decreasing the number of women diagnosed with advanced disease. It is important to note that the organizations

Perioperative Management

Wound closure is straightforward. Even for tumors that have required an extensive skin excision, primary wound closure is virtually always possible by elevating the skin flaps superiorly toward the clavicle and inferiorly onto the abdomen. We recommend closed suction drainage for mastectomy, and we instruct all patients in shoulder exercises to maintain or restore range of motion. There is no evidence to support any of the "standard" recommendations for the avoidance of lymphedema, and patients are encouraged to use their arms as normally as possible.

Postoperative Management

Postoperative consultations should include referral to genetic counseling (BRCA testing is appropriate for all patients with MBC and especially appropriate if there is a family history of breast or ovarian cancer), to medical oncology (the criteria for adjuvant hormonal therapy and chemotherapy in MBC are the same as with female breast cancer), and to radiation oncology (for patients with more locally advanced disease requiring PMRT). Plastic surgical consultation is also reasonable for the small minority of men who are bothered by loss of the nipple; nipple reconstruction by a local skin flap and tattooing gives excellent results in appropriate patients. It is vital to recognize that cosmetics are important to some male patients. NSQIP data shows 8% of men opted for immediate reconstruction and another 13.9% chose BCS even in the setting of the challenges with the procedure discussed previously.

Postoperative follow up for MBC, as for female breast cancer, should also include regular physical examination. Unlike female breast cancer, contralateral MBC is very rare and there are no data to support screening of the contralateral breast by mammography; however, patients may be unconvinced of this (in fact, NSQIP data shows 6.7% of men choosing contralateral prophylactic mastectomy) and mammography every 2 to 3 years is a reasonable compromise. As with female breast cancer, there are no data to support routine screening for distant metastases, but further workup is indicated for all new and persistent complaints suspicious for metastatic disease. ER positive breast cancers in women have a long natural history, with as many breast cancer events in years 5 to 10 as in years 0 to 5, and relapses beyond 10 years are not rare. The same is probably true for men, and because 90% of MBC are ER positive there is a strong rationale for lifelong surveillance of all MBC.

A Surgeon's Practical Guide to Breast Imaging

Ashley L. Hoppe, MD, Christine E. Teal, MD, and Rachel F. Brem, MD, FACR, FSBI

Breast imaging is a constantly evolving, technology-driven specialty that is often in the spotlight due to the impact of breast imaging on mortality reduction, cost, and direct patient care. Additionally, breast imaging is the only subspecialty in radiology that is regulated by the federal government. This results in breast imagers undergoing annual evaluation with regard to image quality and radiation dose, as well as requiring an annual practice audit that allows physicians to objectively evaluate their practice against established benchmarks. The interaction of the breast radiologist and breast surgeon plays an integral role in the optimal diagnosis and treatment of the breast cancer patient as well as the identification and surveillance of patients at elevated risk for breast cancer. This chapter is a guide for the surgeon to better understand the wide array of imaging modalities utilized by the radiologist and their indications; the terminology of the standardized lexicon and the techniques of percutaneous, image-guided procedures as well as known localization prior to surgery. A discussion of breast cancer screening will also be provided, as screening has become controversial and thus relevant to any provider caring for women.

BREAST CANCER SCREENING

Current Recommendations and Controversy

Breast cancer is the second leading cause of cancer-related death in women and was the cause of death in an estimated 40,610 women in the United States in 2017. It is well established that breast cancer is a treatable disease when detected early, with a vast amount of data demonstrating up to 45% reduction in mortality over the last 30 years—a laudable accomplishment achieved by both improved screening and improved therapies. While there are many factors that can increase a woman's risk for breast cancer, approximately 75% of breast cancers occur in women who have no risk factor other than being a woman. Despite the indisputable evidence supporting screening mammography, there remains significant controversy stemming from the interpretation of the data, varying opinions on risk versus benefit, and the potential harms of mammography (false positives, patient anxiety, overdiagnosis, and radiation exposure).

There are numerous organizations that have released recommendations and guidelines for breast cancer screening, among them the American College of Radiology (ACR), Society of Breast Imaging (SBI), the American Cancer Society (ACS), and the United States Preventive Services Task Force (USPSTF), all of whom agreed until about 10 years ago that all women over the age of 40 should be routinely screened with annual mammography. Since then, the ACR, SBI and American College of Obstetrics and Gynecology (ACOG) have continued to support this screening schedule, maintaining that this is not only the most effective method to save the most lives, but also has the additional benefit of reducing aggressive surgery and chemotherapy treatments by decreasing the number of women diagnosed with advanced disease. It is important to note that the organizations

that have differing recommendations from that of annual screening beginning at age 40 (maintained by the ACR, SBI and ACOG) all concur that annual screening beginning at age 40 will save the most lives, though have tempered their recommendations due to the harms of mammography. As of 2015, the ACS recommends that women of average risk be given the opportunity to begin annual screening at age 40 to 44 (qualified recommendation) and should undergo annual screening mammography starting at age 45 to age 54 (strong recommendation) and that women 55 and older be given the option for annual or biennial screening (both qualified recommendations). These updated and qualified recommendations are based on uncertainty regarding the benefits and risk and the patients' values and preferences. The USPSTF updated its guidelines in 2016, stating that women should undergo biennial screening from age 50 to 74, that screening prior to age 50 should be an individualized decision, and that there are no data to support screening in women over the age of 74, not because of data demonstrating lack of efficacy, but rather due to the lack of studies that included women over the age of 74. When considering the recommendations of organizations that recommend screening begin at age 50 it must be noted that over 23% of all breast cancers in the United States occur in women in their 40s, further emphasizing the need to begin annual screening at age 40. The USPSTF states that with their current recommendations, 81% of the achieved mortality reduction will be maintained. Of course, the corollary to this is by following the USPSTF recommendations there is an expected 19% increase in mortality from breast cancer.

The two most significant noted harms of mammography are the anxiety women experience from false positive mammograms and the radiation dose. With regard to anxiety, studies have definitively demonstrated that the anxiety that occurs as a result of a false positive outcome, whether it be a false positive mammogram necessitating additional imaging or a false positive finding resulting in a minimally invasive breast biopsy, is transient, with no long-lasting consequences. Furthermore, the radiation dose from a mammogram is stringently limited by law and is equivalent to four round trips across the United States via airplane, with no demonstrable case of cancer ever documented as a result of a mammogram. These issues should be considered when discussing screening mammography with women.

Technology and Data Reporting

Recent advances in technology have resulted in marked changes in mammography. The transition from analog to digital mammography resulted in increased detection of breast cancer in women under 50, premenopausal women, and in women with dense breast tissue. More recently, digital breast tomosynthesis, commonly referred to as three dimensional (3D) mammography, has been introduced, which uses a low dose x-ray system to create multiple planar images of each breast that are reconstructed into a set of 3D images, thus reducing the masking effect of overlapping fibroglandular tissue. Studies demonstrated that tomosynthesis modestly increased cancer detection over digital mammography, with a concomitant significant decrease in recall rate, thereby addressing one of the most cited harms of mammography, the false positive rate. However, studies evaluating tomosynthesis have not all been consistent, with some, largely from Europe, demonstrating no impact on cancer detection and variable impact on the false positive rate. Recently, a large multiinstitutional study from the United Kingdom has demonstrated a lower biopsy rate and a higher positive predictive value of biopsy in women undergoing tomosynthesis as compared to full field digital mammography. Initially, tomosynthesis was Food and Drug Administration (FDA) cleared for two dimensional (2D) plus 3D mammography, thereby having a higher radiation dose, albeit still within the federally allowable limit. More recently, the FDA has cleared tomosynthesis with a synthetic 2D image, a 2D like image obtained from reconstituted 3D data. This approach is increasingly being integrated into clinical practice, thereby harnessing the benefits of tomosynthesis while utilizing a lower dose of radiation. The studies evaluating the sensitivity of the reconstructed 2D image are limited, but the data supports equal accuracy of both types of 2D images, whether directly obtained or reconstructed from 3D data. From the patient's perspective, acquisition of tomosynthesis is no different than 2D digital mammography. Currently, virtually all insurance carriers cover tomosynthesis for both screening and diagnostic mammography.

All mammographic reports require a BIRADS (Breast Imaging Reporting and Data System) assessment, a lexicon that was created to provide a standardized terminology to assist in the communication of breast imaging findings. BIRADS assessments consist of numbered recommendations (I through 6, given for both screening and diagnostic imaging (Table 1). A screening mammogram consists of a standardized set of images performed similarly on all patients and should only receive one of three assessments: BIRADS category 1 (normal), category 2 (benign, with the mammogram demonstrating a pathologically benign finding such as a fibroadenoma, diffuse fibrocystic calcifications, or a stable mass), or category 0 (needs additional evaluation). BIRADS categories 3, 4, and 5 are used exclusively with diagnostic mammography, with BIRADS 3 used for findings with a less than 2% risk of malignancy where a short term follow up is recommended to assess interval growth. BIRADS 4 and 5 are similar in that both recommend a tissue diagnosis, with the difference being the likelihood of malignancy. BIRADS 4 is a broad category used for findings with a more than 2% but less than 95% likelihood of malignancy, while BIRADS 5 is reserved for lesions with a 95% or greater likelihood of malignancy, and for which a benign pathology diagnosis would be considered discordant and not accepted. BIRADS 6 is used in women with biopsy proven cancer. After treatment for breast cancer, and with no evidence of residual disease, the BIRADS assessment returns to categories 0 to 5.

TABLE 1: BIRADS Final Assessment Categories

	Category	Management	Likelihood of Cancer
0	Need additional imaging or prior examinations	Recall for additional imaging and/or await prior examinations	N/A
1	Negative	Routine screening	Essentially 0%
2	Benign	Routine screening	Essentially 0%
3	Probably benign	Short interval follow up	>0% but <2%
4	Suspicious	Tissue diagnosis	>2% but <95%
5	Highly suggestive of malignancy	Tissue diagnosis	>95%
6	Known biopsy proven malignancy	Surgical excision when clinically appropriate	N/A

BIRADS, Breast Imaging Reporting and Data System; N/A, not applicable.

Screening Versus Diagnostic Mammography

Screening mammography is for women with no signs or symptoms of breast cancer. The indications for diagnostic mammography include assessment of clinical findings (such as palpable abnormalities, focal pain, nipple discharge, or skin retraction or discoloration), the workup of a finding on a screening mammogram (callback), or for short-term interval follow-up of BIRADS 3 findings. Of note, the use of diagnostic mammography for women with a personal history of cancer is variable, and is at the discretion of the facility, the referring physician and patient preference without definitive recommendation. The Affordable Care Act (ACA) mandates coverage of screening mammography with no deductible or copay. In contrast, diagnostic mammography is subject to possible deductibles and copays dependent on the patient's individual insurance coverage. Women with implants, strong family history of breast cancer, and/or prior benign breast biopsies may have once opted for an annual diagnostic mammogram, where all imaging required was performed at the time the patient presented. In addition, with the significant change in financial considerations following the implementation of ACA and without direct standards, there has been a shift in women opting to undergo screening mammography, likely due to the financial considerations.

Other differences in screening and diagnostic mammography include the frequent use of batch reading for screening, which may be read the same day the examination is performed or days later. Women who undergo diagnostic evaluation will obtain the imaging necessary for triage and will not be recalled on another day, as the findings will be evaluated during the diagnostic examination. Additionally, women who present for a diagnostic mammogram who require ultrasound will obtain that study at the time of the diagnostic mammogram.

High-Risk Screening

There are numerous reasons a woman is at increased lifetime risk for breast cancer; a situation that results in the need for supplemental screening to optimize detection of early, curable breast cancer. Various risk assessment models have been developed to calculate a woman's lifetime risk for breast cancer, with factors such as age, ethnicity, genetics, history of chest irradiation, family history of breast or ovarian cancer, as well as personal history of breast cancer and atypia taken into account. It is noteworthy that these risk assessment models, of which the Gail and Tyrer-Cuzick are the most commonly employed, have substantial variability in risk determination due to the variability in factors utilized. Another significant risk factor that has gained attention more recently is breast density, a factor not traditionally included in the currently used risk models (although the most recent updated version of Tyrer Cuzick now includes density). Breast density is determined by a subjective assessment of the amount of fibroglandular tissue on the mammogram, with four BIRADS categories, A through D, ranging from least to most dense (Fig. 1). The only way to determine breast density is with a mammogram. Approximately 40% of American women have dense breast tissue, defined as heterogeneously or extremely dense, or BIRADS categories C and D. Both breast tissue and breast cancers are white on a mammogram. Therefore, dense breast tissue decreases the sensitivity of mammography from approximately 85% in all women to ≤50% in women with dense breast tissue. Furthermore, dense breast tissue is an independent risk factor for developing breast cancer, with the risk of breast cancer to women having extremely dense breasts (category D) being fourfold higher than those with fatty breasts (category A), and a nearly twofold increased risk of breast cancer when comparing dense (BIRADS density C and D) to nondense breast tissue (BIRADS density A and B). Therefore, having dense breast tissue both decreases the sensitivity of mammography as well as independently increases the risk of breast cancer.

With 40% of American women having dense breasts, women with dense breast tissue constitute the largest population of intermediate-risk women. Breast density has also become a political issue, with over 36 states and the District of Columbia enacting laws that require women be informed of their breast density. There is variability among the state-mandated information women must receive, with some requiring women to be informed of additional screening that can detect mammographically occult breast cancer. In two states and the District of Columbia, there is mandated insurance coverage of adjunct screening in women with dense breast tissue. Studies have demonstrated that while screening mammography detects 2 to 7 breast cancers in 1000 women screened, screening breast ultrasound in women with dense breast tissue can detect an additional 2 to 7 cancers per 1000 women screened. Of note, mammographically occult

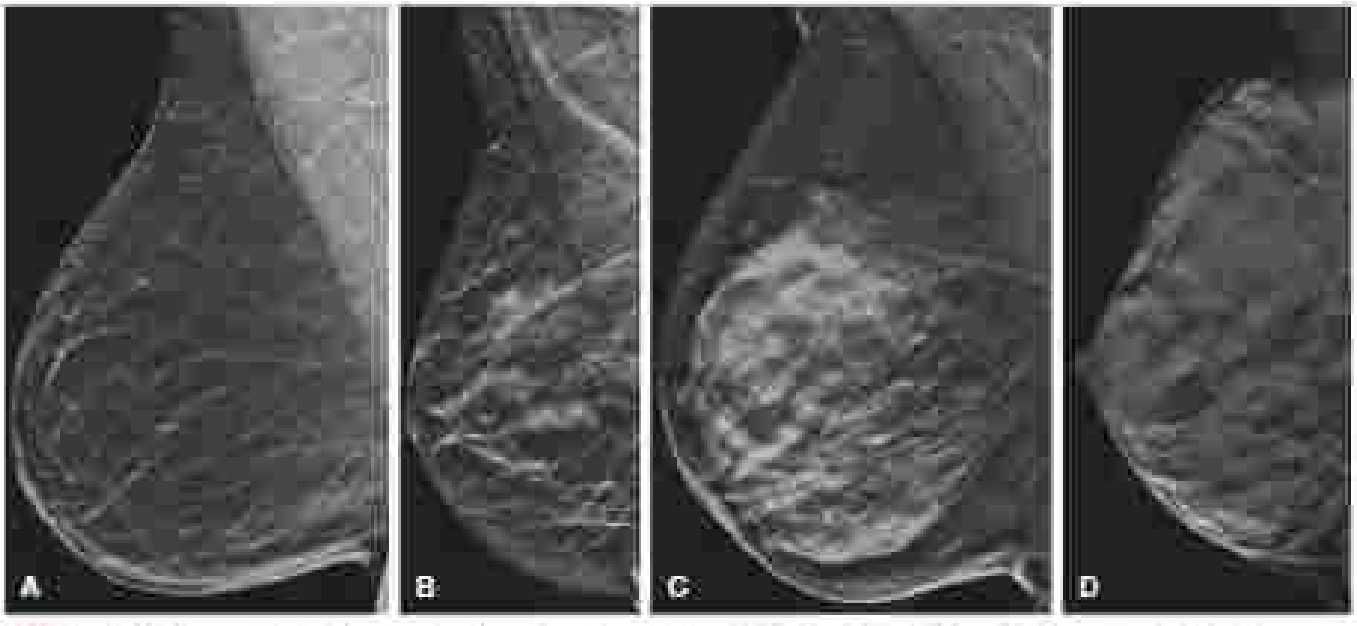

FIG. 1 Examples of the Breast Imaging Reporting and Data System density categories using a synthetic two-dimensional mammogram in the right mediolateral oblique projection. (A) Almost entirely fatty. (B) Scattered areas of fibroglandular density. (C) Heterogeneously dense. (D) Extremely dense.

cancers detected with screening breast ultrasound are frequently small, invasive, node-negative cancers. When widespread screening breast ultrasound began, there was concern that the rate of additional cancer detection would not be sustained. However, this has not been the case. Studies have continued to demonstrate that screening ultrasound detects an additional 2 to 4 cancers per 1000 women screened in subsequent years, nearly doubling the rate of cancer detection. Studies have also evaluated magnetic resonance imaging (MRI) and molecular breast imaging (MBI) as adjunct screening modalities in women with dense breast tissue. These technologies detect more cancers than screening breast ultrasound; however, they are much higher cost and require an injection and therefore are currently not in widespread use in screening women with dense breast tissue.

Currently, there is no consensus on how to screen women at intermediate risk for breast cancer, which includes women with dense breast tissue, a history of atypia, a personal history of breast cancer, and some women with a family history of breast cancer. While breast ultrasound is the most commonly used supplemental screening, While initial studies demonstrated the added benefit of screening-based ultrasound using a hand-held technique by a radiologist, this method has limitations of scanning time and operator dependence. More recently, the development of screening 3D automated whole breast ultrasound (ABUS) has been shown to be a promising technique to circumvent the limitations of hand-held ultrasound. ABUS allows for uncoupling of image acquisition from interpretation, with the breast imaged using a specialized, long field of view ultrasound probe in a standardized, reproducible method, which can later be reviewed in entirety by the interpreting radiologist. Although this is a relatively new technology, it is a promising solution to the increasing need for additional screening. One of the most significant limitations of screening breast ultrasound is the false-positive rate. Recent developments in enhanced sonographic tissue characterization utilizing technology such as sound speed and transmission ultrasound, in addition to reflective imaging, will likely allow for a substantial decrease in the false positive rate, possibly with an increase in sensitivity. Additionally, artificial intelligence is being developed to improve both the sensitivity and specificity of lesions detected with breast ultrasound.

MRI has a very high sensitivity for breast cancer, over 95% for invasive breast cancer and slightly lower for the detection of ductal carcinoma in situ. MRI is used for numerous clinical indications including as a problem-solving tool in women with palpable findings with no mammographic or sonographic correlate, evaluation of extent of disease, and additional foci in women with newly diagnosed breast cancer, evaluation of response to neoadjuvant chemotherapy, evaluation of silicone implant integrity, and the most frequent indication, surveillance of high-risk women (Fig. 2A). The American Cancer Society recommends that women with a lifetime risk of breast cancer of 20% or greater undergo annual supplemental surveillance for breast cancer with MRI. This includes women with genetic mutations that are associated with a predisposition for breast cancer such as BRCA 1 and 2, untested first-degree relatives of women with known genetic mutations, women with a history of mantle radiation for Hodgkin's during adolescence, as well as women with syndromes such as Li-Fraumeni, Cowden, and Carney, which increase the risk for breast cancer. With recent advances in the understanding of genetic mutations, the number of mutations that are associated with increased predilection for breast cancer is increasing and the number of mutations of unknown significance is decreasing. Recent studies have demonstrated that women who are found to have atypical ductal hyperplasia (ADH) under the age of 50, and who have multiple foci of ADH have a greater than 20% lifetime risk of developing breast cancer and should undergo annual surveillance with MRI. It has also been shown that women with a personal history of breast cancer have substantially more cancers detected with annual MRI. Although these indications are not routinely recommended, it is likely that the population of women for whom MRI surveillance is recommended will likely be expanded.

With the increased use of screening MRI, abbreviated MRI, which utilizes fewer sequences resulting in a shorter, more cost effective,

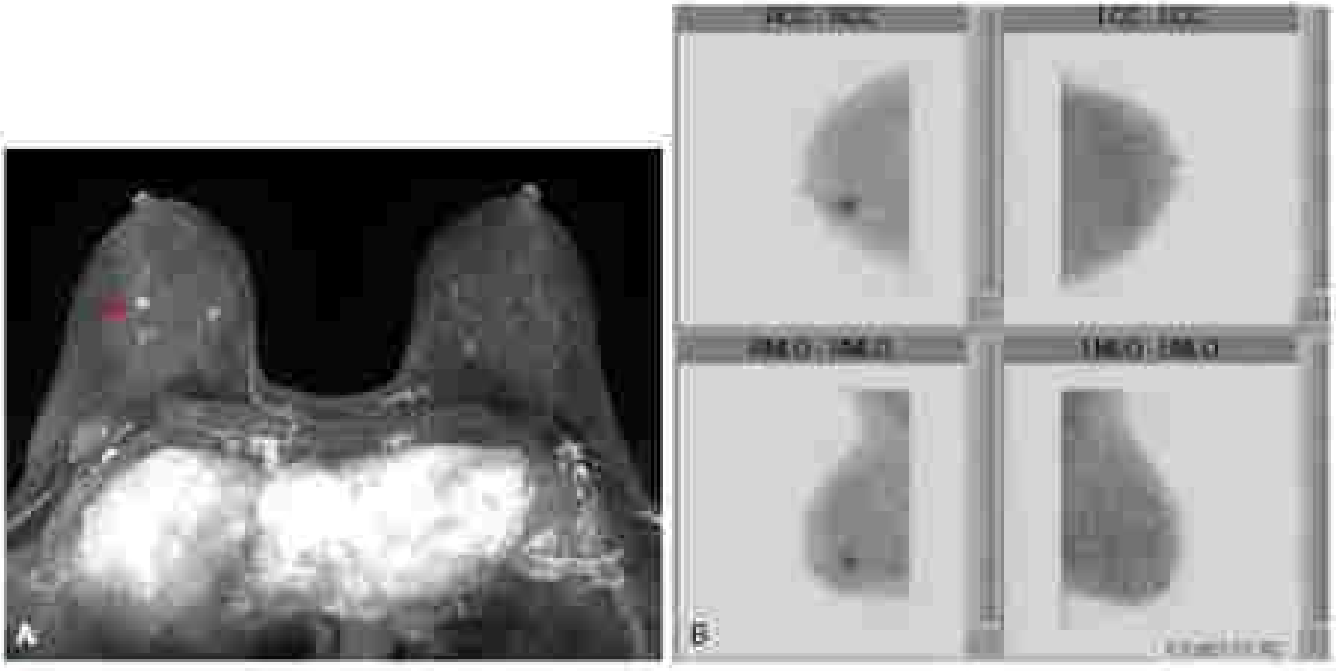

FIG. 2—(A) A maximum intensity projection image of a screening breast magnetic resonance imaging performed on a 48-year-old woman with *BRCA*-gene mutation demonstrating an 8-mm irregular enhancing mass in the right breast (arrow) at 1 o'clock. This was later biopsy-proven to be a grade 2 invasive ductal carcinoma, and node negative following definitive surgical management. (B) Standard screening molecular breast imaging images in a 41-year-old high-risk female demonstrating focal radiotracer uptake in the lower right breast, with subsequent ultrasound-guided biopsy demonstrating a grade 1 invasive ductal carcinoma.

better ultrasound examination has been shown in single institutional studies, to be equally effective in screening high risk women. There is an ongoing large, multiinstitutional trial evaluating abbreviated MRI protocols. Increasingly, abbreviated MRI protocols are being utilized to screen high risk women with MRI, however, the definitive ability of abbreviated MRI to equally detect breast cancer awaits the results of the trial.

MBI, also called breast specific gamma imaging (BSGI) is a physiologic imaging modality that uses 99m Tc sestamibi. Sestamibi uptake is increased in vascular and hypermetabolic tissue. The sensitivity of MBI has been shown to be comparable to MRI with slightly greater specificity. For women in whom MRI is contraindicated (i.e., women with renal insufficiency, implanted devices, claustrophobia and body habitus that precludes MRI imaging), having MBI has been extremely helpful and may be the only physiologic imaging modality available to them. The sensitivity of MBI in detecting cancer and high risk lesions in women at increased risk for breast cancer is comparable to MRI. MBI also has equal sensitivity in women with dense and non-dense breasts. In challenging clinical situations such as implants, and silicone injections, MBI can be extremely helpful in detecting otherwise occult cancers. In addition, MBI has detected additional foci of occult cancer in 7% to 10% of women with newly diagnosed cancer. Of course, radiation is always a concern. Initially, the dose used in MBI studies was 20 to 30 mCi. More recently studies have shown no difference in the ability to detect and diagnose cancer using 5 to 8 mCi, resulting in a radiation dose comparable to two mammograms, albeit the radiation is full body and not limited to the breast. Several studies have evaluated MBI for screening women with dense breasts and have reported detecting more cancers than that detected with ultrasound screening (Fig. 28). Nevertheless, the issue of injection and radiation remains, and MBI is generally used as a problem-solving tool and in women with newly diagnosed breast cancer.

MRI is commonly used for the workup of clinically suspicious abnormalities in the face of negative mammography and ultrasound, such as palpable findings, and pathologic nipple discharge (Fig. 3). The use of galactography, or ductography is decreasing. In women with new onset pathologic nipple discharge, a negative mammogram and ultrasound is generally followed by evaluation with MRI, which provides higher sensitivity than ductography and uses a noninvasive approach. Furthermore, evaluation with MRI does not require the ability to extract the nipple discharge. When initially introduced, MRI was predominantly used as problem solving tool. However, with time, the indications for MRI have shifted and the current most common indication is surveillance in high risk women.

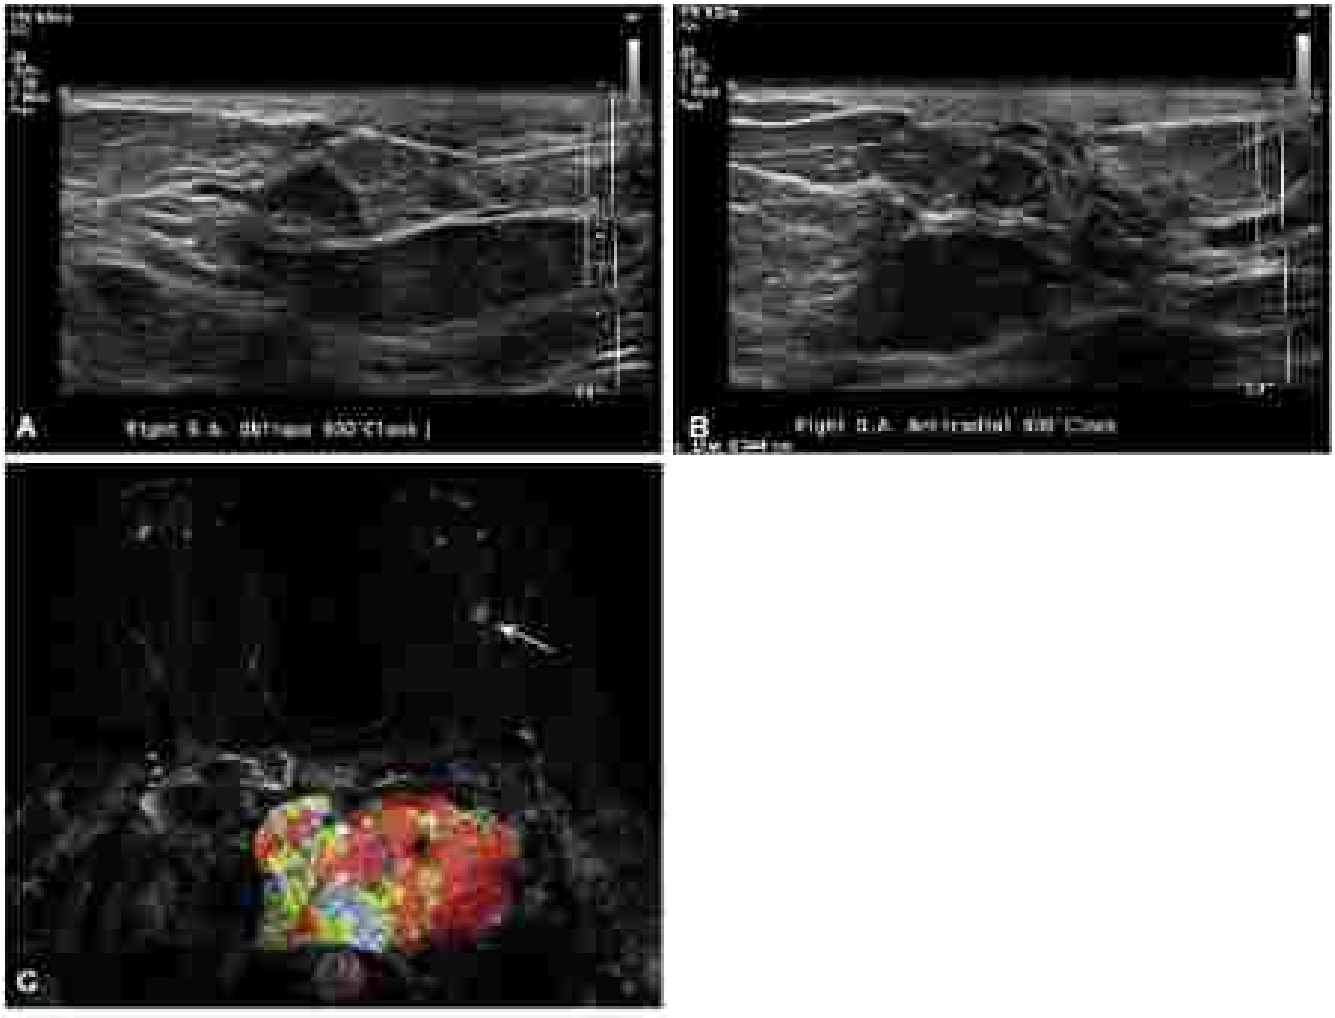

FIG. 3 Oblique (A) and sagittal (B) sonographic images of a solitary intraductal mass in a 55-year-old woman who presented with unilateral, bloody, spontaneous nipple discharge, later biopsy-proven to be an intraductal papilloma. (C) Contrast-enhanced magnetic resonance image with color kinetic overlay performed on a 51-year-old woman with spontaneous and clear nipple discharge in the left breast, which demonstrates a subcentimeter heterogeneously enhancing mass in the central left breast, also later biopsy proven to be a papilloma.

The use of MRI in women with newly diagnosed breast cancer varies greatly and is controversial. Studies have demonstrated that MRI detects additional foci of breast cancer in approximately 18% of women with newly diagnosed breast cancer, 7% in the ipsilateral breast, and 3% in the contralateral breast. In our institution, all women with newly diagnosed breast cancer obtain physiologic imaging with either MRI or MRI prior to definitive surgery. In other institutions, MRI in women with newly diagnosed breast cancer is reserved for women with dense breast tissue where the sensitivity of mammography is decreased, in women with invasive lobular carcinoma, which can be more difficult to detect with mammography and ultrasound or in other clinical situations. Recent studies have demonstrated that the preoperative use of MRI in women with newly diagnosed breast cancer not only results in higher rates of negative margins but increases survival. The concerns regarding the routine use of MRI in women with newly diagnosed breast cancer include the decision to change conservative therapy to a mastectomy as a result of the MRI finding, and the cost of detection of *false positives* that require biopsy prior to determination of definitive *optimal* surgical approach. Currently, there are no definitive recommendations regarding MRI in women with newly diagnosed breast cancer.

IMAGE-GUIDED PROCEDURES

Breast Biopsy

There are over 3 million breast biopsies performed in the United States annually. The vast majority, if not all, are optimally approached with minimally invasive tissue acquisition. Minimally invasive breast biopsy is more cost effective, less invasive, and better tolerated by the patient than open surgical biopsy. The vast majority of breast biopsies (i.e., 70% or more) result in benign findings, thereby further emphasizing the need for minimally invasive breast biopsy. Additionally, studies have shown that women who undergo minimally invasive breast biopsy that demonstrate malignancy have higher rates of negative margins at lumpectomy, thereby improving the patient experience and decreasing the cost of care.

Image-guided minimally invasive breast biopsy can be performed by ultrasound, mammogram (stereotactic), MRI, and gamma guidance. In our practice, following all minimally invasive breast biopsies, with the consent of the patient, a marker is placed at the site of biopsy. There are an increasing number and types of biopsy markers available, varying in shape, size, and material. Markers are most frequently made of titanium or a stainless steel alloy, although newer markers made of carbon are available. There are numerous purposes for the routine placement of the marker, including confirmation of ultrasound biopsy with a targeted mammographic finding, marking a site of benign biopsy so that repeat biopsy is not recommended at a later time, and marking a site of malignancy or atypia for identification for localization prior to surgical excision. This is especially important if the imaging evidence of the targeted lesion is removed or altered by the biopsy itself, or the patient undergoes neoadjuvant chemotherapy, which can render the cancer invisible by imaging. In our practice, we utilize different shaped markers in women with multiple biopsies to definitively identify a specific biopsy site. Other considerations include the signal void of the marker on MRI, with some markers being difficult to identify on MRI and others resulting in a large signal void that can obscure substantial areas of the breast. The selection of the type and shape of biopsy marker is important and should be carefully considered.

The patient experience and the time and difficulty of a biopsy can vary by the guidance method used. Minimally invasive breast biopsy utilizing ultrasound guidance is generally quick, allows for real-time imaging of the biopsy device, and is generally performed with the patient supine, generally the most comfortable position for the patient. It is for these reasons that ultrasound guidance is the modality of choice for any lesion visualized with ultrasound. If a lesion is seen with mammography and is not sonographically visible, which is frequently the case with microcalcifications, stereotactic biopsy is used. Stereotactic biopsy can be performed with the patient prone or upright, depending on the equipment available. More recently, the introduction of minimally invasive biopsy with tomosynthesis guidance allows for the targeting and accurate biopsy of lesions seen only with tomosynthesis and not visible on 2D mammography. This situation is becoming increasingly frequent with the growing use of tomosynthesis and detection of subtle areas of architectural distortion not previously appreciated with 2D mammography. MRI guided biopsies are reserved for findings seen only by MRI, as MRI guided biopsies are more time consuming, involve an additional injection of intravenous gadolinium, and are less comfortable for the patient. Of note, MRI biopsy can be performed bilaterally with availability of appropriate biopsy coils. With the increasing availability of MRI, gamma guided biopsy can be performed and is similar to MRI biopsy, although the patient is comfortably seated during the procedure. If a lesion is initially visualized with mammography, correlation with ultrasound must be attempted to confirm that the same lesion is being visualized in both imaging modalities. Furthermore, it is imperative that correlation with the postprocedure mammogram be performed to ensure accurate lesion targeting. No minimally invasive biopsy is complete without radiologic-pathologic concordance. If the pathology obtained for a lesion is discordant, then re-biopsy is required. Both surgical and minimally invasive breast biopsy obtain accurate pathology in 98% of biopsies. It is for this reason that, aside from well-circumscribed masses found to be fibroadenomas and cysts with complete resolution, we choose to obtain a 6-month follow-up of all lesions biopsied to evaluate for interval change and to identify the 2% of missed lesions. The imaging modality used to target the lesion should be utilized to evaluate the lesion at the 6-month interval to confirm its stability.

Localization

Preoperative needle localization is an integral component of breast imaging and is a collaborative procedure between the breast imager and breast surgeon. Localization is typically performed by the radiologist prior to lumpectomy for malignancy, or prior to excisional biopsy for high-risk lesions such as atypia, complex sclerosing lesions, tubular carcinoma in situ and papilloma, among others. The traditional method of localizing nonpalpable breast lesions has been by image-guided wire placement immediately prior to surgery. This has many disadvantages, including wire displacement, suboptimal positioning of the wire entry point related to the planned surgical incision, and the risk of a vasovagal reaction during the procedure with the patient not eating or drinking for extended periods prior to the localization. Furthermore, preoperative wire localization must be performed the same day of the surgery and therefore presents workflow and scheduling challenges in terms of timing of the localization and the surgery. The need to transport the patient from radiology to surgery with the wire protruding from the breast is challenging, particularly as there may not be adjacency of the radiology department and the operating room. As a result of these limitations, new techniques have been developed and are rapidly replacing wire localizations. Currently, the most widely used alternative to radioactive seed localization (RSL), which involves placing a small metallic radioactive (I^{125}) seed into the lesion, either by mammographic or sonographic guidance. The surgeon can then accurately localize the lesion in the operating room by way of a hand-held gamma probe. Not only does this provide major logistical advantages for the surgeon, but it is also more convenient for the patient as this can be done up to 7 days prior to surgery. Although RSL has significant advantages over wire localization, the use radioactive materials results in Nuclear Regulatory Council stringent oversight and extensive regulations that can make implementation difficult. Several nonradioactive devices have recently been introduced with advantages similar to RSL, though without the stringent regulatory issues. These include Localite, which uses a radiofrequency localizer; Magseed, which is a paramagnetic steel and iron oxide seed; and SentiMag, which uses a radar

localization system. These devices are placed similar to the approach used with radioactive seed and then detected in the operating room by specialized probes. Until recently, the ability to detect deeply situated localization devices has been challenging. Additionally, the FDA has recently cleared the Localite for long-term placement, for up to a year, as long as there is the intent to remove it surgically. Another consideration of the surgeon during the selection of a nonradioactive, nonwire localizing device is the size of the probe used during intraoperative detection, as this can vary widely. In certain clinical situations it is also possible for the surgeon to localize the biopsy site with intraoperative ultrasound during surgery.

Multidisciplinary Care

Optimal care of the breast cancer patient requires a multidisciplinary approach throughout the care cycle. From the time of abnormal mammogram or clinical finding, the interaction of the entire breast "team" can include, though is not limited to, the breast surgeon, imager, pathologist, oncologist, plastic surgeon, genetic counselor, social worker, physical medicine, psychologist, complementary medicine, survivorship practitioners, navigators, nurses, and others, resulting in overall improved care. From the time of an abnormal mammogram to the subsequent additional appointments, the value of navigation has been well established. The navigator has become an integral component of the breast imaging center resulting in coordinated and efficient care, helping patients understand their pathology, and partnering with them for appointments, support, and guidance. In our practice, every patient who has a diagnosis requiring surgery, whether it be a high-risk lesion requiring excision or a patient with a diagnosis of breast cancer, is partnered with a navigator. This results in improved patient experience, and a more efficient and compassionate approach to the care of women with breast disease. The ability to later review what was discussed during the initial appointment when told of a breast cancer diagnosis is invaluable to the patient.

The interaction of the breast imager and breast surgeon can impact the surgical approach with imaging rendering insight into the possibility of nipple sparing during mastectomy, the opportunity for conservative therapy dependent on extent of disease and additional foci of disease identified, as well as a collaborative decision regarding optimal screening protocols for high-risk women. The interaction of the medical oncologist and the imager during neoadjuvant chemotherapy can impact the choice of regimens, further emphasizing the critical importance of the multidisciplinary team. Furthermore, with the average age at breast cancer diagnosis decreasing, we are seeing younger women with fertility concerns and women diagnosed during pregnancy, underscoring the need for multidisciplinary care. Finally, as we continue to gain knowledge regarding the vast amount of genetic factors associated with both increased risk of and care of the women with breast cancer, the multidisciplinary approach, which includes an ever expanding cadre of specialties, is critical.

CONCLUSION

Breast imaging is a rapidly evolving field that is intimately associated with breast surgery, and the best outcomes for the patient result from the combined, multidisciplinary efforts of the breast care team. Optimization of patient care can be achieved when each subspecialist has an appreciation and basic knowledge of each other's fields and maintains an open line of communication.

Genetic Counseling and Testing

Michele A. Gadd, MD, and Kevin Hughes, MD

Genetic testing for hereditary cancer syndromes has evolved significantly since the identification of the *BRCA1* and *2* genes in 1994 and 1995, and the mapping of the human genome in 2003. Technologic advances in genetic science and the Supreme Court ruling in 2013, preventing genes from being patented, paved the way for direct to consumer genetic testing. For several hereditary cancer syndromes, genetic testing provides an opportunity to identify high-risk individuals and take action before they develop cancer. In an increasing number of cases, however, the discovery of a less well-characterized genetic mutation is not as informative and the future of the individual's health less certain. Thus the issue of who to test and how best to counsel patients regarding their cancer risks is an increasing challenge to healthcare delivery.

MECHANISM OF CANCER DEVELOPMENT

More than 100 genes have been identified with activating or inactivating mutations that can increase the risk of cancer, and many more will be found in the near future. The majority of these genes are tumor suppressor genes, in which the protein produced by the gene actively works to prevent the development of cancer. Tumor suppressor genes tend to be organ specific, each preventing cancer in a subset of organs (or leading to cancer in that subset when inactivated through mutation), thus establishing a spectrum of susceptible organs for each syndrome. The responsible gene (or genes) has been identified for the major hereditary cancer syndromes (Table 1). These genes tend to be predominantly inherited. This means a single mutation in one of the two paired genes causes cancer susceptibility but tend to behave recessively at the cellular level. Therefore not every cell of the specific organ will become cancerous. As humans, we have two sets of genes, one inherited from each parent (Fig. 1). When a germline tumor suppressor gene has an inactivating mutation, the other copy of the gene continues to function normally. It is only when the second gene is damaged by a somatic event and loses function that the cell begins to accumulate other mutations, eventually leading to cancer. This is known as the Knudson two-hit hypothesis and helps to explain why most patients with a mutation develop cancer sometimes in a single organ but often in multiple organs.

A small number of genes, such as the *RET* gene, which causes multiple endocrine neoplasia type 2 (MEN2), are exceptions. Oncogenes are the mutant form of proto-oncogenes, the genes that regulate cellular proliferation and apoptosis. In cancers involving oncogenes, a single germline mutant gene can drive cancer development without a second hit causing the cancer to often develop at a very young age. This helps explain the need for thyroidectomy in children younger than 5 years in some cases of MEN2.

IDENTIFICATION OF THOSE AT RISK

To identify patients with a hereditary predisposition to cancer, it is critical to take a thorough family history. A pattern of multiple cancers associated with a specific syndrome, occurring in a single bloodline, is the key to identifying families who are more likely to harbor a germline mutation associated with a specific syndrome. The second hallmark of hereditary cancer is young age at diagnosis. Cancers diagnosed in young adults are more likely to be hereditary because the first mutation is already present at birth. Multiple cancers in a single individual is a third indicator, and an unusual cancer, such as male breast cancer or medullary thyroid cancer, is the fourth indicator of hereditary cancer. In addition, the threshold required for testing drops significantly in groups with an established high probability of mutation, such as Ashkenazi Jewish individuals, who may be eligible for testing even without one of these indicators. If any of these indicators are observed in the family history, genetic testing should be considered. Guidelines, such as those established by the National Comprehensive Cancer Center (NCCN) or the United States Preventive Services Task Force, provide examples of notable patterns, whereas risk models (e.g., BRCAPRO, Tyrer Cuzick) can be helpful for quantifying risk and setting thresholds for testable families.

Identifying individuals who are at risk for hereditary cancer is critical and can occur at multiple stages in the patient's care. Within your practice, you will find potential mutation carriers among (1) patients who do not have cancer, (2) patients with newly diagnosed cancer, and (3) patients being followed for past cancers. It is critical to have a system in place to identify high-risk individuals in each of these categories.

Patients Who Do Not Have Cancer

Ideally, mutation carriers should be identified before the development of cancer. It is good medical practice to take a family history for each patient. A strong family history should indicate the need to consider genetic testing. If testing is positive, the patient can be placed on a management strategy that either prevents cancer or aids in earlier diagnosis. In the past, it was recommended that a living affected relative be tested first, to identify the family specific mutation. If testing of a relative can be accomplished expeditiously, this remains the ideal approach because it provides the entire family with clinically actionable information. However, because testing has become more accessible and the cost decreased, it is becoming more common to test patients, whether or not they have cancer, as long as the family history supports an increased risk.

Patients With Newly Diagnosed Cancer

Among patients with a newly diagnosed cancer, more immediate identification of the mutation status may be critical because this information may have implications for treatment.

Patients Being Monitored for a Past Cancer

Follow-up cancer patients may not have had testing at diagnosis. Even some of those tested in the past may have undergone less comprehensive testing than is available today. Updating family history and readdressing additional testing should be part of continued cancer care. For those who tested negative on past screening, even within the last few years, updating their testing with new gene panels may be recommended.

Relatives of Mutation Carriers

When a patient with a hereditary syndrome is identified, it is extremely important to make the patient aware of the need to inform other family members. Close to half of the patient's close relatives, and a high proportion of more distant relatives, may have the mutation and be unaware of the risk. Although informing other family members can be difficult for patients dealing with a new diagnosis, the implications for their relatives can be great.

GENETIC TESTING PANELS

Once a patient has been identified as appropriate for genetic testing, the next decision is which test to order. Labs can now test multiple

cancer gene smaller panels (analogous panel testing). These panels may be organ directed, representing multiple genes that are related to a single organ system, or they may be pan-cancer panels, sometimes covering several or even all known cancer genes. The advantage of these panels is that it is no longer necessary to limit the test to a small subset of genes, and it is far less likely that the responsible gene will be missed. The disadvantage is that many panels include less well-studied genes with fewer evidence-based guidelines regarding preventive and early detection to share with patients. Keeping these limitations in mind, it is now more common to move directly to panel testing unless a known gene mutation has previously been identified to exist in a family. In the latter case, single site mutation testing remains a reasonable option. Surgeons should be involved in this process, ideally referring the patient to a genetics expert for testing. For surgeons who choose to do their own genetic testing, it is important to provide pre-test and post-test counseling, in keeping with the recommendations of the American Society of Clinical Oncology (ASCO). This entails carefully reviewing the ASCO elements of informed consent with patients before testing and counseling patients regarding the implications of their results after testing is completed.

INTERPRETATION OF RESULTS

Mutations or variants in cancer susceptibility genes can be classified into one of five categories: benign, likely benign, variant of uncertain significance (VUS), likely pathogenic, and pathogenic. Benign or likely benign variants basically should be ignored and generally are not reported. Pathogenic mutations, which include deleterious mutations, should be treated appropriately, whereas mutations that are likely pathogenic (suspected deleterious) should be managed based on the family history and the clinical situation, although a low threshold for action may be appropriate (Fig. 2). Mutations that occur in the population and are not associated with cancer are categorized as polymorphisms; some have been reported in the past and others may not. These mutations do not alter management. The results that are most frustrating for patients and clinicians are the VUS. A VUS means that although there is indeed a change in the DNA sequence of the gene, the change may or may not be cancer causing. These variants are seen more commonly in newer, less well-studied genes, such as *PALB2*, but can still be found, although less commonly, in extensively tested genes, such as *BRCA1* or *BRCA2*. Patients with a VUS should be managed based on the family history and the clinical situation, as if the VUS had not been found. Over time, most VUS mutations will be reclassified, at which time the lab involved usually will notify you and you, in turn, should inform the patient. A recent 20-year retrospective study of 1483 VUS demonstrated that the chance of "upgrade" (reclassification to suspected or deleterious) was less than 3% (Slavin et al.).

The number and variety of genes that cause cancer, together with our rapidly accumulating knowledge of cancer genetics, has made it virtually impossible for anyone to know what every gene mutation in every gene means in terms of cancer risk or how it should be managed. One must consider the penetrance and clinical spectrum of that specific gene mutation and then determine the management options that apply to the individual patient. The laboratory generally provides suggested management guidelines but one may still need to go to the literature to learn more. The NCCN and many specialty societies have produced excellent guidelines for many of the major cancer syndromes. Counseling patients about management often requires a multidisciplinary approach. It is important to identify a set of consultants in your area to whom you can refer the patient. For *BRCA* mutations, experts in gynecologic oncology, medical oncology, and breast surgery are helpful, whereas for Lynch syndrome, experts in gynecologic oncology, medical oncology, gastroenterology, and colorectal surgery are helpful.

There is a website, Adv2MetOnc, available to assist with calculating the risk of cancers associated with a deleterious mutation. The tool was developed by the Jiayu Mendel Lab at Dana-Farber Cancer Institute and the Hughes Lab at Massachusetts General Hospital. Reliable studies for each gene are used to convert results into clinically

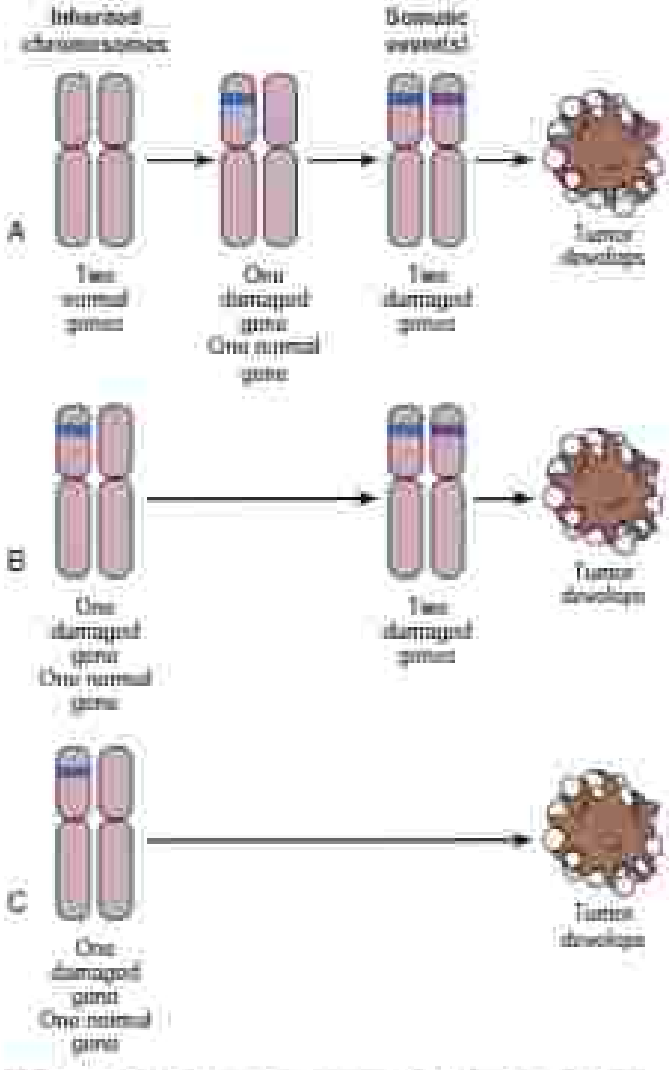

FIG. 1 (A) In sporadic cancers, two mutations in the same gene need to occur before developing cancer. These events generally take decades to occur. (B) In the major hereditary cancer syndromes the responsible gene (often a tumor suppressor gene) is inherited and already damaged. When the second gene is damaged, the loss of function leads to cancer. This can still be generally occurs at an earlier age. (C) When the inherited mutated gene is an oncogene, cancer develops without a second mutation. In this case, cancer may develop in childhood.

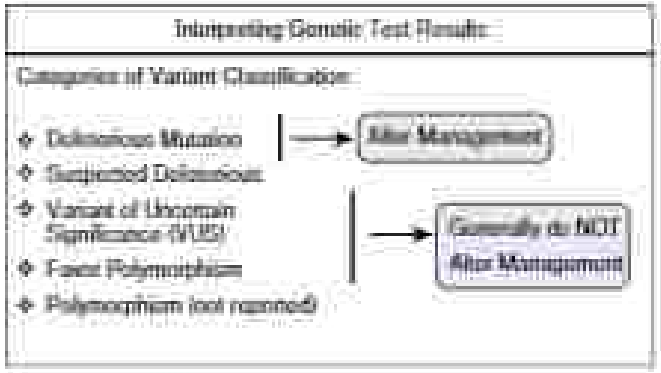

FIG. 2 Interpreting genetic test results.

relevant absolute risk estimates. The database is updated often and is considered a work in progress.

CANCER SYNDROMES

Breast and Ovarian

The majority of patients with hereditary breast and ovarian cancers have mutations in either the breast cancer type 1 or 2 susceptibility genes (*BRCA1* and *BRCA2*). Mutations in these genes are associated with approximately 10% of women with familial breast cancer and women with ovarian cancers. *BRCA* mutations are also associated with an increased incidence of prostate, male breast and pancreas cancers. Components of the patient's history that should lead one to consider genetic testing are listed in Box 1. Guidelines for screening and prevention for *BRCA1* and *BRCA2* carriers are listed in Box 2. Mutations in other genes such as *TP53*, *PTEN*, *CHEK2*, and *PALB2* occur less often and are associated with varying penetrance and risk (Table 2).

BOX 1 Risk Factors for Hereditary Breast and Ovarian Cancer

Breast cancer before age 50 years
Multiple primary breast/ovarian cancers
Triple negative breast cancer
Male breast cancer at any age
Ovarian cancer at any age
Ashkenazi Jewish ancestry
Early onset pancreas or (metastatic) prostate cancer
Relatives of a *BRCA* mutation carrier

BOX 2 Guidelines for Screening and Prevention for *BRCA1/2* Carriers

Risk training and education and regular monthly BSE starting at age 18 years
Semiannual clinical breast exam starting at age 25 years
Annual breast MRI screening starting at age 25 and mammogram age 30 years
Discuss option of prophylactic mastectomy
Recommend ovary/fallopian tube removal from age 35 for *BRCA1* and age 40–45 years for *BRCA2*
For those who have not elected ovary/fallopian tube removal: consider vaginal US and Ca 125 every 6 months starting at age 25 or 5–10 years earlier than earliest age of first diagnosis of ovarian cancer
Consider chemoprevention options for breast and ovarian cancer
Consider investigational imaging and screening studies

BSE, breast self exam; MRI, Magnetic resonance imaging; US, ultrasound.

Colorectal

It is estimated that 20% to 30% of colorectal cancers are familial and that there is a 5% to 10% chance of relating the cancer to a known genetic syndrome. Greater than 20 genes have been identified and linked to hereditary colon cancer risk (Table 3). Identifying individuals with a mutation associated with early colorectal cancer is critical for prevention and early detection. Most panel tests today include genes associated with increased colorectal cancer risk. Comprehensive cancer panel testing should be considered when there are overlapping syndromes being considered. The best understood are the high penetrance genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*, EPCAM) responsible for Lynch syndrome and the high penetrance gene (*APC*, *MUTYH*) responsible for Familial Adenomatous Polyposis/MUTYH associated polyposis. Patients with hereditary colorectal syndromes are at risk of earlier cancer development, metachronous

TABLE 4 National Comprehensive Cancer Network Surveillance Recommendations for Hereditary Colorectal Cancer Syndromes

Syndrome	Site	Age to Begin Surveillance (y)	Surveillance Interval (y)	Procedures
HNPCC	Colon	20–25 or 2–5 y before earliest colorectal cancer diagnosis	1–2	Colonoscopy
	Endometrial and ovarian	No evidence to support	1	Consider annual endometrial sampling Consider prophylactic TAH/BSO after childbearing No evidence to support ovarian screening
	Urinary tract	30–35	1	Consider annual urinalysis
	Small bowel and gastric	30–35 No evidence to support	3–5	Consider EGD with ascendent duodenoscopy in at-risk individuals
Familial adenomatous polyposis	Colon Upper GI	10–15 20–25 Earlier if colectomy at <20	1 1–3	Flexible sigmoidoscopy or colonoscopy EGD with complete visualization of the papilla Surveillance by Spigelman staging Consider CT or MRI for small bowel if duodenal polyposis advanced
	Thyroid	Late teenage years	1	Annual thyroid exam, consider annual ultrasound
	Intra-abdominal desmoids	No evidence to support	1	Annual abdominal exam Consider CT or MRI 1–2 y after colonoscopy then every 5–10 y or symptom based
Attenuated familial adenomatous polyposis	Colon Upper GI Thyroid	Late teenage years 20–25 Earlier if colectomy at <20	2–3 1–3 1	Colonoscopy EGD with complete visualization of papilla Annual thyroid examination and thyroid ultrasound
MUTYH-associated polyposis	Colon Upper GI	25–30 30–35	2–3 1–3	Colonoscopy EGD with complete visualization of the papilla
Serrated polyposis syndrome	Colon	40 10 y before earliest CRC diagnosis	1–3	Colonoscopy

CT, Computed tomography; EGD, esophagogastroduodenoscopy; HNPCC, hereditary nonpolyposis colorectal cancer; MRI, magnetic resonance imaging; TAH/BSO, total abdominal hysterectomy with bilateral salpingo-oophorectomy.

cancers, and extracolonic manifestations. Guidelines for surveillance are listed in Table 4.

Pancreatic

Approximately 10% to 20% of cases of pancreatic cancer are associated with inherited predisposition (two first-degree relatives affected). Pancreatic cancer is a component of hereditary breast ovarian syndrome, Lynch syndrome, familial adenomatous polyposis, familial atypical multiple mole melanoma syndrome, Peutz-Jeghers syndrome, hereditary pancreatitis and Li-Fraumeni syndrome (see Table 1). A high proportion of patients with pancreatic cancer with a family history of a variety of solid tumors will likely carry a pathogenic mutation in a known cancer predisposition gene. Relatives of an individual with pancreatic cancer found to carry a mutation in a high-risk gene may benefit from screening.

Melanoma

Approximately 7% to 12% of melanoma occurs in patients with a strong family history of melanoma. About 40% of familial melanoma is attributed to the inheritance of a mutation in a highly penetrant predisposition gene (Fig. 3). Other well-known predisposition genes may increase susceptibility to melanoma but with lower penetrance.

SUMMARY

Genetic testing is a critical part of medical practice today, especially among specialists who treat cancer. It is imperative that we identify patients at risk, facilitate their testing and know to whom to send the patients for up-to-date information on how to manage dealing with the associated cancer risks. Whether surgeons opt to test their own patients or refer them to a genetic counselor, the surgeon must be involved intimately in the management of the genetic syndrome that ultimately is revealed. Changes in management prompted by the results of genetic testing can have a meaningful impact on the lives of affected individuals and their families.

Acknowledgment

I acknowledge Dr. Lori Ellison for writing and editorial support.

Contralateral Prophylactic Mastectomy

Amanda Kupstas, MD, and Judy C. Boughey, MD, FACS

CONTRALATERAL PROPHYLACTIC MASTECTOMY

The question of whether to perform a risk reducing contralateral prophylactic mastectomy (CPM) on a patient with unilateral breast cancer is complex and a topic of increasing interest. The most recent guidelines do not recommend CPM for women with unilateral breast cancer who are of average risk for developing contralateral breast cancer (CBC). However, rates of CPM continue to rise despite these recommendations. It is not hard to imagine why this trend is continuing. Patients tend to have an exaggerated perspective of their risk of contralateral cancer. Meanwhile the surgical complications, psychosocial impact, and economic implications may not be fully understood and symmetry and patient perception of control seem to dominate the decision. An evidence-based approach understanding individual risk of CBC, CPM outcomes, and patient values must be employed and a recommendation should be offered.

RISK OF CONTRALATERAL BREAST CANCER

Average-Risk Patient

CPM offers a risk reduction of breast cancer development of 90% to 95%. This impressive number can be misleading if it is not taken into the context of the individual patient's absolute risk. The risk of CBC in the average risk patient with unilateral breast cancer is reported to be 0.6% per year in historic series and 0.2% to 0.5% per year in contemporary series in patients receiving adjuvant therapies for their index breast cancer. For the majority of patients, the absolute risk of CBC is low, and therefore the risk reduction from CPM is small and does not warrant an aggressive surgical approach.

Young Age and Family History of Breast Cancer

Two important factors found to be associated with increased risk for a CBC are young age at diagnosis and family history. The WECARE study (Women's Environmental Cancer and Radiation Epidemiology Study) described 10-year cumulative risk of developing CBC in these subgroups. Patients younger than 45 years at diagnosis who had an affected first-degree relative had a risk of 9% to 13% compared to

Patients tend to have an exaggerated perception of their risk of contralateral cancer. Meanwhile the surgical complications, psychosocial impact, and economic implications may not be fully understood and symmetry and patient perceptions of control seem to dominate the decision. An evidence based approach understanding individual risk of CBC, CPM outcomes, and patient values must be employed and a recommendation should be offered.

RISK OF CONTRALATERAL BREAST CANCER

Average-Risk Patient

CPM offers a risk reduction of breast cancer development of 90% to 95%. This impressive number can be misleading if it is not taken into the context of the individual patient's absolute risk. The risk of CBC in the average risk patient with unilateral breast cancer is reported to be 0.6% per year in historic series and 0.2% to 0.3% per year in contemporary series in patients receiving adjuvant therapies for their index breast cancer. For the majority of patients, the absolute risk of CBC is low, and therefore the risk reduction from CPM is small and does not warrant an aggressive surgical approach.

Young Age and Family History of Breast Cancer

Two important factors found to be associated with increased risk for a CBC are young age at diagnosis and family history. The WECARE study (Women's Environmental Cancer and Radiation Epidemiology Study) described 10-year cumulative risk of developing CBC in these subgroups. Patients younger than 45 years at diagnosis who had an affected first-degree relative had a risk of 9% to 13% compared to

3.7% to 8.6% in patients older than 45 years. Young patients with a first-degree relative with bilateral cancer had a risk of 4% to 13%.

Gene Mutations

BRCA1 and BRCA2 and High Penetrance Gene Mutations

The risk for patients with highly penetrant deleterious gene mutations of developing a CBC is considerable. Carriers of *BRCA1* and *BRCA2* deleterious mutations have a relative risk of CBC ranging from 10 to 30 times that of average risk women and a lifetime risk of 40% to 80%. Other less common but highly penetrant mutations include *TP53* (Li-Fraumeni) and *PTEN*, which confer a lifetime risk of 50% to 90% for development of CBC. For patients with *BRCA1* and *BRCA2* mutations and breast cancer, consideration of CPM and bilateral salpingo-oophorectomy (after child bearing, if desired) is recommended. The other highly penetrant mutations are far rarer but confer a significant risk and CPM should be considered in their management.

Low-Penetrance Gene Mutations

As our understanding of hereditary breast cancer evolves beyond *BRCA1* and *BRCA2*, and panel testing is becoming more popular, the significance of other low- to moderate-penetrance alleles is being brought into question. While *BRCA1* and *BRCA2* account for the cancer risk in the majority of women with multiple affected family members, families with a less strong family history are more likely to have low-penetrance alleles, such as *CHEK2*, *PALB2*, *ATM*, and *BRIP1*, which each have been found to confer a two- to threefold increased risk of breast cancer. Typically, the patients found to have these mutations are already categorized as high risk based on their family history. Little is known about the risk of CBC associated with these mutations, so there is not adequate evidence to recommend CPM based on the presence of these mutations alone.

Prior Chest Wall Irradiation

Patients who have undergone treatment with chest wall irradiation for Hodgkin's lymphoma and other malignancies have an incidence of breast cancer of 30% by the time they reach 50 years of age. Their risk approaches that of *BRCA* mutation carriers. Current national guidelines recommend breast cancer screening 8 years after completion of treatment or at 25 years of age. CPM should be considered in the treatment of women with breast cancer who have been previously treated with chest wall irradiation given the increased risk.

Breast Density

Breast density is a significant risk factor for the development of breast cancer increasing the lifetime risk of breast cancer by 4.6 times for a women with greater than 75% breast density compared to a woman with 5% breast density. A version of the Gail model risk assessment tool modified to include breast density (>75% dense) resulted in improved predictive value of the risk assessment tool. Breast density also poses a particular challenge to surveillance and can contribute to increased biopsies and imaging. This might be considered for the patient who has significant surveillance anxiety.

Characteristics of the Primary Cancer

It is intuitive that the biology of the index cancer will influence the risk of CBC. Some model based studies suggested lobular histology in particular as a risk factor. A recent study by Langagaard et al. reported an increased risk of CBC in patients with invasive lobular compared to invasive ductal histology. Other proposed characteristics include multicentricity and presence of other high risk lesions in the primary affected breast. While some may advocate for magnetic resonance imaging in these patients, these factors are not an indication for CPM in the context of the current knowledge.

ONCOLOGIC OUTCOMES

Risk Reduction and Survival

CPM consistently provides a 90% to 95% reduction of risk regardless of the patient population. However, it does not eliminate risk of breast cancer development. Additionally, this risk reduction has not translated to a survival benefit. Multiple retrospective studies found no significant association between CPM and breast cancer–specific survival. In the studies that did find a statistically significant improvement in breast cancer–specific survival there is a question of whether a healthier, younger cohort in the CPM group may confound the data. With regards to overall survival, many studies demonstrated that there was no benefit with CPM. Two studies that found an overall survival benefit in the CPM group appeared again to be confounded by patient selection bias, with a healthier CPM cohort. Overall, patients should be counseled that there is no definitive evidence that CPM improves survival.

Recurrence of the Primary Cancer

Concern regarding recurrence of the primary cancer locally and as metastatic disease is a major concern of patients undergoing treatment. While CPM protects against a new cancer in the contralateral breast it offers no protection against recurrence of the index tumor and in most cases risk of recurrence of the primary tumor exceeds the risk of development of a CBC.

Contralateral Prophylactic Mastectomy and Adjuvant Therapy

Delays in systemic therapy and radiation therapy can potentially interfere with the chemo- free survival benefit provided by adjuvant therapy. Time to initiation of chemotherapy is longer in patients undergoing mastectomy with reconstruction than mastectomy without reconstruction. Additionally, since CPM increases the complication rate associated with surgery, there is concern that this could contribute to delay to adjuvant therapy. This is a particular concern for patients with advanced stage disease and aggressive tumor biology. In these cases, if CPM is warranted it may be advisable to consider performing it in a delayed fashion.

NONONCOLOGIC OUTCOMES OF CONTRALATERAL PROPHYLACTIC MASTECTOMY

Surgical Complications

The surgical complications evaluated in most studies pertaining to CPM include hematoma, infection, flap necrosis, delayed wound healing, and also those related to reconstruction (implant loss, nipple necrosis, and microvascular thrombosis of free tissue flaps). Regardless of whether the patient has reconstruction or not, CPM has been shown to double the risk of complications. Complications related to reconstruction including additional unanticipated procedures must be considered as well. One series estimated a 40% to 60% risk of complications over the course of reconstruction, with an estimated 32% requiring an additional unanticipated surgery. Patient dissatisfaction with CPM was found to be linked to the requirement of subsequent procedures (anticipated or unanticipated). This should therefore be included in the counseling process when reconstruction is desired.

Psychosocial Impact and Satisfaction

Psychosocial impact is difficult to study and it is hard to predict how a patient will respond to their surgical treatment. Studies evaluating long term satisfaction, which analyze the variables that contribute to the level of satisfaction, provide some insight. After a mean of 20 years after CPM 90% of women were satisfied or very satisfied with their decision to undergo CPM.

"Peace of mind" in the perception of risk reduction is described as being the most common motivating factor for CPM as well as the

most likely cause of satisfaction with treatment. The second most common reason was cosmetic outcome or symmetry. While most women were content overall with their treatment many reported dissatisfaction with body image, poor cosmetic outcomes, wound/pain related complications, and sexual changes. An open discussion taking into consideration the patients values and the possible psychosocial impact of the procedure can help reduce dissatisfaction and allow the patient to be better prepared for the informed decisions they make.

Surveillance and Cost-Benefit Analysis

Equality in distribution continues to be a challenging public health issue. Several model based studies have evaluated cost effectiveness and quality adjusted life years (QALYs) across the financial benefit of CPM. Three factors that were found to influence the results are the patient's age, risk level of breast cancer, and quality of life. For patients with hereditary cancer syndromes, CPM was cost effective over surveillance and it provided more QALYs. Zendejas et al. found the cost of unilateral mastectomy (UM) and surveillance of the other breast and CPM are equivalent in women age 40 and younger, however, the CPM group provided more QALYs. In a recent study by Kerkvy et al. UM and CPM were compared and there was a clear advantage to UM with respect to cost and quality. For young patients and those with a high risk of breast cancer without a known deleterious mutation there is a questionable quality advantage but this relies heavily on quality of life assumptions.

SURGICAL CONSIDERATIONS

Types of Mastectomy

A simple mastectomy can be offered for patients who do not wish to undergo reconstruction. An elliptical incision is made incorporating the nipple areola complex and the majority of the extra skin overlying the breast. The breast tissue, nipple areola, and extra skin is resected. The edges are approximated to create a smooth flat surface, which is ideal for use of a prosthetic as desired. Due to the operation of choice for the therapeutic mastectomy in patients with inflammatory breast cancer or locally advanced cancers with skin involvement. Advantages include lower rate of complications and usually no requirement for subsequent procedures and reoperation.

For women who desire reconstruction the two most common options are skin sparing mastectomy (SSM) and nipple sparing mastectomy (NSM). The primary difference being in NSM the dermis and epidermis of the nipple areolar complex (NAC) is preserved, while in skin sparing the NAC is excised with the specimen. Women with bloody nipple discharge or with central tumors close to the NAC should not undergo NSM on the therapeutic side, although may still consider NSM for the CPM. Gould et al. report complication rates are higher for NSM than SSM (36% vs 9%).

Nipple necrosis can occur in 10% to 20% of patients but actual nipple loss as a result is only 2% to 3%. Nipple necrosis may also occur secondary to presence of ductal carcinoma in situ or malignancy in the retroareolar tissue on final pathology in up to 4% of patients. The patient should be counseled explicitly that there is loss of sensation of the breast and nipple despite preservation of the skin and NAC. While preservation of the nipple can give excellent natural looking results, nipple reconstruction and tattooing can be offered, if desired, for patients who undergo SSM.

Options for Reconstruction

The involvement of an experienced plastic surgeon early on in the decision process is invaluable. When the patient's motivation for CPM with reconstruction is driven by a desire for symmetry other options such as mastopexy, augmentation, and reduction mammoplasty should be discussed and offered. These offer the ability to achieve symmetry without loss of the breast and result in less sensation loss and a more natural texture to the breast. There is no reconstruction

BOX 1 Points for Patient Counseling

- CPM decreases the risk of CBC by 90%–95%
- CPM offers no survival benefit
- CPM does not protect against recurrence of the primary cancer
- CPM doubles the chance of a surgical complications
- CPM with reconstruction may require multiple procedures and possible reoperation
- CPM results in severely decreased or loss sensation of the once living skin and nipple if preserved
- CPM results in the inability to breast feed
- CPM may impact sexuality and body image
- 10% of patients who undergo CPM regret their decision
- Alternatives to CPM for risk reduction include chemoprevention, BSO, and surveillance

Modified from Boughey JC, et al. Contralateral prophylactic mastectomy (CPM) consensus statement from the American Society of Breast Surgeons: data on CPM outcomes and risks. Ann Surg Oncol 2010;17(5):1320–7310.
CPM, Contralateral prophylactic mastectomy; BSO, bilateral salpingo-oophorectomy.

method that is superior for every woman. Individualized counseling will improve patient satisfaction.

If the decision is to proceed with CPM the two general options for reconstruction are autologous and autoplastic reconstruction. Autologous reconstruction consists of free flaps like the deep inferior epigastric perforator flap and rotational flaps such as the transverse rectus myocutaneous flap. Autologous reconstruction options provide an excellent cosmetic outcome that closely resembles the natural breast. They do require a longer initial hospital stay and may be associated with more short-term complications. Alloplastic reconstruction usually consists of tissue expander placement, with a second procedure to exchange the tissue expander to a permanent implant. Consultation direct to implant reconstruction can be performed.

Sentinel Lymph Node Surgery

Sentinel lymph node (SLN) surgery in prophylactic mastectomy is not recommended because of the low risk of occult malignancy and increased complication rate. The risk of occult malignancy in the contralateral breast is only 1.8% and the chance of axillal positivity in that case is only 1.3%. By meta-analysis, the risk of lymphedema after SLN surgery alone was found to be 5.6%. Therefore, routine SLN surgery in all patients undergoing CPM is not recommended. However in cases where a suspicious lesion is identified in the contralateral breast and malignancy is not excluded by preoperative percutaneous biopsy, SLN surgery should be done at the time of surgery.

COUNSELING AND SHARED DECISION MAKING

Optimizing Informed Consent

The surgical consultation should first include a discussion of the facts. A surprisingly large number of women who considered and underwent CPM were unaware it did not improve survival. Over half did not know that CPM did not completely eliminate the risk of breast cancer or risk of distant metastases. As mentioned previously, the value of poor or mild and perception of risk of the patient is one of the most important factors influencing the decision to have CPM. Any discrepancies between perceived risk and the actual individualized risk of the patient should be reconciled. The potential psychosocial impact should be discussed. If reconstruction is desired, discussion of possible complications and the need for multiple anticipated and unanticipated procedures may be necessary. Box 1 summarizes major points that should be addressed during the consultation.

BOX 2 Summary of Recommendations

- CPM should be discouraged in women at average risk
- CPM should be offered to *BRCA* carriers along with RSO after childbearing
- CPM can be considered in patients with other gene mutations, young women with a history of mantle radiation, and young women with a strong family history without a gene mutation
- CPM can be considered for women who desire symmetry or a change in the size and shape of their breasts
- CPM can be considered for women who have extreme risk–related anxiety, have had surveillance failure, or have dense breasts

Modified from Boughey JC, et al. Contralateral prophylactic mastectomy (CPM) consensus statement from the American Society of Breast Surgeons: data on CPM outcomes and risks. Ann Surg Oncol. 2010;17(10):2631. CPM, Contralateral prophylactic mastectomy; RSO, bilateral salpingo-oophorectomy.

Importance of Shared Decision Making

A survey-based study by Jagsi et al. demonstrated almost half of women, including both high risk and average risk, received no recommendation for or against CPM. Of the women who were advised against CPM (37%) almost all followed the physician's recommendation (97.9%). This suggests the physician's recommendation can be an important contributing factor. While the decision is very personal and must take into consideration the patient's values it is important to ensure the patient has a clear understanding of their options and to overcome misconceptions and offer a recommendation.

Rates of Contralateral Prophylactic Mastectomy in the United Kingdom

Rates in the United Kingdom are significantly lower than in the United States. All the same variables that contribute to the individual decision to undergo CPM are similar, including poor understanding of actual risk, and fear of recurrence. One key difference is that private health insurers and some National Health Service commissioners in the United Kingdom will not fund CPM with the exception of *BRCA* carriers. Also, breast surgeons are trained in oncoplastic procedures as part of their training, which can be employed to improve symmetry without reconstruction.

CONCLUSION

As more and more patients are asking about CPM for the treatment of their breast cancer the physician must be equipped with the knowledge to help patients arrive at the right decision for them. An evidence-based shared decision method is the best approach. (Box 2).

MARGINS: HOW TO AND HOW BIG?

Hiram S. Cody III, MD

Negative margins of excision optimize local control in breast conserving surgery (BCS) and are the subject of an extensive literature. Two recent meta-analyses concluded that for invasive cancer that local control following BCT with whole breast radiotherapy (RT) was not improved by margins wider than "no tumor in ink," and for ductal carcinoma in situ (DCIS) that local control was optimized by margins of 2 mm and not significantly improved by wider margins. The apparent simplicity of these recommendations is deceptive. Local control is a function of many variables beyond margins width, including preoperative imaging, image guided tumor localization, surgical technique, pathologic processing, tumor extent, tumor biology, radiotherapy, systemic therapy (chemo and hormonal), and patient preferences regarding cosmesis and benefit versus risk. Since many of these are modifiable by surgeons and their multidisciplinary colleagues, this chapter is the composite of a long personal experience and the consensus protocols of our Breast Disease Management Team at Memorial Sloan Kettering Cancer Center.

PREOPERATIVE IMAGING

Prior to surgery, it is not sufficient to rely on written reports. An in person review by the surgeon of all imaging with the radiologist—preferably breast specialized—is particularly helpful (1) to fully define the extent of all abnormalities seen on mammography and/or ultrasound (US), (2) to take additional views and perform additional biopsies as necessary, (3) to establish imaging fiducials concordance for all biopsy sites, (4) to confirm the position of any localizing clips placed at the time of core biopsy, and (5) to jointly plan for localization of nonpalpable lesions. We strongly discourage routine breast magnetic resonance imaging (MRI) prior to BCT. MRI false positives for submammary true positives, but require additional core biopsies, delay surgery, may increase the extent of excision, and almost always

MARGINS: HOW TO AND HOW BIG?

Hiram S. Cody III, MD

Negative margins of excision optimize local control in breast conserving surgery (BCS) and are the subject of an extensive literature. Two recent meta-analyses concluded that for invasive cancer that local control following BCT with whole breast radiotherapy (RT) was not improved by margins wider than "no tumor in ink," and for ductal carcinoma in situ (DCIS) that local control was optimized by margins of 2 mm and not significantly improved by wider margins. The apparent simplicity of these recommendations is deceptive. Local control is a function of many variables beyond margins width, including preoperative imaging, image guided tumor localization, surgical technique, pathologic processing, tumor extent, tumor biology, radiotherapy, systemic therapy (chemo and hormonal), and patient preferences regarding cosmesis and benefit versus risk. Since many of these are modifiable by surgeons and their multidisciplinary colleagues, this chapter is the composite of a long personal experience and the consensus protocols of our Breast Disease Management Team at Memorial Sloan Kettering Cancer Center.

PREOPERATIVE IMAGING

Prior to surgery, it is not sufficient to rely on written reports. An in person review by the surgeon of all imaging with the radiologist—preferably breast specialized—is particularly helpful (1) to fully define the extent of all abnormalities seen on mammography and/or ultrasound (US), (2) to take additional views and perform additional biopsies as necessary, (3) to establish imaging fiducials concordance for all biopsy sites, (4) to confirm the position of any localizing clips placed at the time of core biopsy, and (5) to jointly plan for localization of nonpalpable lesions. We strongly discourage routine breast magnetic resonance imaging (MRI) prior to BCT. MRI false positives for submammary true positives, but require additional core biopsies, delay surgery, may increase the extent of excision, and almost always

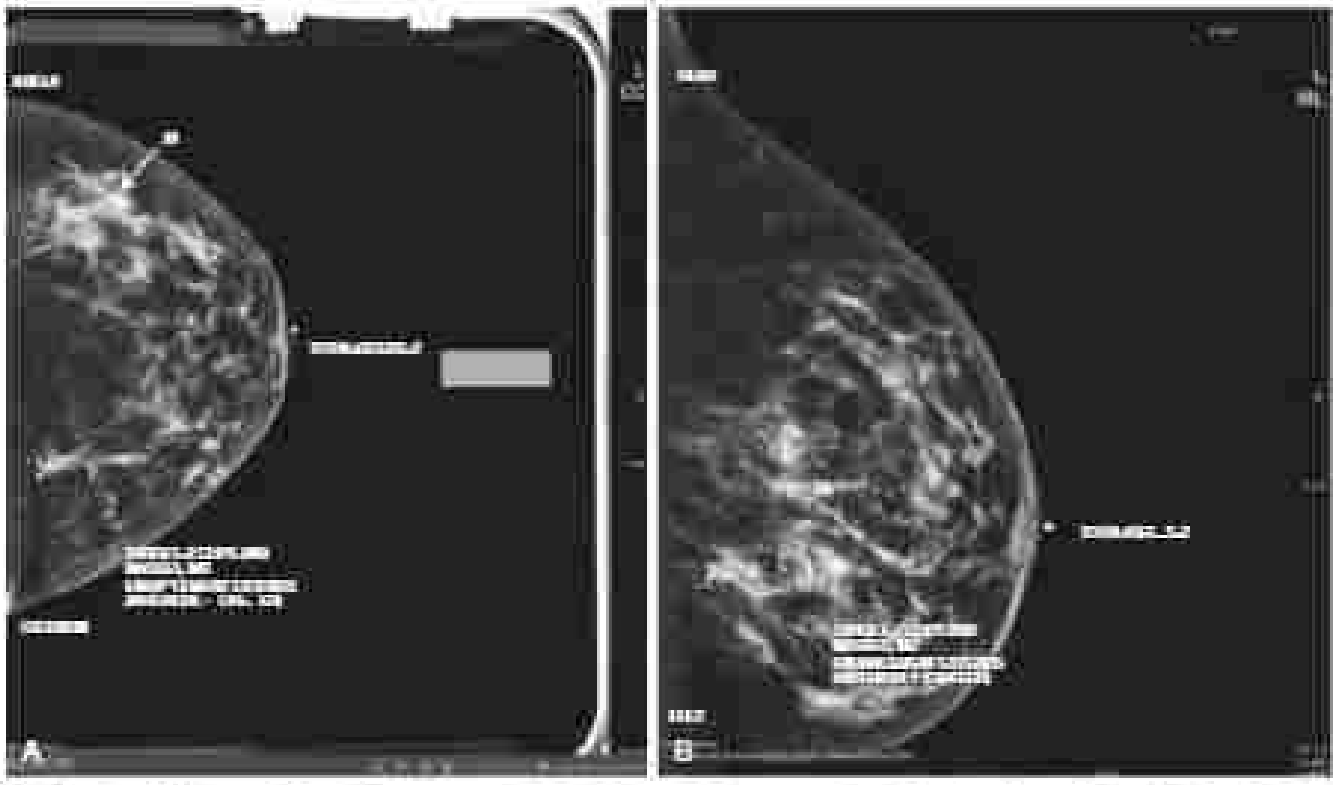

FIG. 1 Craniocaudal (A) and mediolateral (B) mammography of the left breast following preoperative localization with two I-125 seeds. The radiologist's annotations indicate irradiation, the site of a previous benign biopsy at 3 o'clock, the site of a microcalcific biopsy at 9 o'clock showing ductal carcinoma in situ (DCIS) despite short course and the site of focal MRI enhancement requiring anatomy from which an MRI-guided biopsy showed DCIS. I-125, radioactive; MRI, magnetic resonance imaging. (*C. Vince Alcalá, J. Mango, MD.*)

require a follow-up MRI at 6 months and longer. There are no convincing data to suggest that MRI reduces the rates of positive margins, reexcision or local recurrence, and MRI may be associated with an increased rate of mastectomy. To be sure, MRI—*done selectively*—makes sense whenever mammography and US fail to clearly delineate the extent of the lesion, especially for patients with *dense* breasts or following neoadjuvant chemotherapy.

IMAGE-GUIDED LOCALIZATION

For nonpalpable lesions we currently use radioactive (I-125) seed localization, for which the results are comparable to those of traditional wire localization, and which can be placed by the radiologist under mammographic or US guidance prior to the day of surgery, allowing flexible scheduling and minimizing operating room (OR) delays. We place one seed for small lesions, "bracket" larger lesions with multiple seeds, and confirm seed position with a post-localization mammogram. Annotation of the films by the radiologist, especially in patients with multiple abnormalities, is particularly helpful in the OR (Fig. 1A and B). "Head First," "Medial Lateral," "site of cancer," "Site of nipple," "Displaced clip," and so forth help to minimize errors of orientation.

SURGERY

Preliminaries

In the OR prior to starting surgery, we review the patient's medical record (especially the pathology report), review and display all necessary imaging studies, and conduct a time-out confirming laterality, procedure, and number of I-125 seeds with all members of the OR team. Once prepped and draped, we use a gamma probe to localize the "hot spot" corresponding to each I-125 seed and mark the overlying skin.

Incision

The first step in obtaining negative margins is proper incision placement. We typically make a circumareolar or a (diametric incision to the natural (Kraissl) skin lines, which is sufficient to allow excision of the cancer under direct vision and is designed to maximize skin sparing should a completion mastectomy be required. I only excise skin if the tumor is adherent, having found that many patients with dimpling do not have skin involvement; elliptical skin excisions, especially in the 12:00 to 6:00 axis of the breast, and even if limited in extent, can cause striking asymmetry. Many difficulties with specimen margins result from a well-intentioned incision placed to optimize cosmesis but far from the tumor, leading to tunneling, inadequate exposure, piecemeal excision, and positive margins. For excision of multiple lesions (for example, one site with cancer and another with atypical ductal hyperplasia [ADH]), the initial incision should be placed closest to the cancer and will often suffice for removal of the additional sites.

Benign but Possibly Malignant Lesions

Except for fibroadenomas, which can simply be enucleated and submitted without orientation, all other benign conditions requiring surgery (bloody nipple discharge, ADH, imaging/histologic discordance, subareolar abscess, etc.) should be regarded as potentially malignant and excised conservatively but as an intact specimen, oriented, imaged (if appropriate), inked, and processed as a possible cancer. For the minority that prove malignant, most will be DCIS and the initial excision may be sufficient to avoid a reoperation.

Malignant Lesions

Malignant lesions require an intact excised specimen, orientation, specimen radiograph (for nonpalpable lesions), and inking of the

specimen margins. There is no single "right" way to do this, and each institution's protocol should represent a consensus of radiologist, surgeon, and pathologist. The overall goal is to minimize the rate of reexcision while maximizing local control.

Our current reexcision rate of about 10% is based on a very favorable experience of more than 10 years with the following technique:

1. Conservative excision of the cancer
2. Specimen radiograph to confirm lesion/clip/seed retrieval
3. Excision of separate specimens from each face of the excision cavity
4. Orientation of each specimen with a single suture on the outermost face
5. Inking by the pathologist of only the outermost/sutured face of each margin specimen
6. Sectioning and submission of all specimens for permanent sections

Although this technique is often referred to as cavity shave, the margin specimens should be sufficiently thick (at least 5–10 mm) to assess the distance from tumor to ink, and with enough surface area to honestly represent the circumference of the cavity, not tiny portions of it. In taking margin specimens, one should go as wide as possible consistent with an acceptable cosmetic result. My preference is to begin the initial excision in the subdermal plane, eliminating the need to submit a specimen of anterior margin, and to extend the separate posterior margin specimen to the pectoral fascia, eliminating the need to reexcise for a positive posterior margin. Our technique avoids the use of multicolored inks, which can bleed into each other giving ambiguous results. It allows the surgeon to control specimen orientation and labeling at the moment of excision, and clearly delineates the source and site of each margin specimen for the pathologist. Clear communication between surgeon and OR staff is essential, with the surgeon naming each specimen for the scrub nurse and circulator, and with a confirmatory "read back" from the circulator to the surgeon.

Although intraoperative margin assessment by touch prep cytology or frozen sections may reduce rates of reexcision, most institutions, ours included, have found the logistics of intraoperative margin assessment to be prohibitive. Investigation of electrical impedance and fluorescent devices for immediate intraoperative margin assessment is ongoing and benefit remains unproved.

INTERPRETATION OF THE PATHOLOGY REPORT

The pathology report contains a wealth of information beyond margin width, all bearing on the adequacy of excision. Our reports include the following:

1. Width of margin: "positive (tumor on ink), close (<1 mm), or exact width in mm"
2. Extent of positive or close margins: "positive/close along a broad front, positive/close in 3 of 6 slides, or locally positive/close"
3. Size of initial excision and of each margin specimen: "3 × 4 × 1 cm"
4. Tumor burden in each margin specimen: "in the superior margin specimen, tumor is present in 3 of 6 slides"
5. Invasive cancer type/size in each margin specimen: "the superior margin specimen contains a 5 mm focus of invasive ductal carcinoma"
6. DCIS type/size in each margin specimen: "the superior margin specimen contains a single 3 mm focus of intermediate grade DCIS"
7. Presence/extent of lymphovascular invasion (LVI).

In discussing the pathology report with the patient, I find it very helpful to draw out a simple diagram of the breast, indicating the location of the tumor excision and the margin specimens, drawing the extent of tumor in each, and then discussing whether to reexcise.

WHEN TO REEXCISE

On one hand, reexcision is never required for margins beyond "no tumor on ink" (for invasive cancer) or 2 mm (for DCIS). On the other hand, reexcision is almost always required for patients with positive or locally positive margins (tumor on ink). Exceptions to this rule include (1) a positive anterior margin of the initial excision biopsy at the subdermal plane, (2) a positive posterior margin if the initial excision was carried to the pectoral fascia, or (3) positive margins at the breast periphery (i.e., whenever there is no breast tissue beyond the margin site). Careful documentation of these details in the operative note can help avoid reoperation.

The decision to reexcise for margins between 0 and 2 mm is the most problematic, is subject to the greatest variation between surgeons, and cannot be made on the basis of margin width alone. Especially for patients with DCIS, reexcision of margins of less than 2 mm need not be mandatory. I am in general much more influenced by tumor burden (a composite of specimen size, tumor size, and the extent of tumor in each margin) than by margin width. One must also find a balance between those patient and tumor characteristics associated with increased risk of ipsilateral breast tumor recurrence (IBTR) and those treatment factors that act to reduce the risk of IBTR. Among the former are younger age, larger tumor, higher grade, triple negative/ (human epidermal growth factor receptor 2) HER2+ subtype, LVI, nodal metastasis and genetic predisposition. Among the latter are breast RT and systemic adjuvant therapy: chemotherapy, anti-HER2 therapy, and hormonal therapy. Multidisciplinary input from the medical and radiation oncologist may help to reach a decision in borderline cases. Finally, the decision must be shared with the patient, some will prefer to err on the side of more surgery and others will not.

I do not perform post-BCT mammography routinely, but for all patients who need reexcision and whose tumors presented as microcalcifications, mammography is required to identify and localize any suspicious residual calcifications prior to reoperation.

HOW TO REEXCISE

Following localization of any residual calcifications, reexcision is best done within a few weeks of the first operation, when the excision cavity is easily opened. I reopen the previous incision without resecting it. The margin in question is simply grasped and resected, going from subdermal plane to pectoral fascia, and taking as much tissue as possible, at least 5 to 10 mm, within the limits of cosmesis. The specimen is oriented and submitted for inking as done at the initial procedure. For patients with layered wound closures or healed excision cavities, one can be guided by the presence of subcutaneous sutures, or surgical clips.

SPECIAL CIRCUMSTANCES

Isolated Tumor Foci or Lymphovascular Invasion at the Margin

Margin specimens sometimes contain an isolated focus of tumor at the margin ("the specimen measures 3 × 3 × 1 cm and there is a 1 mm focus of DCIS at the inked margin in 1 of 4 slides"). Here the disease is clearly low volume and not contiguous with the tumor site. In the mastectomy era, about 20% of patients harbored such foci in the other quadrants of the breast and these foci were the justification for mastectomy. In the era of BCT these foci are the rationale for whole breast RT, which clinical trials show is very effective in eradicating occult multicentricity. Accordingly, I generally recommend against reexcision for such noncontiguous low volume "incidentalomas." LVI is clearly associated with an increased risk of IBTR (and of distant metastasis) but, as stated previously, when found as noncontiguous isolated foci does not require reexcision.

UNEXPECTEDLY EXTENSIVE DISEASE

Some patients have surprisingly extensive disease, typically DCIS—extending to all margins and which was not apparent on preoperative evaluations. Postoperative MRI is very useful in this setting: it can identify those patients with extensive residual disease who should undergo mastectomy and, if negative, allows the option of reexcision for those patients in whom it can be done with acceptable cosmesis. For patients with unexpectedly extensive disease and a responsive tumor subtype (estrogen receptor, progesterone receptor negative, HER2+), another reasonable option is to proceed directly to chemotherapy (including anti HER2 agents), and then perform the resections. Rates of pathologic complete response for this subtype exceed 50%, allowing BCT for some patients who would otherwise have required mastectomy. Patients will have their own preferences and many will opt for mastectomy regardless but for those who prefer BCT mastectomy need not be automatic.

MORE THAN ONE SITE OF DISEASE

BCT is feasible for a highly selected group of patients with multicentric (typically two small foci in separate quadrants) or multifocal cancers (multiple foci in the same quadrant). For multicentric tumors, I excise each site separately and take additional margins from each site in the usual fashion. For multifocal tumors, I try to encompass all sites within a single excision specimen. When a two site excision results in a single cavity, I document the relationship of the two sites and their margins to each other ("the inferior margin of the 2 o'clock site was contiguous with the superior margin of the 8 o'clock site") aiming to avoid a reexcision if either or both of the contiguous margins were reported positive.

MARGINS POSITIVE FOR BORDERLINE LESIONS

ADH and classic lobular carcinoma in situ (LCIS) are not cancers, and therefore when present at specimen margins do not require reexcision. Reexcision makes sense for truly borderline lesions ("almost ADH bordering on DCIS") or for patients with pleomorphic LCIS, an unusual variant of LCIS for which natural history data are inadequate, but which, unlike classic LCIS, may behave more as a true cancer than a marker of risk.

POSITIVE MARGINS IN MASTECTOMY

Few topics arouse more debate for the multidisciplinary team than this one. Should one reexcise and, if so, where and how? Are we treating the pathology report or the patient? As for anterior margins in BCT, the first consideration is whether the mastectomy skin flaps were dissected in the subdermal plane, outside the superficial fascia of the breast, leaving no visible breast tissue on the flap. This can be challenging, especially in thin patients where the breast tissue is very close to the skin or in nipple sparing mastectomy (NSM) where meticulous placement may limit exposure but can always be done and is the responsibility of the operating surgeon. After removal of the breast specimen, I find it very helpful to "critique" the flaps with my assistants and take additional specimens wherever the flaps are too thick or there seems to be residual breast tissue. *The time to do this is the first operation, not by guesswork at a reoperation.* The second consideration relates to taking of the mastectomy specimen. The anterior surface is fatty, irregular, and, in thin patients, very close to the underlying breast parenchyma and the posterior surface comprises the pectoral fascia. Anteriorly, ink runs into the interstices of the specimen, generating a falsely "positive" anterior margin. Posteriorly, there is no breast tissue beyond the pectoral fascia.

"Positive" mastectomy margins are a rare event in my practice and for the above reasons I do not reexcise when I have performed the initial operation. For a positive anterior margin, precise localization is impossible, the benefit of reoperation is unproved, and the added risk of local recurrence, independent of other tumor characteristics, is unclear. For a positive posterior margin, gross muscle invasion is obvious at the first procedure and addressed upfront by taking additional tissue, whereas microscopic disease at the pectoral fascia is insignificant. Patients with mastectomy margins positive for invasive cancer or with muscle invasion typically receive post mastectomy RT, for which local control is excellent whether one reexcises or not.

Occasional patients will present with positive margins after a poorly done mastectomy with thick skin flaps and obvious residual breast tissue. In this setting, I do recommend reoperation, aiming to re-dissect the skin flaps throughout. This is also my practice when such patients present metachronously with post mastectomy local recurrence.

NIPPLE-SPARING MASTECTOMY

NSM appears to be a safe procedure in properly selected patients, with short term local control comparable to that of conventional mastectomy techniques. In our own practice we typically recommend NSM for the good risk patient with a smaller breast and minimal ptosis, having surgery for prophylaxis or for a stage 0 to II cancer more than 2 cm from the nipple. The main challenge in NSM is exposure, which through a typical unilateral or reframmamary incision can be limited, especially in the more medial and superior aspects of the breast, where removal of all breast parenchyma is particularly important, especially for patients with genetic predisposition or larger tumors. A second challenge is removal of all the subareolar breast parenchyma by dissecting in the subdermal plane and by taking a "nipple margin," inverting the nipple and shaving off the remaining ductal tissue up to the level of the dermis. The nipple margin specimen is often so small that it is best evaluated by permanent section, not frozen. NSM is a setting where the conundrum of positive mastectomy margins is more likely for the above reasons, and if all visible breast parenchyma has been carefully removed at the initial surgery I see little value in reoperation. For patients with a positive nipple margin, we recommend removal of the nipple, although in many patients the areola can be spared.

CONCLUSIONS

Surgical margins in BCT should be managed in a standardized fashion, representing a consensus of radiologist, surgeon, and pathologist. In general, positive margins require reexcision and negative margins do not. For patients with intermediate margins of 0 to 2 mm, especially for DCIS, the decision to reexcise should be multivariate and multidisciplinary, taking into consideration patient, tumor, and treatment characteristics and should not be based on margin width alone.

Breast Reconstruction Following Mastectomy: Indications, Techniques, and Results

Asad A. Khan, MD, MPH, PhD, and Gadge D. Pierson, MD

Breast cancer remains the most common cancer in women and is the second most common cause of cancer death in women. The American Cancer Society estimates that in 2019 there were 268,600 new cases of breast cancer, representing a 0.4% increase in incidence. The Agency for Healthcare Research and Quality estimates the rate of mastectomy to be at 90 per 100,000 and increasing. The steepest increases in mastectomy rates have been for bilateral procedures, which have been driven, in part, by the increased uptake of genetic screening for *BRCA1/2* mutations and the evolving role of contralateral risk–reducing mastectomies in non-BRCA breast cancer patients. The demand for breast reconstruction therefore continues to increase, and the beneficial effects of reconstruction on quality of life and self-esteem patient-derived outcomes are now well established. Decision making in breast reconstruction is a shared process between the surgeon and patient, and no one type of reconstruction is universally suited. The approach to reconstruction is bespoke and considerations that influence decision making will include the timing of adjuvant therapies (particularly radiotherapy), the availability of donor tissues, the management of the contralateral breast and, most important, patient preference.

PREOPERATIVE CONSIDERATIONS

Mitigating Perioperative Risk

As with any surgery, modifiable perioperative risk factors should be identified well ahead of time and optimized to minimize the risk of complications. In patients with cancer, it is essential to have a clear plan for venous thromboembolism prevention and this may entail preoperative (for example, cessation of tamoxifen), perioperative (heparin, sequential compression devices, fluid management), and postoperative (early ambulation, sequential compression devices, ongoing heparin) strategies.

Patients who are smokers should be counseled about the increased surgical risks attributable to smoking and encouraged to cease any and all forms of nicotine, including smoking, vaping, and second-hand smoke. From a reconstructive perspective, the effects of smoking in diminishing cutaneous blood flow are well established and wound-related complications and infections, particularly in the context of implant-based reconstructions, can be disastrous.

Obesity

Body mass indices greater than 25 kg/m^2 are associated with an increase in perioperative complications and higher rates of reconstructive failure both in implant-based and autologous reconstructions. Again, patients should be counseled as to the increase in risks attributable to obesity and offered support to reduce their weight before reconstruction when feasible, especially for prophylactic mastectomies and in later stages when timing is not urgent.

BREAST RECONSTRUCTION

Although reconstruction is often considered separately from ablative surgery, it is influenced heavily by the requirements of tumor excision and the delivery of adjuvant therapies. For this reason, it is imperative that surgical decision making between both oncologic and reconstructive teams is communicated clearly and effectively to present coherent and cohesive treatment options to the patient (Fig. 1). No one form of reconstruction is superior and the approach must be tailored to the patient. In some cases, no reconstruction may be the best way forward; therefore, this should not be discounted from the surgical armamentarium. In reaching the optimal surgical plan, there are many additional forms of patient information and support that are available in most healthcare systems. Breast reconstruction awareness events, the opportunity for patients to talk to other patients who have undergone differing forms of reconstruction, and Internet-based resources are increasingly important in shared decision making and are championed by all professional organizations. These tools are also instrumental in leading patients control of their cancer management and guiding them to arrive at the best choice of reconstruction for them.

Effect of Mastectomy Incision Choice and Skin Flap Thickness on Reconstruction

The choice of mastectomy incision is predicated by whether the nipple is to be preserved or removed with the breast. For skin-sparing mastectomies, a transverse or vertical elliptical incision encompassing the nipple-areolar complex is chosen and closed primarily after mastectomy as is most commonly used when an implant-based reconstruction is planned. If an immediate autologous breast reconstruction is planned, skin-sparing mastectomy can also be performed through a periareolar incision. For nipple-sparing mastectomies, an inframammary, lateral, or partial periareolar incision may be used and as the decision making must be communicated clearly between ablative and reconstructive teams. Most centers find that inframammary incisions give the best results and the incisions are not easily seen. From a reconstructive perspective, the choice of incision should: (1) facilitate tension-free skin closure over an implant if required or (2) allow adequate access to recipient vessels for free tissue transfer (commonly, the internal mammary at the level of the second or third costal cartilages or thoracodorsal vessels).

In performing a mastectomy, the surgical oncologist is faced with the challenge of removing a tumor while preserving the blood supply to the skin of the breast. The latter comes from a variety of cutaneous perforating vessels from the internal mammary, the thoracodorsal vascular axis, and the lateral intercostal perforators that run in the subcutaneous tissues. In removing the glandular portion of the breast, however, these are often interrupted and the skin is then reliant on blood flow from the more tenuous subdermal plexus. Although it is sometimes possible to identify a clear anatomical plane between the glandular and subcutaneous portions of the breast and so preserve the perforating vessels, this is not always the case. Factors such as neoadjuvant chemotherapy may obscure this plane, or a very superficial large tumor may necessitate a thinner mastectomy flap to be taken. The subdermal vascular supply is also very sensitive to disruption from mechanical stresses (e.g., retraction) and environmental temperature; therefore, thin flaps, particularly in large-breasted patients, are at higher risk of skin necrosis. This risk may be compounded by patient factors such as smoking, diabetes, and previous radiotherapy. This is particularly problematic in patients undergoing implant-based reconstructions because it may lead to implant exposure, infection, or extrusion. Prolonged wound care and healing by secondary intention may also delay the delivery of adjuvant therapies. Although this risk is still applicable to autologous reconstructions, the sequelae are less severe because the necrotic skin can be excised and the resultant defect skin grafted to achieve wound healing. It is not always possible to predict the extent of skin necrosis at the time of mastectomy; however, more recent technologies such as indocyanine green perfusion imaging of mastectomy skin flaps may aid in the diagnosis. If skin

to felt to be of dubious viability require measures such as warming, the application topical vasodilators, consideration of sildenafil, and possibly hyperbaric oxygen therapy may mitigate the final amount of skin necrosis.

Te Timing of Reconstructioo

Definitive breast reconstruction can be performed at the time of mastectomy (immediate), at a later time (delayed), or a temporizing tissue expander can be placed at the time of mastectomy with a view to performing a definitive autologous reconstruction at a later date (delayed-immediate, or staged). From the plastic surgeon's perspective, the optimal timing is driven largely by the requirements for postmastectomy radiotherapy because this increases significantly the complication profiles of both implant based and autologous reconstructions. The decision to delay definitive reconstruction may also be chosen by the patient as the decision making processes can be complex and patients may elect to defer these until their cancer treatment is complete.

Immediate Breast Reconstruction

Immediate reconstruction at the time of mastectomy is preferable for most patients and can entail placement of a tissue expander, direct-to-implant, or autologous reconstruction. Many centers deliberately avoid immediate autologous reconstruction if it is known, a priori, that radiotherapy will be required after the mastectomy. Immediate reconstruction offers excellent aesthetic outcomes because the breast envelope is preserved and can shape the reconstructed breast to give a more natural aesthetic. Overall, patients require fewer surgical procedures and a shorter, cumulative hospital stay. Disadvantages include the need to overcome scheduling problems to bring together ablative and reconstructive teams and a longer operative time, particularly for immediate autologous reconstructions. The stability of mastectomy skin flaps is a greater consideration in the immediate setting because of the risk of flap ischemia as mentioned previously.

Delayed Breast Reconstruction

Delaying reconstruction offers the benefit of being able to deliver adjuvant therapies (e.g., radiotherapy) without the problems of radiation induced fibrosis compromising the reconstructed breast. It may also be the preferred option for patients who are undecided as to what form of reconstruction they wish to pursue. The disadvantages of delayed reconstruction include somewhat inferior aesthetic outcomes compared with immediate reconstructions because of the loss of the breast envelope. This may make implant based reconstruction more challenging because it necessitates a period of tissue expansion to restore the breast envelope before it will accommodate an implant of the desired size. Delayed autologous reconstructions usually also require a greater import of donor site skin to restore the breast envelope so the final reconstruction will have a larger skin paddle than an immediate.

Delayed-Immediate (Staged) Breast Reconstruction

The delayed immediate paradigm aims to circumvent the problems associated with loss of the breast envelope encountered with delayed reconstructions. A temporizing tissue expander is placed at the time of mastectomy to maintain the skin envelope over the course of adjuvant radiotherapy. Once this is complete, if the envelope has contracted it can be expanded gently to accommodate an implant, or the expander can be removed and replaced with autologous tissue. This latter route is perhaps more preferable because of the significant risks of both short- and long-term reconstructive failure with implant-based reconstructions in the irradiated breast.

RECONSTRUCTIVE TECHNIQUES

Breast reconstruction is often a staged process consisting of three or more stages. The first stage aims to recreate the breast mound by the import of either autologous tissue or an implant. The second stage addresses the symmetry of the breasts and may require the addition (or removal) of volume from either the reconstructed breast or the contralateral side. The final stage entails further revisions and refinements, nipple reconstruction, and/or tattooing.

Implant-Based Reconstruction

Techniques in implant based reconstruction have evolved over time resulting from the availability of newer adjunctive technologies that help achieve robust implant coverage. Implant based reconstruction is traditionally performed as a two-stage procedure. Stage 1 places a tissue expander (most often with an integrated injection port) into a subpectoral pocket and, once this is healed, the patient returns to the clinic and begins the process of expansion by the injection of saline into the expander port. Once the desired volume is achieved the patient is scheduled for stage 2, which is removal of the expander and exchange for a fixed volume implant. The disadvantages of this paradigm include a longer treatment time (expansion can take up to 3 months) and multiple procedures, a slightly higher risk of expander related complications (infection, rotation/malposition, rupture, exposure); however, the two stage paradigm offers much better control over breast size and, proponents argue, pain less stretch on fresh mastectomy flaps. Although tissue expanders have traditionally been

placed in the subpectoral plane, there is increasing popularity with prepectoral (subcutaneous) placement.

Single-stage implant-based reconstruction has grown in popularity and feasibility because of the advent of acellular dermal matrices (ADMs). ADMs are animal-derived biologic sheets of dermis that support revascularization by ingrowth of blood vessels from adjacent tissues and ultimately integrate into the skin. Their use in breast reconstruction has largely obviated the need for tissue expansion because they can provide coverage of the implant either in part (e.g., lower pole coverage for implant placement in the subpectoral plane) or in total (e.g., in prepectoral implant placement). Although the one-stage paradigm offers the opportunity for immediate implant–based reconstruction, it is absolutely reliant on healthy mastectomy flaps to achieve implant coverage and prevent exposure, and some studies have shown a slightly higher overall failure rate with direct-to-implant techniques. Many surgical oncologists deliberately make the skin very thin for oncologic reasons, making it highly risky to place a direct-to-implant owing to the likelihood of some skin necrosis.

Types of Implants

Implants consist of a silicone shell containing either silicone or saline. The cohesiveness of the gel in modern-day implants is high, meaning that the gel can retain its shape to a greater degree, resulting in less of a cosmetic deformity and leakage in case of rupture. Implant shells can be either smooth or textured, where the surface of the implant has a coarse texture applied to it. There is some evidence to suggest that capsular contracture rates are lower with textured implants. The degree of texturing can vary from so called nanotexturing to macrotexturing as is the case with polyurethane implants. In shape, implants are either round or anatomical, and the choice of which implant is best suited to a patient depends on factors such as base width, implant coverage, and the desired projection. Most implant manufacturers will offer a variety of implant choices that offer a range of base widths, heights, and projections in both smooth and textured prostheses.

Acellular Dermal Matrices

ADMs are derived from either bovine or porcine dermis and are available in a variety of dimensions and thicknesses. As a biologic, they support the ingrowth of blood vessels and connective tissue and so become integrated into the body over time. In the context of breast reconstruction, their use is primarily for providing soft tissue reinforcement and thereby better implant coverage for prepectoral breast reconstruction, or lower pole coverage in subpectoral reconstruction. They are particularly useful for defining the implant pocket when the normal anatomical boundaries have been transgressed to achieve tumor clearance. Complications specific to the use of ADMs include increased seroma rates and cutaneous hypersensitivity resulting in the appearance of a red breast, which can mimic an implant infection.

Implant-Related Complications

Implant Rupture

US Food and Drug Administration–mandated studies have quantified the implant rupture rate, for breast reconstruction, to be as high as 10% at 10 years. These rates do vary by implant type and by whether they are being used in the context of primary reconstruction or revision reconstruction. The majority of ruptures, particularly with newer generation devices, are often silent but may also present with changes in breast shape/volume, capsular contracture, palpable lumps (breast or axilla), and pain. The gold standard investigation for diagnosing implant ruptures is magnetic resonance imaging; however, high-resolution ultrasound examination is sometimes performed in the first instance as a screening test.

Capsular Contracture

This is defined as the presence of a pathologic, fibrous capsule around the implant that can result in palpable, visible, or painful distortion of the breast. Breast implant capsules are a normal physiologic response to the insertion of foreign material, but in some instances, this response becomes exaggerated. Risk factors that increase the risk of contracture include implant infection, hematoma, radiotherapy, and implant rupture. Capsular contracture rates from US Food and Drug Administration postapproval studies range from 10% to 15% at 10 years but vary between implant manufacturers. The capsular contracture associated with radiation treatment is actually combined with fibrosis of the skin, subcutaneous tissue, pectoralis muscle, intercostal muscles, and the ribs, and should therefore be thought of as a regional radiation fibrosis rather than simple isolated capsular contracture, as would be seen in breast augmentations.

Breast Implant–Associated Anaplastic Large Cell Lymphoma

Recognized by the World Health Organization as a new form of peripheral T cell non-Hodgkin's lymphoma in 2016, breast implant–associated anaplastic large cell lymphoma (BIA-ALCL) is a lymphoma arising within the capsule of breast implants and is currently thought to arise in relation to textured devices. The true incidence is unknown, but current estimates place it between 1 in 3407 to 30,000 women with textured implants. The etiology of BIA-ALCL remains elusive but toxic activation of the immune system in relation to either subclinical infection, inflammation, or response to foreign material is considered the underlying drive for lymphomagenesis. Patients commonly present with late-onset effusions of the breast (on average, 7 years after insertion), or, less commonly, with a lump. BIA-ALCL is anaplastic lymphoma kinase negative and CD30 positive. For disease confined to the capsule, capsulectomy alone is curative but adjuvant therapies, such as chemotherapy (cyclophosphamide, doxorubicin hydrochloride, vincristine sulfate, and prednisone) or monoclonal antibodies (brentuximab vedotin, anti-CD30) may be required if extracapsular spread is evident.

Implant Infections

Implant infections can arise in the early postoperative period or even much later as a result of systemic bacteremia from any other cause (e.g., urinary sepsis, dental work). Most commonly, patients will present with a red breast and a history of pyrexia or feeling generally unwell. Implant infections should be managed by systemic antibiotics, and if no improvement then explantation of the implant and irrigation of the pocket before closure over closed suction drainage. In exceptional circumstances, it may be possible to irrigate and replace the implant in the immediate setting, but infection rates are high and patients must be counselled accordingly.

Autologous Reconstruction

Autologous breast reconstruction is gaining in popularity because of the problems associated with implant-based reconstructions for cancer. Autologous reconstruction is most commonly performed following the completion of radiotherapy because this is known to be harmful to normal tissues and leads to volume loss, fat necrosis, and contracture. The primary advantage of autologous reconstruction is that prosthetic devices are not used and reconstructions have a more natural feel as they are made of vascularized tissue. Disadvantages relate to the management of the donor site and include long scars, delayed healing, seroma formation, and possible muscle weakness. Although autologous reconstructions require a greater investment of time at the time of reconstruction, over a lifetime they offer better outcomes and incur less of a healthcare and economic burden than implant-based reconstructions.

Donor tissue can be obtained from a variety of anatomical sites but in the current era the first line in autologous reconstruction is an abdominally based free flap such as the deep inferior epigastric artery perforator (DIEP), muscle sparing transverse rectus abdominis myocutaneous, free TRAM (fTRAM), or superficial inferior epigastric artery (SIEA) flap. Other donor sites for free tissue transfer include

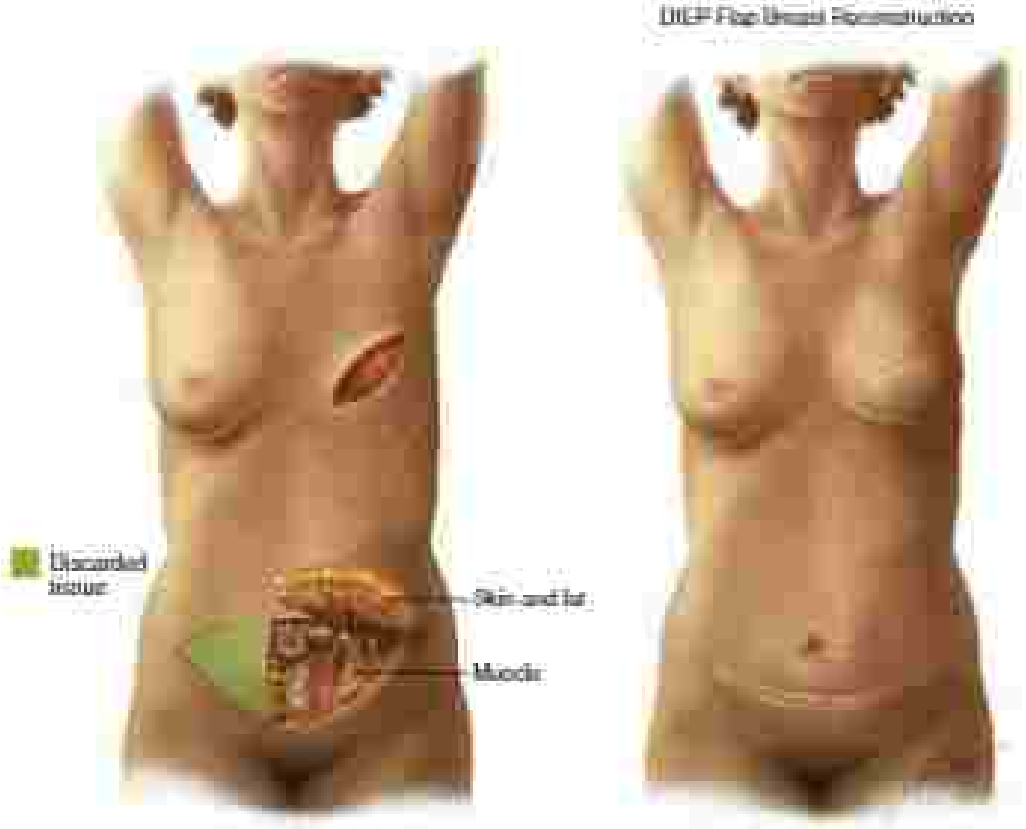

FIG. 2. Deep inferior epigastric artery perforator flap illustration.

the thigh (transverse upper gracilis [TUG], profunda artery perforator flaps), the buttock (superior gluteal artery perforator [SGAP] or inferior [IGAP]), or the back (lumbar artery perforator). In addition, the latissimus dorsi myocutaneous and pedicled TRAM flaps remain valuable fall back options if the above microsurgical options are not feasible or have failed.

Abdominal Free Flaps (DIEP, Muscle-Sparing TRAM, fTRAM, SIEA)

With the exception of the SIEA flap, all other abdominal free flaps derive their blood supply from the deep inferior epigastric artery (Fig. 2). The skin of the abdomen is supplied by perforating blood vessels from this axis that traverse the rectus abdominis muscle in a predictable manner. Depending on the pattern of supply, the skin/fat of the abdomen can be raised on the deep inferior epigastric artery with a varying degree of accompanying muscle. In the majority of patients, it is possible to raise this flap without sacrificing muscle because the perforator supply is robust enough to supply the flap on one to two perforators of suitable caliber. Consequently, donor site morbidity is minimized by preserving the musculature to reduce the risk of later bulge/hernia. In some instances, however, the caliber of perforators is too small and as, to ensure adequate blood supply to the flap, some or all of the rectus muscle must be included. Both sides of the abdomen can be harvested to reconstruct both breasts at the same time, or both sides can be used to reconstruct one breast where greater volume is required. In rare cases, the dominant blood supply to the abdomen comes not from the deep inferior epigastric artery but from the superficial system (SIEA). In these cases, the flaps can be raised on the SIEA without violating the anterior rectus fascia at all; however, SIEA flaps are at higher risk of developing fat necrosis and their blood supply is not as predictable as that from the deep system. Abdominal flaps can also be raised with cutaneous nerves that pierce the anterior rectus fascia to supply the overlying skin. These can be coapted to nerves at the recipient site with a view to restoring protective and proprioceptive sensation to the breast. The incidence of abdominal bulge/hernia is reported to range from 1% to 3% for DIEP flaps to up to 20% with TRAM flaps. It is therefore recommended that where muscle is taken, a formal permanent mesh repair is performed to reduce the risk of this. The resultant donor site scar from an abdominal flap harvest is designed to stay as low as possible based on the perforator location seen on three-dimensional computed tomography angiogram or magnetic resonance imaging angiogram and extends from hip to hip.

While the flap is being raised, the breast pocket is created and recipient vessels exposed (Fig. 1). Most commonly the internal mammary artery and vein (internal mammary vessels) are used as recipients and can be exposed either by removal of the second, third, or fourth costal cartilage or by dissection at the interspace. Other recipient vessels that can be used are the thoracodorsal vessels in the axilla. Microvascular anastomoses between flap and recipient vessels usually proceed by first connecting the veins using a venous coupling device before then performing a handsewn anastomosis of the artery under the microscope. The flap is then inset and shaped to match the contralateral side and the patient recovers. Free flaps require intensive monitoring for the first 48 to 72 hours postoperatively to ensure that the vascular supply (inflow and outflow) are maintained.

Thigh Free Flaps

The thigh is currently regarded as the second line choice for autologous tissue when the abdomen is unavailable and offers a discrete donor site scar in the groin crease. The TUG myocutaneous flap is based on perforating blood vessels traversing the gracilis muscle to supply the overlying skin. The flap is raised to include the gracilis muscle on the descending branch of the medial circumflex femoral artery. The profunda artery perforator flap is also raised from the medial thigh but sits posteriorly to the TUG flap. It is supplied by the perforating branches (second or third) of the profunda artery that pierce adductor magnus posterior to the gracilis. The advantage of this over the TUG is that it usually offers a longer pedicle, however, both medial thigh flaps usually offer only a small amount of volume for insetting and bilateral flaps (or an implant) can be required to achieve greater reconstructed volume. The disadvantage of the thigh

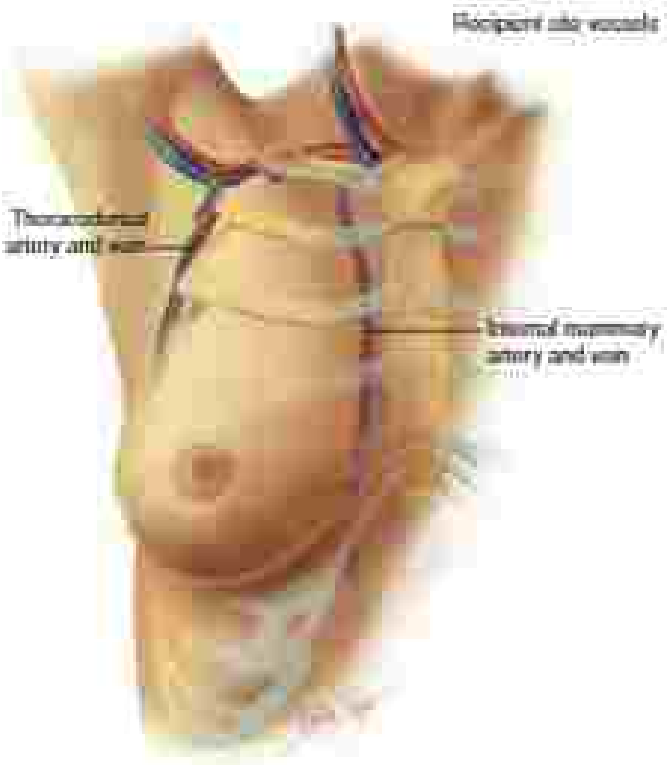

FIG. 3 Most common recipient vessels for autologous microvascular breast reconstruction.

donor site is that it can be difficult to heal, is prone to wound breakdown, and prolonged seroma formation.

Gluteal Free Flaps

Gluteal flaps are based on perforators from either the superior or inferior gluteal arteries. These flaps are not as popular as they once were because they have been superseded by medial thigh flaps. Advantages of the GAP flaps are that they offer a discrete gluteal scar; however, raising the flaps is very challenging, the pedicle length is always short, and the quality of the fat being transferred is much more rigid than abdominal or medial thigh fat and lacks the feel of a breast. In addition, GAP flaps are logistically challenging because they require the patient to be turned intraoperatively.

Pedicled Flaps for Breast Reconstruction

Latissimus Dorsi

The latissimus dorsi flap is raised from the back as a myocutaneous flap pedicled on the thoracodorsal artery. Various design options for the cutaneous element exist but most commonly the skin paddle can be designed transversely below the tip of scapula to be hidden in the bra line when closed. For breast reconstruction specifically, the extended latissimus dorsi flap is preferred where the muscle is raised with overlying fat and with discrete pockets of fat (e.g., scapular) to enhance the volume for transfer. More recently, immediate lipofilling of latissimus flaps has become popular because this can also increase significantly the volume for transfer; alternatively, the latissimus can be used in combination with a breast implant to achieve volume. Advantages of this procedure include a shorter operative time and reliability but, on its own, the latissimus flap rarely provides sufficient volume to reconstruct a breast. The donor site can be problematic with prolonged seroma drainage and larger studies suggest that there may be some degree of upper limb weakness attributable to it. In addition, the latissimus flap can be at risk of developing challenging animation deformities if the thoracodorsal nerve is not identified and cut at the time of surgery.

TRAM Flap

TRAM flaps are designed from the lower abdomen in the same way as DIEP/TRAM flaps, however, they are raised pedicled on the costal origins of the rectus abdominis. The blood supply to these flaps comes from the superior epigastric artery, but the cutaneous supply from this axis is not as robust as the deep inferior epigastric artery system. The incidence of fat necrosis and partial flap loss is consequently higher in these flaps and so the volume of tissue that can be transferred reliably is less. Abdominal wall weakness is inherent in this procedure because the entire rectus muscle is harvested.

Lipofilling

Fat grafting, fat transfer, or lipofilling has become a very useful tool in the second stage breast reconstruction to deal with minor contour deformities, or to add volume or soft tissue coverage over implants. It is also very good for managing skin changes after radiation; recent data suggest that fat grafting reduces inflammation and hypoxia in irradiated tissues. The volumes of fat that can be transferred are limited and, typically, 50% to 80% of the transferred volume will be resorbed with time, hence the requirement for multiple stages of lipofilling to achieve the desired clinical goals.

Lipofilling is performed by harvesting fat from suitable donor site areas (not the abdomen if an abdominal free flap may be used) using traditional wet liposuction techniques. The lipoaspirate is then processed to separate the cellular fat components (consisting of adipose-derived stem cells and adipocytes) from the oil and blood components. This can be achieved by centrifugation (Coleman's technique) or longer techniques using commercial devices that wash away the fat and aspirate the undesired elements. The cellular fat component is then loaded into syringes and injected using a blunt lipofilling cannula. The fat is deposited in multiple layers (subcutaneous, superficial, subfascial) within the target areas to gradually build up the volume. Advantages of the procedure are that it can be performed in the day case setting and works very well where retention is good. Disadvantages include unpredictability with outcome and the need for multiple procedures. There is also a theoretical risk that the transfer of stem cells into a resected tumor bed might encourage recurrence but this has not been borne out in larger clinical studies. Some centers have reported complete breast reconstruction with multiple sessions of serial fat grafting, thus obviating the need for implants and/or flaps in certain select patients.

Adrenal Incidentaloma

Ibeoma T. Nwagu, MD, and Quan-Yang Duh, MD

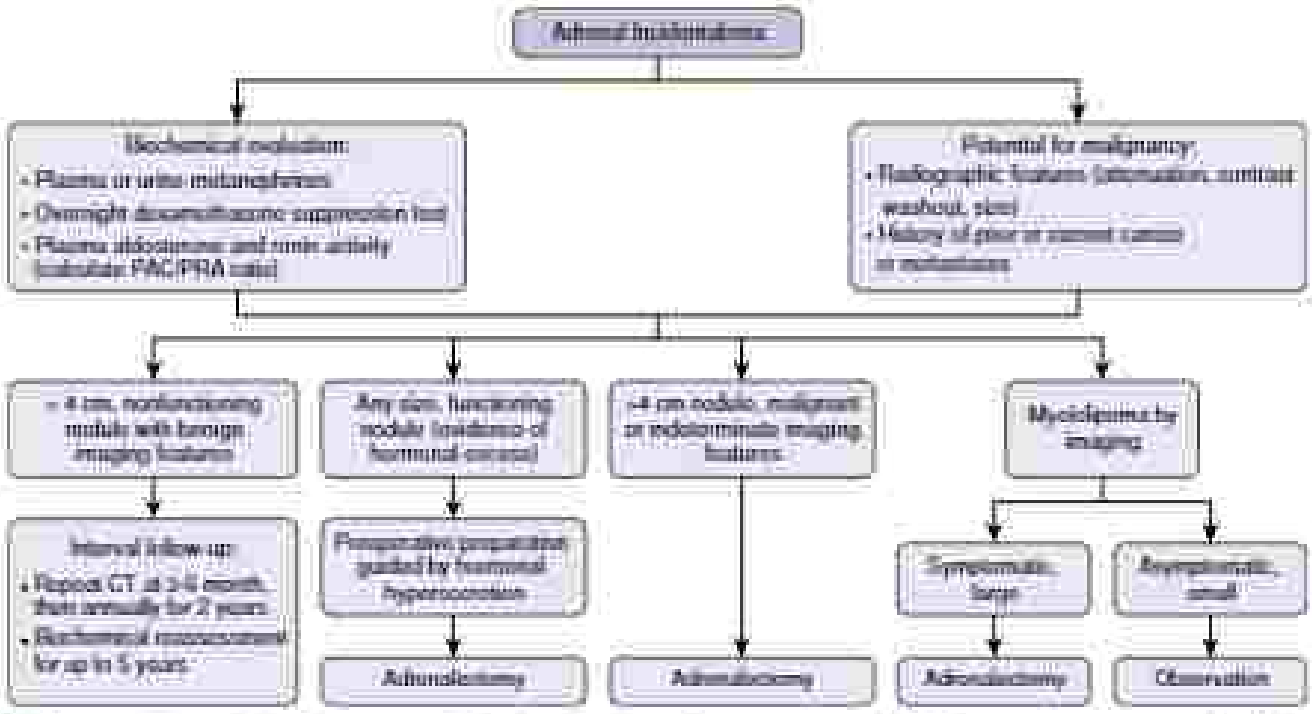

FIG. 1 Algorithm for the evaluation and [illegible] a patient with [illegible] CT, [illegible] to age [illegible] years, [illegible] plasma renin ratio.

TABLE 1 Imaging Features That May Help to Distinguish Benign and Malignant Adrenal Lesions[a] in Identical [illegible]

	Benign		Malignant	
Imaging Features	Lipid-Rich Adenoma	Lipid-Poor Adenoma	Adrenocortical Carcinoma	Pheochromocytoma or Extra-adrenal Paraganglioma
Noncontrast CT	<10 HU	< 10 HU	> 10 HU	> 10 HU
CT scan with contrast	<30 HU; rapid washout of contrast (> 50%)	<30 HU; rapid washout of contrast (> 50%)	> 30 HU; no rapid washout of contrast	> 30 HU; No rapid washout of contrast
Size	Usually <3 cm	Usually <3 cm	Usually > 5 cm	Variable size
Growth rate	Usually stable	Usually stable	Usually significant growth	Usually significant growth

CT = computed tomography, HU = Hounsfield unit.

CT scans today are done with contrast enhancement and therefore unenhanced attenuation measurements cannot be obtained unless dual imaging was originally performed, and (2) up to 30% of adenomas are lipid poor and, hence, have attenuation values greater than 10 HU (Table 1).

Another imaging feature that can prove useful in the characterization of adrenal nodules when contrast-enhanced CT scans are performed is a phenomenon termed contrast washout, in which adenomas take up the intravenous contrast rapidly but also rapidly lose the contrast medium on delayed images. Malignant lesions usually enhance rapidly but have a slower washout of the contrast medium. Lipid poor adenomas, which have higher HU measurements similar to malignant lesions on unenhanced CT, show a rapid contrast washout on contrast-enhanced CT, just like the lipid rich adenomas. Thus, contrast washout kinetics allows a distinction to be made between lipid poor adenomas and malignant lesions. Studies have shown that a relative contrast washout of 50% or greater on the 10-minute delay images of a contrast-enhanced CT has a 98% sensitivity and a 100% specificity for characterizing adenomas (Fig. 1).

Fine-Needle Aspiration Biopsy

The role of fine-needle aspiration (FNA) biopsy has a very limited role in the diagnostic evaluation of the adrenal incidentaloma. Mansfield and Meschia showed in their retrospective analysis that cytopathology from an FNA biopsy was unhelpful in distinguishing between benign and malignant primary adrenal lesions. Its value was largely in the diagnosis of metastatic carcinoma to the adrenal gland in patients with a nonadrenal primary malignancy.

Other studies evaluating the role of FNA biopsy in the adrenal incidentaloma concluded that the FNA biopsy rarely changed management and was associated with a significant risk of complications (including hematoma, pain, error or delay in diagnosis, and inadvertent biopsy of a pheochromocytoma with resulting severe hypertension) and subsequent increased difficulty of adrenalectomy. Vandewiele and Thompson et al. specifically noted biopsy-related complications in 25% of their patients who underwent FNA biopsy of their adrenal tumors. In light of this, we typically recommend not performing an adrenal FNA biopsy. We find that clinicians can almost always make the decision to proceed with adrenalectomy based on clinical, biochemical, and radiologic assessment alone.

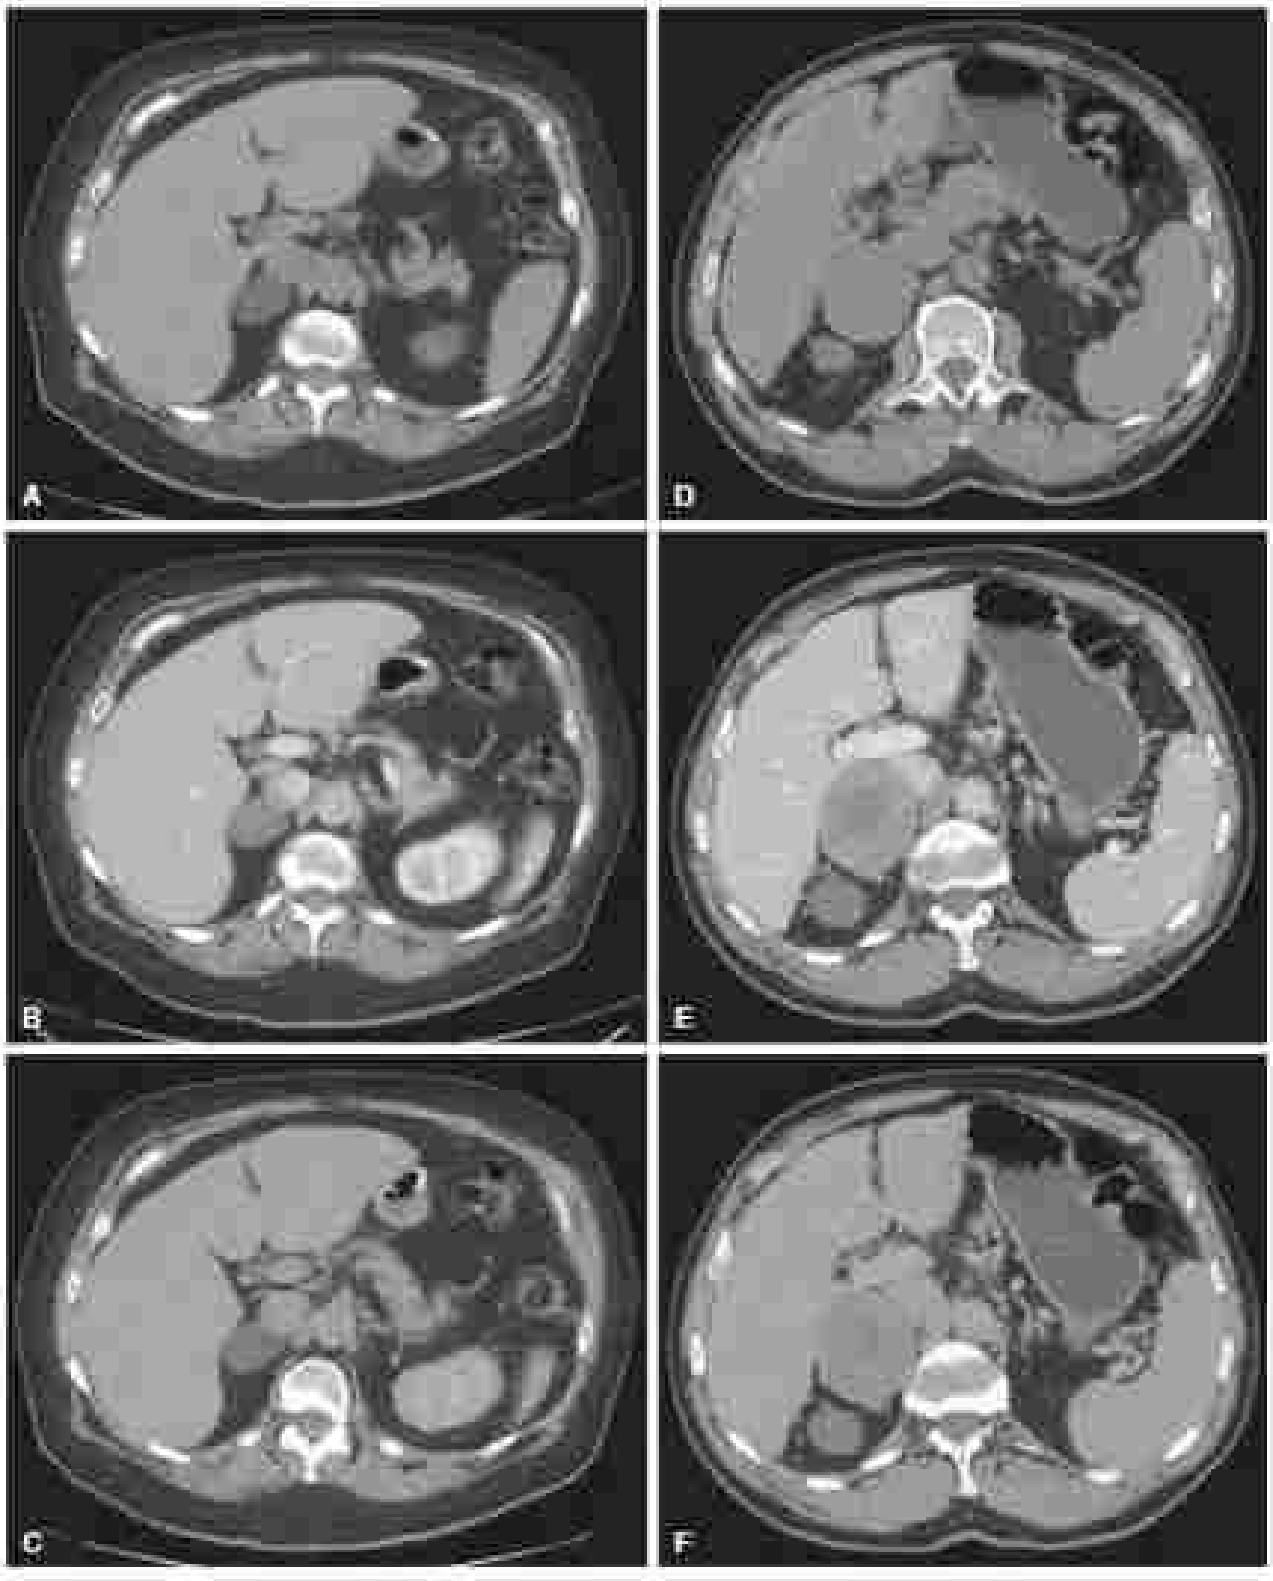

FIG. 2. Cross-sectional computed tomography scans showing a benign adrenal adenoma and an adrenocortical carcinoma. (A) Noncontrast image of a benign adenoma showing a homogeneous lesion with an low attenuation of −3 Hounsfield units (HU). (B) Contrast-enhanced computed tomography scan (portal venous phase) showing rapid contrast uptake with attenuation of 61 HU. (C) Contrast-enhanced computed tomography scan (delayed phase) showing rapid contrast washout with attenuation of 52 HU (relative contrast washout of 39.2%). (D) Noncontrast image of an adrenocortical carcinoma showing a high attenuation lesion (47 HU). (E) Contrast-enhanced computed tomography scan (portal venous phase) of an adrenocortical carcinoma showing a heterogeneous lesion with attenuation of 72 HU. (F) Contrast-enhanced computed tomography scan (delayed phase) showing slow contrast washout with attenuation of 71 HU (relative contrast washout of 1%).

Assessment for Adrenal Hormone Excess

Hormone assessment is critical to the workup of an adrenal incidentaloma as biochemically active lesions should undergo resection (Fig. 1). Several factors should be considered when performing a biochemical evaluation in a patient with an adrenal nodule, including patient age, sex, medications, and limitations of assays or varying reference ranges of tests. With these important considerations in mind, we recommend performing the following tests on all patients with a new adrenal incidentaloma.

Screening for Hypercortisolism

If no clinical features of hypercortisolism, an overnight 1 mg dexamethasone suppression test should be performed. Here, the patient is instructed to take 1 mg of dexamethasone the night before a blood draw. Serum cortisol levels are checked the following morning between 8 AM and 9 AM. In normal individuals, the cortisol level should suppress to less than 1.8 μg/dL. A cortisol level above 5 μg/dL after administration of dexamethasone is usually diagnostic of hypercortisolism. Cortisol levels between 1.8 and 5 μg/dL should spur further workup for possible hypercortisolism. The patient usually undergoes confirmatory testing with an adrenocorticotropic hormone (ACTH) level as well as a 24-hour urinary cortisol level or a midnight salivary cortisol level. An elevated urinary cortisol and a low or suppressed ACTH level further support the diagnosis.

Screening for Hyperaldosteronism

Plasma potassium, aldosterone, and renin activity are measured and a ratio of plasma aldosterone concentration to the plasma renin activity is calculated. A ratio of more than 20 while not taking mineralocorticoid receptor antagonists such as spironolactone should spur further confirmatory testing with aldosterone suppression testing: either a saline infusion test or a 24-hour urinary aldosterone test while the patient maintains a high sodium diet. Patients should be off mineralocorticoid receptor antagonists for 4 weeks before testing.

Once primary hyperaldosteronism is confirmed, it is important to differentiate idiopathic hyperaldosteronism from bilateral cortical hyperplasia. Adrenal vein sampling for aldosterone and cortisol is recommended for all patients with bilateral adrenal nodules, a unilateral nodule less than 1 cm, normal appearing glands, or age older than 45 years to determine if there is unilateral aldosterone hypersecretion which would be amenable to surgical management.

Screening for Pheochromocytoma

The simplest screening test to rule out pheochromocytoma is measurement of plasma free metanephrines (metanephrines and normetanephrines). False-positive results, primarily with the normetanephrine component of the assay, can occur. If either the metanephrine or normetanephrine is elevated mildly, then further testing with 24 hour urine for catecholamines and fractionated metanephrines should be done to confirm or rule out this diagnosis.

Screening for Sex Hormone-Secreting Tumors

Screening for virilizing or feminizing tumors is only performed if suggestive clinical features or suspicion for adrenocortical carcinoma is present. Plasma dehydroepiandrosterone sulfate levels should be measured. Elevated levels are concerning for an adrenocortical carcinoma. 17 β-estradiol can also be checked if clinical features of feminization are noted in men and postmenopausal women only.

Management

In patients with a unilateral adrenal incidentaloma, surgery is usually indicated for the following:

- A hormonally active tumor
- A hormonally inactive tumor size greater than 4 cm and/or radiographic imaging features
- Any tumor, hormonally active or otherwise, with a rapid growth rate on serial imaging
- Known or suspected adrenocortical carcinoma
- Large, symptomatic myelolipomas
- Metastatic tumors

Laparoscopic adrenalectomy (transabdominal lateral approach) or retroperitoneoscopic approach) is the preferred approach for most patients with incidentalomas who require adrenalectomy. The exception is the patient with a large suspected adrenocortical carcinoma (greater than 10 cm) because of a greater difficulty in removing these tumors laparoscopically and the potentially increased risk of breaching the tumor capsule leading to higher local recurrence rates. Either the transabdominal lateral or the retroperitoneoscopic approach can be considered for incidentalomas depending on local surgical expertise. The retroperitoneoscopic approach has the advantage of avoiding entry into the abdominal cavity particularly in patients who may have had prior intraabdominal operations and provides the most direct route to the adrenals. It is more difficult in patients with larger tumors (>4–5 cm) and who are obese (BMI >35); however. A laparoscopic approach appears to be appropriate for selected patients with adrenal metastases, provided the surgeon has substantial experience in performing laparoscopic adrenalectomy. Long-term follow-up studies of resection of adrenal metastases are lacking, however, so these patients should be approached with caution. Removal of an intact specimen with negative surgical margins should be the primary goal regardless of the nature of the underlying lesion.

Perioperative Management

The perioperative management is critical to the success of most adrenal operations and avoiding hormonal complications.

Patients with pheochromocytomas require pharmacologic preparation with an alpha adrenergic receptor blocker such as phenoxybenzamine or doxazosin for 1 to 3 weeks preoperatively to avoid intraoperative blood pressure instability. Therapy is started at a low dose and titrated upwards to achieve normotension. Occasionally, β-adrenergic blockade is given in addition to α-blockade for control of persistent tachycardia, arrhythmias, or hypertension. It should only be started after adequate α-blockade. Other important aspects of preoperative care for this group of patients include encouraging a high sodium diet and liberal fluid intake to counteract the catecholamine-induced intravascular volume depletion. Additionally, clinicians should consider screening patients diagnosed with pheochromocytomas for genetic syndromes. Postoperatively, phenoxybenzamine is discontinued and close monitoring for hypotension and hypoglycemia is instituted. Other antihypertensive medications should be resumed only if it appears the patient has underlying essential hypertension. The exception to this rule is in the instance of long-standing beta adrenergic receptor blocker therapy, where abrupt discontinuation perioperatively is not advised.

Patients with hypercortisolism generally need preoperative optimizing of the specific comorbidities associated with their disease such as hypertension, diabetes, dyslipidemia, infections, and poor physical fitness. These patients also benefit from venous thromboembolism prophylaxis perioperatively because they are at significantly increased risk of developing thromboembolic complications. Hypercortisolism also increases the risk of wound complications and stress ulcer formation so perioperative prophylactic antibiotics and perioperative stress ulcer prophylaxis should be given. Further, these patients may undergo a period of adrenal insufficiency after adrenalectomy and should be given supplemental glucocorticoids perioperatively. In uncertain cases, a morning plasma cortisol level and/or ACTH stimulation tests on postoperative day 1 may be obtained and glucocorticoid replacement therapy initiated if the cortisol level is low.

Patients with hyperaldosteronism are almost always treated preoperatively with a mineralocorticoid receptor antagonist, such as spironolactone. Some might still require potassium supplementation. In the postoperative period, mineralocorticoid receptor antagonists

are stopped and close blood pressure monitoring is initiated. Other antihypertensive medications are reduced or stopped to maintain normotension. Sawka et al. showed that factors such as having one or more relatives with hypertension as well as the preoperative use of two or fewer antihypertensive medications were associated with postoperative resolution of hypertension. In our experience also, patients who have had longstanding hypertension are generally unable to be weaned off all antihypertensive medications postoperatively and normotension without drug treatment may never be achieved in this group, likely because of the vascular remodeling that occurs. Additionally, postoperative potassium supplementation is withdrawn (including in the multivitamin intravenous fluids). The Endocrine Society clinical practice guidelines for management of primary aldosteronism recommend measurement of serum potassium and aldosterone levels the morning after surgery as an early indication of biochemical response.

Follow-up of Adrenal Incidentalomas

Recommended Follow-up if Adrenal Adenoma Was Performed

In the immediate postsurgical period, it is imperative to review the surgical pathology report to ensure concordance with the preoperative diagnosis. In the long term, patients with pheochromocytomas should undergo annual biochemical testing with plasma metanephrines to identify possible recurrence which can occur in up to 16% of patients with benign disease. Patients with hypercortisolism often require glucocorticoid therapy postoperatively. The replacement is weaned under the guidance of an endocrinologist when the hypothalamic-pituitary-adrenal axis has recovered, typically within 6 to 18 months in most adults. In all of these patients, blood pressure monitoring and antihypertensive medication wean remains important as normotension could take several months to achieve.

Recommended Follow-up of an Incidentaloma if Surgery Was Not Performed

Patients with nonfunctioning adrenal incidentalomas that have benign radiographic features with sizes smaller than 4 cm do not need to have immediate surgery. In these patients, the recommended follow up is repeat cross sectional imaging with CT at 3 to 6 months and then annually for the next 1 to 2 years. A recent cost effectiveness analysis showed that more frequent imaging or a longer duration of imaging surveillance is without incremental benefit and is not cost effective. Biochemical screening is recommended annually for up to 5 years. Surgical excision should be considered for lesions that increase in size or have emerging evidence of hormonal hyperactivation. Beyond the initial 5-year period, the expert guidelines do not address what the subsequent follow up should be for a stable, hormonally inactive adrenal incidentaloma.

Management of Adrenal Cortical Tumors

Barbra S. Miller, MD

Adrenal tumors are increasingly being diagnosed, currently with a prevalence of 4% to 10% due to the surge in use of multiple imaging modalities. With this, the rate of adrenalectomy nearly doubled in just over a decade. Adrenal nodules of cortical origin are most commonly found incidentally on imaging studies pursued for various unrelated reasons. Adenomas, metastases to the adrenal gland, pheochromocytomas, myelolipomas, angiomyolipomas, cystic neoplasms, cysts, lymphoma, and abscesses/infections of various origin have been described. Adrenocortical carcinoma (ACC) is an extremely rare malignancy with an incidence of 1 to 2 per million in the population. As classic pheochromocytoma is of medullary origin, there will be limited further discussion of this type of adrenal tumor. Adrenocortical nodules may also be identified if suspicion of adrenal hormone excess is noted based on patient history, physical examination, or laboratory studies and imaging pursued as a result.

Formal evaluation of a patient with an adrenal nodule begins with taking a complete personal and family history and performing a full physical examination. Specific evaluation of an adrenal nodule is completed by seeking evidence of adrenal hormone excess and characterizing tumor appearance by imaging studies. The history should focus on onset of any hypertension, electrolyte abnormalities, signs or symptoms associated with hypercortisolism (Cushing disease or syndrome), pheochromocytoma, or primary aldosteronism (Conn) syndrome. Changes in secondary sexual characteristics may indicate the presence of a virilizing or feminizing tumor. Signs and symptoms suggestive of primary aldosteronism may include hypertension, generalized edema, weight gain, muscle cramping due to hypokalemia, and weakness. Signs and symptoms consistent with hypercortisolism may include weight gain, hypertension, impaired glucose tolerance and diabetes, thinning of the skin, easy bruising, central adiposity, development of a buffalo hump, striae, proximal muscle weakness, and change in fat distribution from the periphery to the abdomen. Signs and symptoms associated with pheochromocytoma may include hypertension, episodic palpitations, diaphoresis, sudden onset headaches, pallor, anxiety, or feeling of doom. These may be exacerbated in certain situations or after eating certain foods. A family history should be taken to investigate the possibility of a genetic mutation driving development of an adrenal abnormality. This will also prompt possible investigation for other disease processes that may be part of a particular genetic syndrome (multiple endocrine neoplasias, von Hippel-Lindau, neurofibromatosis, etc.). Patients should be questioned about a previous history of malignancy or any signs or symptoms, which may lead to consideration of recurrent metastatic disease or a previously undiagnosed malignancy.

Biochemical evaluation of an adrenocortical nodule in most should be carried out in a systematic fashion. In patients found to have evidence of adrenal hormone excess, 25% have subclinical disease. Biochemistry commonly obtained as part of the hormonal evaluation can be noted in Table 1. If there is suspicion for adrenal hormone excess based on laboratory results, adrenal specific imaging should then be pursued if not done already, the most common being an adrenal protocol computed tomography (CT) scan (Fig. 1) with magnetic resonance imaging (MRI) as an alternative modality. Routine CT of the abdomen or of the chest will not adequately evaluate an adrenal abnormality. Table 2 lists characteristics and criteria to differentiate benign from indeterminate adrenal masses. Various washout percentages, most commonly 50% to 60%, have been proposed as cutoffs to differentiate lipid poor benign adenomas from potentially malignant adrenal tumors. An alternative imaging modality to MRI. A 16% loss of signal between in- and out-of-phase images

are stopped and close blood pressure monitoring is initiated. Other antihypertensive medications are reduced or stopped to maintain normotension. Sawka et al. showed that factors such as having one or more relatives with hypertension as well as the preoperative use of two or fewer antihypertensive medications were associated with postoperative resolution of hypertension. In our experience also, patients who have had longstanding hypertension are generally unable to be weaned off all antihypertensive medications postoperatively and normotension without drug treatment may never be achieved in this group, likely because of the vascular remodeling that occurs. Additionally, postoperative potassium supplementation is withdrawn (including in the multivitamin intravenous fluids). The Endocrine Society clinical practice guidelines for management of primary aldosteronism recommend measurement of serum potassium and aldosterone levels the morning after surgery as an early indication of biochemical response.

Follow-up of Adrenal Incidentalomas

Recommended Follow-up if Adrenalectomy Was Performed for Treatment

In the immediate postsurgical period, it is imperative to review the surgical pathology report to ensure concordance with the preoperative diagnosis. In the long term, patients with pheochromocytomas should undergo annual biochemical testing with plasma meta-nephrines to identify possible recurrence which can occur in up to 16% of patients with benign disease. Patients with hypercortisolism often require glucocorticoid therapy postoperatively. The replacement is weaned under the guidance of an endocrinologist when the hypothalamic-pituitary-adrenal axis has recovered, typically within 6 to 18 months in most adults. In all of these patients, blood pressure monitoring and antihypertensive medication wean remains important as normotension could take several months to achieve.

Recommended Follow-up of an Incidentaloma if Surgery Was Not Performed

Patients with nonfunctioning adrenal incidentalomas that have benign radiographic features with sizes smaller than 4 cm do not need to have immediate surgery. Management of Adrenal Cortical Tumors

Barbara S. Miller, MD

Adrenal tumors are increasingly being diagnosed, currently with a prevalence of 4% to 10% due to the surge in use of multiple imaging modalities. With this, the rate of adrenalectomy nearly doubled in just over a decade. Adrenal nodules of cortical origin are most commonly found incidentally on imaging studies pursued for various unrelated reasons. Adenomas, metastases to the adrenal gland, pheochromocytomas, myelolipomas, angiomyolipomas, adrenocortical neoplasms, cysts, lymphoma, and abscesses of infectious origin have been described. Adrenocortical carcinoma (ACC) is an extremely rare malignancy with an incidence of 1 to 2 per million in the population. Because pheochromocytoma is of medullary origin, there will be limited further discussion of this type of adrenal tumor. Adrenocortical nodules may also be identified if suspicion of adrenal hormone excess is noted based on patient history, physical examination, or laboratory studies and imaging pursued as a result.

Formal evaluation of a patient with an adrenal nodule begins with taking a complete personal and family history and performing a full physical examination. Specific evaluation of an adrenal nodule is completed by seeking evidence of adrenal hormone excess and characterizing tumor appearance by imaging studies. The history should focus on onset of any hypertension, electrolyte abnormalities, signs or symptoms associated with hypercortisolism (Cushing disease or syndrome), pheochromocytoma, or primary aldosteronism (Conn) syndrome. Changes in secondary sexual characteristics may indicate the presence of a virilizing or feminizing tumor. Signs and symptoms suggestive of primary aldosteronism may include hypertension, generalized edema, weight gain, muscle cramping due to hypokalemia, and weakness. Signs and symptoms consistent with hypercortisolism may include weight gain, hypertension, impaired glucose tolerance and diabetes, thinning of the skin, easy bruising, central adiposity, development of a buffalo hump, striae, proximal muscle weakness, and change in fat distribution from the periphery to the abdomen. Signs and symptoms associated with pheochromocytoma may include hypertension, episodic palpitations, diaphoresis, sudden onset headaches, pallor, anxiety, or feeling of doom. These may be exacerbated in certain situations or after eating certain foods. A family history should be taken to investigate the possibility of a genetic mutation driving development of an adrenal abnormality. This will also prompt possible investigation for other disease processes that may be part of a particular genetic syndrome (multiple endocrine neoplasias, von Hippel Lindau, neurofibromatosis, etc.). Patients should be questioned about a previous history of malignancy or any signs or symptoms, which may lead to consideration of recurrent metastatic disease or a previously undiagnosed malignancy.

Biochemical evaluation of an adrenocortical nodule or mass should be carried out in a systematic fashion. In patients found to have evidence of adrenal hormonal excess, 25% have subclinical disease. Biochemistry commonly obtained as part of the hormonal evaluation can be noted in Table 1. If there is suspicion for adrenal hormone excess based on laboratory results, adrenal specific imaging should then be pursued if not done already, the most common being an adrenal protocol computed tomography (CT) scan (Fig. 1) with magnetic resonance imaging (MRI) as an alternative modality. Routine CT of the abdomen or of the chest will not adequately evaluate an adrenal abnormality. Table 2 lists characteristics and criteria to differentiate benign from indeterminate adrenal masses. Various washout percentages, most commonly 50% to 60%, have been proposed as cutoffs to differentiate lipid poor benign adenomas from potentially malignant adrenal tumors. An alternative imaging modality to MRI. A 16% loss of signal between in- and out-of-phase images

is consistent with a benign nodule or mass. In the case of an indeterminate lesion, positron emission tomography (PET) CT may also be used to help differentiate between a benign and potentially malignant mass; however, one should be aware of the pitfalls for various cancers in terms of ^{18}F-FDG avidity. Adrenal cancer is ^{18}F-FDG avid and whereas renal cell cancer is not particularly ^{18}F-FDG avid. Some centers in Europe are using ^{11}C metomidate PET imaging as well as urinary steroid profiles to help differentiate between benign and malignant primary adrenocortical tumors. Imaging evaluation of adrenal masses and differentiation of benign versus potentially malignant adrenal lesions is extremely important because it helps inform the selection of an appropriate operative procedure as surgery for benign adrenal tumors and primary ACC is different.

ROLE OF FINE-NEEDLE ASPIRATION

There is a very limited role for fine-needle aspiration (FNA) of adrenal nodules. The ability to discriminate between benign adrenal tumor and ACC is poor, and the undesirable possibility of seeding the needle tract with tumor has been reported. Treatment should be based on biochemical and radiologic imaging characteristics. The most common circumstance for which FNA may be considered in patients with adrenal masses is (1) patients who are poor operative candidates and need a diagnosis to guide additional treatment, (2) patients with suspected metastatic disease in which the adrenal mass is the most easily accessible metastatic tumor deposit, (3) suspected adrenal lymphoma or abscess/infection due to an infectious etiology (tuberculosis, histoplasmosis) which are often bilateral, (4) patients with presumed unresectable ACC and without evidence of hormonal excess where tissue confirmation is necessary to guide neoadjuvant or palliative chemotherapy. FNA in other situations is not particularly helpful. If FNA of an adrenal mass is pursued, pheochromocytoma must be ruled out before biopsy because hypertensive crisis may result.

TABLE 1 Initial Biochemical Evaluation of Adrenal Tumors

Routine	Consider
Metabolic panel	17-OH progesterone
Aldosterone	17-OH pregnenolone
Renin	11-deoxycortisol
Plasma or 24-hour urine metanephrine and normetanephrine levels	Progesterone
1 mg DST with 0800 ACTH, cortisol	Androstenedione
24-hour urine free cortisol	Estradiol
DHEAS	FSH
Testosterone (total or bioavailable)	LH

ACTH, Adrenocorticotropic hormone; DHEAS, dehydroepiandrosterone sulfate; DST, dexamethasone suppression test; FSH, follicle stimulating hormone; LH, luteinizing hormone.

DECISION TO OPERATE

The decision to proceed with adrenalectomy is based on imaging characteristics, size, and evidence of hormone excess.

Imaging Characteristics and Size

Tumor size alone should not dictate the need for adrenalectomy. In the past, tumor size greater than 4 or 6 centimeters alone was used as a cutoff given an increase in rate of malignancy; however, more recently, imaging characteristics (taking into account washout percentages) are considered in combination with size. A purely nonfunctional tumor with benign imaging characteristics greater than 4 to 6 cm does not necessarily need resection based on size alone. Follow-up imaging should be obtained 6 to 12 months later to assess for change in size or imaging characteristics. Myelolipomas and other benign adrenal tumors may grow to fairly large sizes without causing significant symptoms. Local symptoms of compression in the form of pain or early satiety are not well studied, but tumors can grow to become quite large and result in minimal to no symptomatology. If a benign-appearing tumor reveals evidence of growth, resection is indicated. A decision to pursue resection for benign-appearing nonfunctional tumors reaching 6 to 10 cm may also be made because tumors of this size are still potentially amenable to a minimally invasive approach. With growth, an open approach is more likely needed simply to remove the tumor through an incision because mobilization of an adrenal tumor is to be avoided to allow for adequate pathologic examination. Patient age and comorbidities should also be taken into consideration to aid in the decision-making process regarding resection of benign nonfunctional tumors. In those patients who are young, continued follow-up over many years adds to medical costs, and the patient may prefer resection sooner rather than later, especially while still healthy and with few comorbidities. Patients with adrenal cysts need to be considered in a slightly different manner. Pure cysts without evidence of a solid component can often be

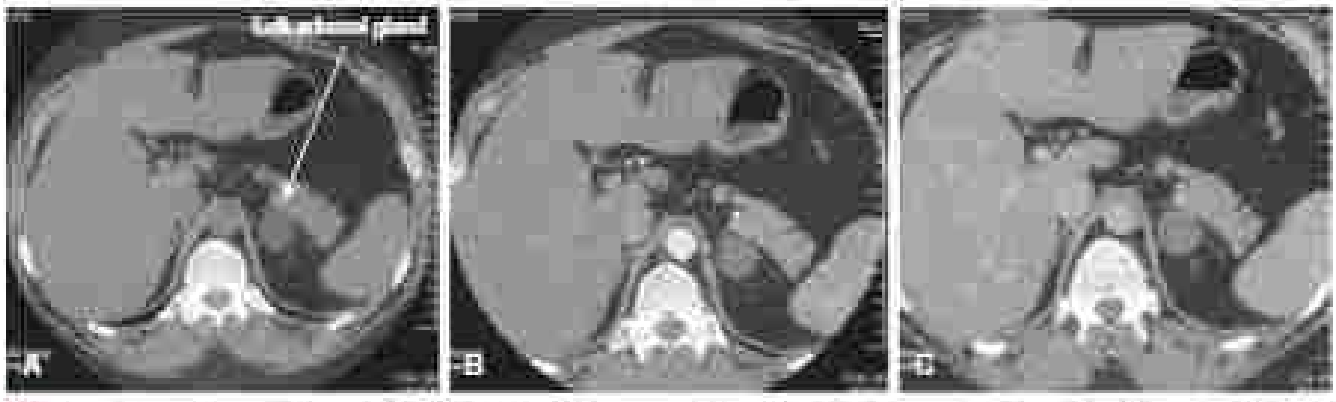

FIG. 1 Adrenal protocol computed tomography (CT) scan. (A) Initial noncontrast CT scan with thin cuts through the adrenal gland is obtained. If the nodule or mass is homogeneous Hounsfield units (HUs) are calculated. If HUs within the nodule are <10, contrast is administered and HUs again measured shortly thereafter (B) and again at 15 minutes (C). A washout percentage is then calculated.

TABLE 2 Imaging Characteristics Utilized to Differentiate Benign From Potentially Malignant Adrenal Tumors

Characteristic	Benign	Indeterminate
Size (cm)	<4 cm if other benign internal characteristics	>4–6 cm if other indeterminate characteristics
Unenhanced CT (Hounsfield units)	≤10	>10 and washout % indeterminate
Percentage washout on CT (if homogeneous tumor)	>60%–40%	<60%–40%
MRI chemical shift	≥50%	<50%
Internal attenuation	Homogeneous	Heterogeneous
Calcification	Absent	Present
Necrosis	Absent	Present
Borders	Regular	Irregular
Invasion of adjacent structures	Absent	Present
Intravascular tumor thrombus	Absent	Present
Lymphadenopathy	Absent	Present
6-NC-PET CT: Tumor SUV	<3.4	>3.4
6-NC-PET CT: Tumor/liver SUV ratio	<1.45	>1.45

CT, Computed tomography; 6-NC-PET CT, 6-beta-iodine-131-iodomethyl-19-norcholesterol positron emission computed tomography; MRI, magnetic resonance imaging.

observed. If small cysts less than 4 to 6 cm are noted to be slowly growing and all other imaging characteristics are otherwise benign, aspiration with injection of ethanol can be considered. The long-term durability of this approach is about 30%, with decreased success rates as cyst size increases. Cysts with a solid component harbor a small risk of malignancy, whereas those with cystic areas within a larger, more solid tumor, the risk of malignancy is even higher because fluid-filled portions may be due to tumor necrosis. Pheochromocytomas may show evidence of necrosis and fluid.

Biochemically Functional Versus Nonfunctional

Those patients with overt hormone excess due to a unilateral adrenal tumor are most often offered surgery as opposed to medical management. For those with hypercortisolism, the management of those with biochemical evidence of subclinical hormone excess can be more difficult from a decision-making standpoint. Most patients with subclinical hypercortisolism will be diagnosed by a one-milligram dexamethasone suppression test. For those with AM cortisol levels greater than 3 μg/dL, resection should be considered, whereas those with AM cortisol levels 1.8 to 3 μg/dL may be able to undergo surveillance. The decision for operation in these patients should be made in the context of the severity of other potential disease processes that may be attributable to hypercortisolism, such as hypertension, diabetes, weight gain, and bone density loss. Studies reporting outcomes of patients with subclinical hypercortisolism do show benefit after adrenalectomy; however, many of these studies have methodologic flaws, and accurately differentiating patients with subclinical disease from those with overt hypercortisolism can be difficult. For those with hypercortisolism due to bilateral excess adrenal production (adrenocorticotropic hormone dependent or independent disease and other types of hyperplasia), the decision for unilateral (starting with the largest adrenal) versus bilateral adrenalectomy should be made jointly with an endocrinologist.

Patients with primary aldosteronism need further evaluation to determine whether surgical resection is appropriate. Assuming the aldosterone level is greater than 15 ng/dL and the renin level is suppressed, an aldosterone/renin ratio greater than 30 suggests the diagnosis. Certain medications should be held before testing because it can affect the renin level most often. Confirmatory tests such as saline suppression tests and others may be pursued. The Endocrine Society published guidelines detailing the biochemical evaluation of these patients. CT imaging has found to be poor in terms of specificity for unilateral versus bilateral excess aldosterone secretion from the adrenal glands. Specificity averages about 40% to 50%. Therefore, once a clear biochemical diagnosis has been made, adrenal vein sampling should be pursued in most patients to determine the unilateral or bilateral nature of the excess hormone production. Understanding how to interpret these studies is critical, as is having an interventional radiologist with high success of entering the left adrenal vein and especially the right adrenal vein.

Aside from those with hormone excess, the decision for operation should also be based on the physical status of the patient and existing comorbidities. Some patients can be easily medically managed, and this may be more appropriate in patients with significant comorbidities. Patients with metastatic disease to the adrenal glands should be evaluated carefully to their overall prognosis as well as future planned therapy should be taken into consideration. Those with metastatic disease may be better served by other treatment modalities. Some malignancies are quite radiosensitive, and in the situation of an aggressive cancer with poor prognosis, radiation therapy or other types of local interventions may be more appropriate; however, these are not recommended as first- or second-line therapy.

For those with suspected or obvious ACC, a chest CT should be obtained as part of the routine preoperative evaluation to evaluate for metastatic disease. In those with metastatic disease, resection is usually delayed in favor of chemotherapy and mitotane, with a select few being able to undergo resection if all sites of disease can be addressed in some form or fashion (medical or procedural). Those with locally invasive tumors where an R0 resection would be unlikely may also benefit from neoadjuvant chemotherapy and mitotane for a period of time.

PREOPERATIVE CONSIDERATIONS

The individual patient's anatomy should be carefully studied when selecting an operative approach. The operative approach is not solely based on size alone, but also includes prior surgical history, concern for malignancy, need for access to other intra-abdominal organs, planned concomitant procedures elsewhere in the peritoneal cavity, cardiac and pulmonary status in terms of toleration of a lateral or

TABLE 3 Anatomic Features to Consider When Choosing Between Laparoscopic and Retroperitoneoscopic Adrenalectomy

Characteristic	Laparoscopic Approach	Retroperitoneoscopic Approach
Tumor size	<10 cm	<7–8 cm
BMI (kg/m^2)	Any BMI	<45
Subcutaneous adipose depth at twelfth rib	>5–6 cm	<5–6 cm
Retroperitoneal fat	Abundant	Sparse
Tumor position (anterior/posterior) relative to kidney	Any position	Adrenal gland in posterior or neutral position to plane of kidney
Position of adrenal gland in relation to renal vasculature	Any position	Separated and superior
Position of twelfth rib in relation to kidney	Rib overlies lower one third of kidney	Rib overlies upper two thirds of kidney
Previous upper abdominal surgery	No	Yes
Stage 3 or 4 renal insufficiency	Yes	No

BMI, body mass index.

TABLE 4 Medications Used to Decrease Excess Production of Adrenal Hormones

Type of Hormone Excess	Primary Medication	Alternative Medications
Cortisol	Metyrapone	Ketoconazole, mitotane, etomidate, mifepristone (ACC)
Aldosterone	Spironolactone	Eplerenone, amiloride
Testosterone	Spironolactone	
Estrogen	Tamoxifen	Raloxifene, anastrozole, letrozole, exemestane

ACC, Adrenocortical carcinoma.

prone position, body habitus, and position of the adrenal gland with respect to the renal vasculature and upper pole of the kidney from the standpoint of selecting an anterior or posterior approach. Important anatomic features to consider when choosing between a laparoscopic and retroperitoneoscopic approach are listed in Table 3.

An attempt to control hormonic excess and correct electrolyte abnormalities should be pursued if possible. Medications to assist in curbing excess hormone production are listed in Table 4. For those with primary aldosteronism, hypertensive control or hypertension is often best achieved with spironolactone or eplerenone. Creatinine, sodium, and potassium levels should be closely followed while titrating these medications. In addition to potassium supplementation, hypokalemia (which occurs in ~50% of patients) may also be controlled in part with amiloride. If patients are found to be hypokalemic in the preoperative area, lower doses than normal should be given due to the potential for rebound hyperkalemia in the postoperative setting.

In patients with hypercortisolism, exercise and consumption of a high-protein diet should be encouraged before surgery as much as possible given muscle deterioration due to the disease process. If time permits, several months of preoperative treatment with one of the previously listed medications can be helpful in better controlling the quantity of cortisol excess. During surgery, patients with overt hypercortisolism should be given stress dose steroids. If undergoing a bilateral adrenalectomy, stress dose steroids can be given after resection of the first adrenal gland. A standard stress dose steroid regimen is 50 to 100 mg of intravenous hydrocortisone every 8 hours. This is then tapered over several days to a lower maintenance dose until return of function of the hypothalamic–pituitary axis, which can take months to a year. Those with suspected subclinical disease may forego stress dose steroids if testing of the hypothalamic–pituitary–adrenal (HPA) axis is planned for the morning after surgery in the form of an early morning cortisol level or formal cosyntropin stimulation test.

OPERATIVE APPROACHES

Adrenalectomy may be accomplished by utilizing a number of approaches. Most commonly for small benign tumors, a laparoscopic transperitoneal approach is preferred. An alternative approach, for those with experience in adrenal surgery, is the posterior retroperitoneoscopic approach. The spleen and liver do not need to be mobilized, and blood loss is often diminished due to increased insufflation pressures and the need for less mobilization of overlying structures. This approach also allows for access to both adrenal glands without repositioning, reprepping, and redraping during bilateral laparoscopic transperitoneal adrenalectomy. Postoperative pain can be less and recovery quicker. However, the retroperitoneoscopic approach does not allow for multivisceral resection or adequate access to the peritoneal cavity. Those with significant renal insufficiency may experience further worsening of their glomerular filtration rate due to the increased insufflation pressures. Robotic assistance may be used for either laparoscopic or retroperitoneoscopic approaches. For those patients with larger tumors not amenable to a purely laparoscopic or laparoscopic hand-assisted approach, tumors concerning for primary adrenocortical carcinoma, prior surgery in the upper retroperitoneum, or those needing multivisceral resection or concomitant retroperitoneal procedures, an open transabdominal approach using a subcostal or midline incision is usually pursued. Although used frequently in the past, the open posterior approach is rarely used anymore but remains a useful approach, especially in those who have undergone prior surgery in the upper quadrants. Finally, a thoracoabdominal approach to the adrenal glands may also be used but is rarely needed except in the situation where access to the chest and abdomen is required or there has been significant prior surgery in the area and an open posterior or posterior retroperitoneoscopic approach is not possible. Most often, these situations involve patients with extensive invasive or recurrent malignant adrenal tumors.

Right Laparoscopic Transperitoneal Adrenalectomy

The patient is placed in left lateral decubitus position at a 45 degree angle as shown in Fig. 2A so that the abdomen and flank are

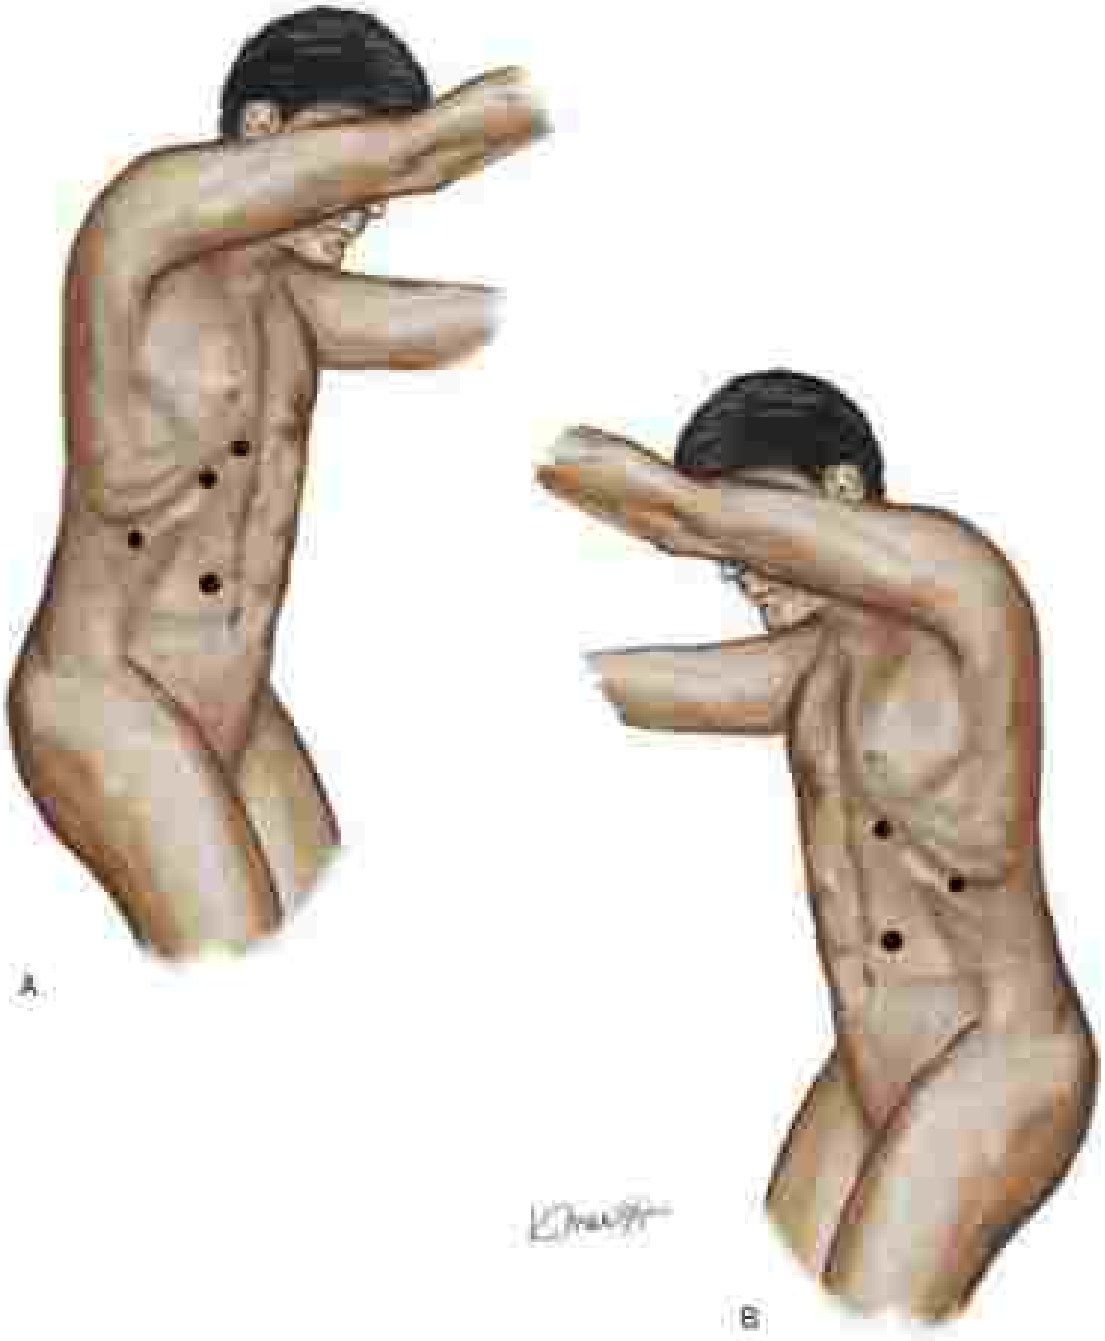

FIG. 2 Patient positioning and port site placement for (A) right laparoscopic adrenalectomy and (B) left laparoscopic adrenalectomy (Patient illustration from www.colorimagery.com Copyright Elsevier Inc. All rights reserved.)

accessible if conversion to an open procedure is necessary. The space between the ribs and pelvis is extended. Port sites are established using standard techniques for access. On the right side, four ports (occasionally more) are most often placed, one of which is for retraction of the liver. The triangular and coronary ligaments of the right lobe of the liver are divided and the liver is retracted medially. The upper pole of the kidney is identified and the space between it and the adrenal gland is identified. The vena cava is also identified. Intraoperative ultrasound can be useful for identifying the adrenal gland when abundant retroperitoneal fat is present. The attachments of the perinephrinal fat are released from the upper pole of the kidney using standard techniques, most often ultrasonic dissection. It is critical to identify and remove the most inferior extent of the adrenal gland, which sometimes overlies the renal vasculature as even a small amount of hormonally functional tissue can lead to postadrenal disease. Once the inferior attachments have been released, some of which may include small vessels coming off the renal artery or renal vein, the dissection continues superomedially along the vena cava until the adrenal vein is identified. Options for ligating and dividing the adrenal vein include ultrasonic instruments, clips, and sometimes a stapler if access is difficult or the vein is wide. The more superior attachments medially and laterally are then released and the adrenal gland is removed. Port sites are closed in standard fashion.

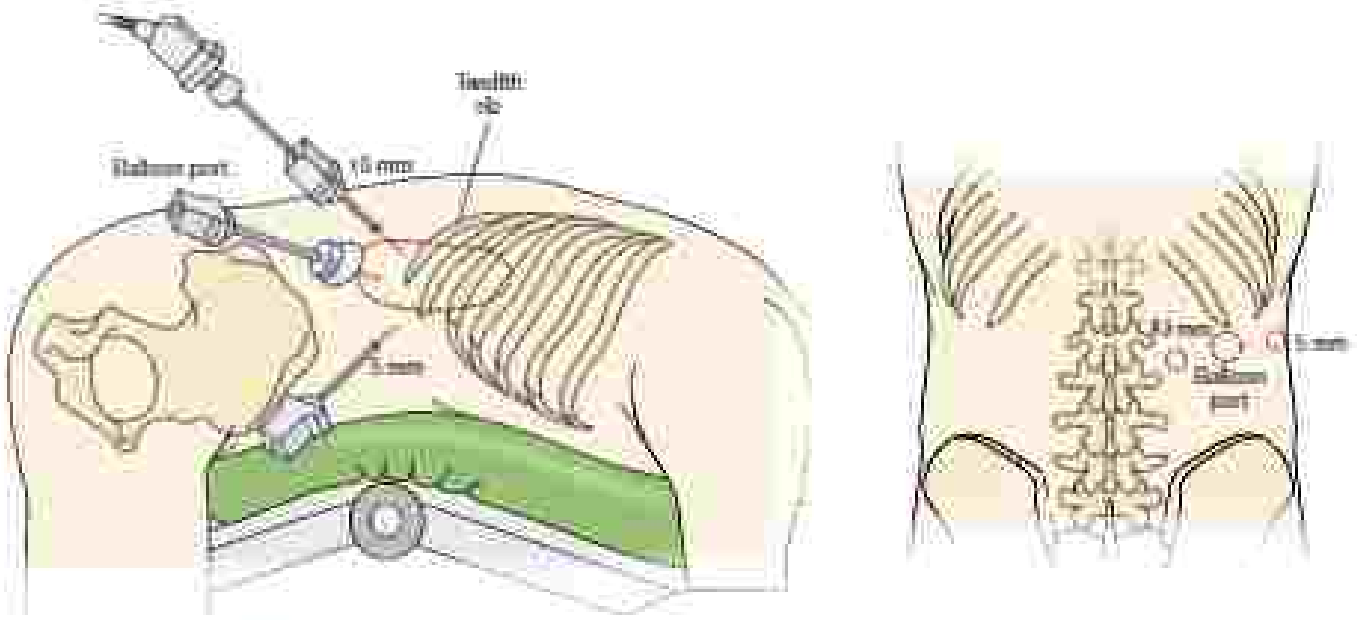

FIG. 3 Patient positioning and port-site placement for posterior retroperitoneoscopic adrenalectomy.

Left Laparoscopic Transperitoneal Adrenalectomy

Three ports (occasionally four or more) are most often required for left adrenalectomy (Fig. 3B). The splenocolic ligament is divided and the colon mobilized inferiorly and medially. The remaining splenic attachments are then mobilized to the esophageal hiatus so that the spleen will remain mobilized, often without the need for a retractor. Left adrenalectomy is then carried out in similar fashion to the right side. The left adrenal vein is usually identified in the 7 o'clock position. This may be visualized on preoperative imaging in many cases. A communicating branch may course longitudinally from the adrenal vein to the phrenic vein along the medial aspect of the adrenal gland. Attachments of the adrenal gland to the surrounding tissue are ligated and divided and the adrenal gland is removed.

Posterior Retroperitoneoscopic Adrenalectomy

The patient is placed in a prone position as shown in Fig. . An initial incision is made near the tip of the twelfth rib. Blunt dissection into the retroperitoneal space is pursued. The retroperitoneal fat is bluntly swept from the musculature using a finger, allowing for placement of a 5-mm port near the tip of the eleventh rib laterally and a 10-mm port medially at the lateral edge of the erector spinae muscles ~30 degrees inferior to the original incision. The retroperitoneum is insufflated to a pressure of 20 to 22 mm Hg. This can be increased if needed to assist with control of oozing or bleeding up to ~28 mm Hg. More tissue is bluntly dissected from the posterior musculature and the dissection carried medially and superiorly. As dissection and exposure proceed, the tone of the liver will be seen superolaterally. It is important not to dissect into the peritoneal cavity because visualization becomes extremely difficult with loss of insufflation of the retroperitoneal space. Once the adrenal gland is identified, dissection should proceed from an inferior to superior fashion. On the right side, surgeons should proceed with caution during the medial dissection until the vena cava is clearly identified because it will be compressed due to increased insufflation pressure. Because the right adrenal vein often emanates from the posterolateral aspect of the vena cava, it will be visualized more anteriorly in this approach than in a traditional laparoscopic approach given the prone positioning. The adrenal vein is ligated and divided and the remaining attachments released. The adrenal is removed, the fascia of the middle port site reapproximated and the wounds closed.

A similar approach is taken for left retroperitoneoscopic adrenalectomy. The tone of the spleen is identified superolaterally, and dissection is carried out as described. The left adrenal vein can be more difficult to identify than the right adrenal vein due to the proximity of the left renal vein to the renal hilum and a more posterior position when compared with the traditional transperitoneal approach.

With all laparoscopic and retroperitoneoscopic procedures, it is important to avoid disturbing the capsule of the adrenal gland because this will lead to bothersome oozing during the case, which may obscure visualization. Some literature supports that partial adrenalectomy is appropriate in select situations. This should be very carefully considered and performed by a high-volume adrenal surgeon because there are nuances to the decision making and conduct of the operation.

Right Open Adrenalectomy

Because open adrenalectomy is most often performed for malignant tumors, this section will describe the operative approach from an oncologic standpoint. Although a midline incision can be made, a wide right subcostal incision extending to the left side is favored because of an improved ability to retract the ribs and mobilize the liver, providing exceptional access to the adrenal gland, kidney, and vena cava. The peritoneal cavity is inspected to a systematic fashion. Intraoperative ultrasound scanning of the liver and evaluation of the adrenal vein and vena cava for tumor thrombus may be performed. The attachments to the liver are divided and the right lobe of the liver rotated medially. A retractor (Omni or Thompson) is placed to provide exposure. Through the surface of the posterior peritoneal lining, the kidney and the adrenal gland are able to be appreciated. If the tumor is found to be invading the posterior aspect of the liver, a rim of normal liver may be resected en bloc as part of the anterior margin. As delineated in Fig. , dissection occurs inferiorly over the superior half of the kidney, taking the posterior peritoneal lining and any fat over the superior half of the kidney to provide an ample inferior margin. This is continued to the plane found between the adrenal gland and kidney. If there is any concern for the invasion of the kidney, removal of a portion of the capsule of the kidney, partial or complete nephrectomy may be performed depending on the extent of suspected invasion because one does not want to create a plane between tumor and the surface of the

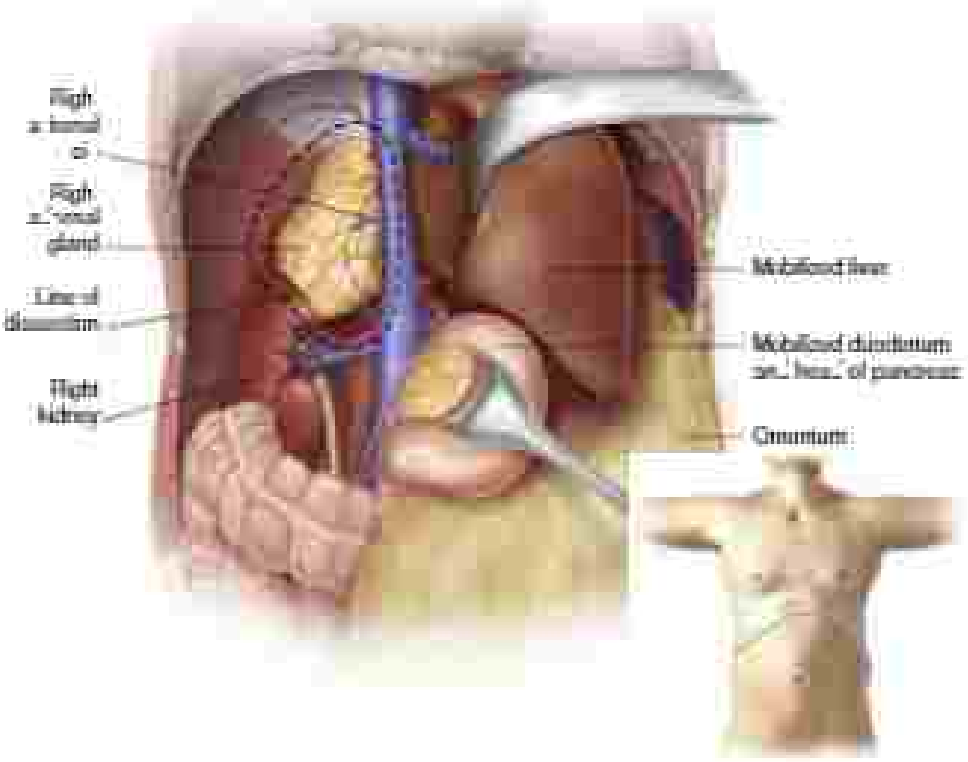

FIG. Use of [illegible] incision to access the left renal vein and adjacent adrenal. Upper A shows the abdominal compartments to be entered.

kidney where none exists, allowing for microscopic dissection and demonstration of tumor. The dissection is continued laterally to the abdominal sidewall, and all [illegible] fat over the psoas muscle is taken as part of the specimen and preserved with the specimen. The posterior adrenal gland is then separated from the diaphragm using electrocautery. The diaphragmatic muscle fibers attached to the adrenal gland are left attached to the specimen. The specimen is then removed and sent to pathology. Hemostasis is confirmed and the wound is closed in standard fashion.

Laparoscopic Adrenalectomy

The patient is placed in lateral decubitus position. A 12-mm trocar is placed in the umbilicus using the Veress technique. Pneumoperitoneum is established and maintained at 15 mm Hg. Two 5-mm trocars are placed in the upper abdomen, one in the midclavicular line and one in the anterior axillary line. The liver is retracted superiorly and the spleen inferiorly. The lateral peritoneal attachments are incised, and the adrenal gland is identified. Dissection proceeds from lateral to medial, with the adrenal vein ligated and divided last. The adrenal gland is placed in a specimen bag and removed through the umbilical port. Hemostasis is confirmed and the trocars are removed under direct vision. The fascial defects are closed with sutures, and the skin incisions are closed with subcuticular sutures.

Laparoscopic Retroperitoneal Adrenalectomy

The patient is positioned in lateral decubitus position. A 12-mm trocar is placed in the midaxillary line at the level of the 12th rib. Pneumoperitoneum is established and maintained at 15 mm Hg. Two 5-mm trocars are placed in the upper abdomen, one in the midclavicular line and one in the anterior axillary line. The liver is retracted superiorly and the spleen inferiorly. The lateral peritoneal attachments are incised, and the adrenal gland is identified. Dissection proceeds from lateral to medial, with the adrenal vein ligated and divided last. The adrenal gland is placed in a specimen bag and removed through the umbilical port. Hemostasis is confirmed and the trocars are removed under direct vision. The fascial defects are closed with sutures, and the skin incisions are closed with subcuticular sutures.

Open Posterior Adrenalectomy

The patient is placed in prone position. A curvilinear or angled incision is made as shown in Fig. 5 from medial to lateral over the twelfth rib. The twelfth rib is identified and removed. The retroperitoneum is entered. It is important to sweep the retroperitoneal fat from superior to inferior and from medial to lateral. Because of the location, the pleural cavity may be inadvertently entered and may be sutured closed. Using hand held retractors to retract the ribs and musculature, the kidney is identified and retracted inferiorly with the surgeon's hand and the adrenal gland identified medially and superior to the renal hilum. Adrenalectomy is performed, albeit from a dorsal approach, in standard fashion. The wound is closed in multiple layers, making sure not to injure the neurovascular bundle of the eleventh and twelfth ribs.

Open Anterior Transperitoneal and Thoracoabdominal Approach

The patient is positioned as shown in Fig. . An incision is made and the pleural cavity is entered. The costal margin is transected using bone cutters. The diaphragm is divided to enter the peritoneal cavity, making sure not to injure the phrenic nerve. A small rim of diaphragm attached to the rib is preserved for later reapproximation. The abdominal cavity is then entered. Resection is then carried out in a similar approach to open adrenalectomy.

ADRENALECTOMY IN THE SETTING OF A GENETIC SYNDROME

In those patients with adrenal tumors resulting from a genetic mutation, patients should be referred to a genetic counselor. Ideally, those suspected of having a possible genetic mutation would undergo this testing in the preoperative setting as knowledge of the specific mutation can impact preoperative testing and conduct of the operative. Adrenal tumors may be found in patients with MEN 1, MEN 2, or found in patients with Cushing syndrome or [illegible] nodulosis.

Pheochromocytoma is associated with MEN 2A, MEN 2B, neurofibromatosis, and von Hippel-Lindau syndromes. Partial adrenalectomy may be pursued in some of these patients depending on the size of the tumor, as well as the position of the tumor in relation to the draining vasculature. Approximately 20% of a normal adrenal gland is required for continued cortical function. Patients who are potential candidates for partial adrenalectomy should be referred to a surgeon with expertise in the disease process, decision-making process, and the nuances of partial adrenalectomy.

ADRENALECTOMY IN PREGNANCY

As with other diagnoses necessitating surgery during pregnancy, it is best if adrenalectomy is delayed until after delivery. Should surgery be required, it is best performed during the second trimester. Most commonly, adrenal disorders encountered during pregnancy include pheochromocytoma, Cushing's syndrome, and adrenal cortical carcinoma, all of which are extremely rare. For those with Cushing's syndrome, the scant amount of literature available suggests adrenalectomy during the second trimester. For those with pheochromocytoma, α- and β-blockade can be pursued and adrenalectomy performed after delivery or at the time of delivery.

POSTOPERATIVE CONSIDERATIONS

Patients undergoing adrenal surgery may require various levels of care depending on the diagnosis and operation performed. Most patients can be managed in a routine inpatient setting. Some cases can be done in an outpatient setting; however, this is only in highly selected situations. For those with evidence of hormone excess, most patients will need monitoring in the hospital for 24 to 48 hours to assess electrolytes, volume status, and blood pressure. For those with primary aldosteronism, all antihypertensive medications and home potassium supplementation regimens should be discontinued after surgery to allow for determination of cure and to assess the need for reinstitution of any of these medications. It can take weeks to months for the body to reestablish a new baseline blood pressure, and patients are encouraged to continue monitoring blood pressure after surgery for optimal titration of medications.

For those patients with overt signs of hypercortisolism, postoperative steroid supplementation will almost always be required. A normal daily total dose of hydrocortisone is 15 to 30 mg, depending on the patient. The total dose is divided two to three times daily, giving a larger dose in the morning and smaller dose to the mid- or late afternoon to replicate the normal diurnal rhythm. Administering steroids at night can adversely affect the normal sleep pattern. Patients with severe hypercortisolism may exhibit signs of steroid withdrawal even when normal replacement doses of steroids are given. Higher-than-normal daily doses of hydrocortisone may be required in the postoperative period, and weaning of steroids should be managed by an endocrinologist. In general, prednisone should not be used for steroid replacement because it increases the length of time for recovery of the HPA axis. For those patients with subclinical production of excess cortisol, these patients may or may not require postoperative steroids. It is recommended that perioperative administration of dexamethasone (Decadron), which may be given during surgery for prevention of postoperative nausea and vomiting, be avoided in these patients because it may impact testing of the HPA axis the morning after surgery.

Any patient undergoing adrenalectomy, whether unilateral or bilateral, should be warned about the possibility of developing Addisonian crisis and the need for steroid supplementation to prevent or treat this life-threatening situation. Warning signs and a management plan are ideally discussed in advance with the patient and their family. The chance of this occurring is dependent on the diagnosis, extent of surgery, and amount of residual adrenal tissue.

BACKGROUND

Pheochromocytomas and paragangliomas (PPGL) are rare chromaffin neoplasms with the potential to synthesize, store, metabolize, and secrete catecholamines. The term pheochromocytoma is limited to tumors that arise from within the adrenal medulla (10%), whereas paragangliomas are similar extraadrenal tumors that arise anywhere from skull base to scrotum along the path of the embryologic neural crest cells in the autonomic ganglia. The incidence ranges from [illegible] to 8 per million people annually. Although rare, a higher prevalence is reported on autopsy, suggesting these tumors are underdiagnosed and may contribute to premature death secondary to a number of cardiovascular and metabolic complications associated with functional PPGLs, including hypertension and diabetes.

Pheochromocytoma was previously described as the rule of 10 tumor: 10% malignant, 10% bilateral, 10% multifocal, 10% pediatric, 10% without hypertension, 10% incidentally discovered, 10% extraadrenal (paraganglioma), and 10% familial. However, with an increased understanding of the inheritance patterns and genetics, it has become clear that a significant percentage of patients with these tumors has a genetic predisposition. Researchers continue to identify genetic associations in up to 35% of these tumors, which may have clinical implications as they are at higher risk for extraadrenal, bilateral, and malignant disease (Table 1).

CLINICAL PRESENTATION

Patients with PPGL may experience a wide range of symptoms related to catecholamine and catecholamine metabolite excess. The symptom triad of paroxysmal headaches, palpitations, and excessive sweating is classically described but is infrequently present. Anxiety, lightheadedness, tremors, fever, heat intolerance, pallor, abdominal pain, nausea, vomiting, blurred vision, dyspnea, chest pain, and feelings of impending doom are some of the many symptoms experienced. These "spells" may occur at varying intervals and may be incited by anxiety or exertion. Metabolic disturbances such as weight loss and glucose intolerance may also occur. Hypertension is frequently present in these patients, and patients with severe or therapy-resistant hypertension should be screened for PPGL to avoid delays in diagnosis. PPGLs are rare in older adults, most commonly presenting in the fourth to fifth decades of life. They are typically found in children, except in patients with hereditary forms of the disorder. Patients with hereditary syndromes will be symptomatic at a younger age than patients with sporadic disease. Additionally, those with hereditary syndromes are more likely to have extraadrenal tumors and have multiple or bilateral lesions.

DIAGNOSIS

Any patient with symptoms consistent with episodic catecholamine excess or refractory or severe hypertension resistant to multiple antihypertensive drugs should undergo biochemical workup. Similarly, any patient with an incidentally discovered adrenal mass should be tested because up to 10% of adrenal incidentalomas are found to have a biochemical profile consistent with pheochromocytoma. Plasma-free fractionated metanephrine and normetanephrine or 24-hour urine fractionated metanephrine and normetanephrine are the main diagnostic tests for PPGL. Because paragangliomas are extraadrenal by definition, they typically do not secrete epinephrine due to the lack of phenylethanolamine *N*-methyltransferase (PNMT). The high sensitivity and specificity of 24-hour urine testing make it the preferred initial test in most patients. Wide specificity and sensitivity ranges are reported and differ by laboratory, as well as the diagnostic threshold used. Values greater than four times the upper limit of normal are considered diagnostic whereas diagnosis may still be made with higher sensitivity using a cutoff of two times the upper limit of normal. Lower laboratory levels may make the diagnosis more difficult to obtain, and numerous food products and medications are associated with false-positive results (Box 1). High-risk patients, especially those with a hereditary syndrome predisposing them to PPGLs, should be screened with plasma metanephrine testing; this has a higher sensitivity but is associated with a false-positive rate as high as 10%. Testing after a period of supine rest and an overnight fast can limit false-positive results. For patients with borderline elevations in catecholamine metabolites, clonidine suppression testing, or chromogranin A measurements may be performed as confirmatory tests. Because of the prevalence of associated genetic syndromes, any patient with confirmed paraganglioma should participate in the shared decision-making process for genetic testing, and a strong recommendation is made for counseling in all patients with pheochromocytoma.

IMAGING AND LOCALIZATION

Localization should only be performed after the diagnosis of PPGL has been confirmed biochemically. Computed tomography (CT) and magnetic resonance imaging (MRI) are adequate for localization in the majority of cases and have thus become the mainstays of PPGL localization. Both modalities provide excellent anatomic information that can be used to assist operative planning.

Adrenal protocol CT uses thin cut noncontrast and phased intravenous (IV) contrast images to assess enhancement and washout. CT characteristics of pheochromocytomas include homogeneity in smaller lesions with Hounsfield units greater than 10 and commonly in the 40 to 50 range on noncontrast CT. Pheochromocytomas enhance vigorously with IV contrast with less than 60% washout. Larger tumors are more likely to display heterogeneity, calcifications, or cystic areas (Fig. 1).

T2 MRI, pheochromocytomas have a hyperintense "light bulb" signal intensity on T2 weighted imaging due to the vascularity and water content. The MRI signature is often capable of discriminating pheochromocytomas from other types of adrenal tumors, and MRI is superior to CT in detecting extraadrenal lesions. Reported sensitivity of magnetic resonance imaging is as high as 100% in some series. MRI imaging for PPGL does not require contrast and does not expose patients to ionizing radiation, making it the preferred imaging choice in children and pregnant or lactating women (Fig. 2).

Functional imaging has improved specificity over CT and MRI in PPGL and plays a large role when localization is inconclusive or when multiple lesions or metastatic disease are present. I-131 metaiodobenzylguanidine (MIBG) is the classic functional imaging used to confirm and localize PPGLs. It is frequently an unnecessary addition to the workup but has increased utility in suggesting malignancy in large pheochromocytomas, in localizing lesions not found on CT or MRI, and for localizing paragangliomas. Positron emission tomography (PET)/CT is an advantageous alternative in malignant and metastatic disease, or when other localization modalities are inconclusive. A variety of isotopes are used in PET for PPGL, such as 18-F fluorodihydroxyphenylalanine, 18F-3,4-dihydroxyphenylalanine, 18F-metaiodobenzylguanidine, and 68Ga-DOTA. Improved CT resolution with functional nuclear scintigraphy imaging technology provides outstanding three-dimensional anatomic information.

PREOPERATIVE MANAGEMENT

Operative preparation for pheochromocytoma and paraganglioma patients requires optimization of blood pressure, treatment of tachycardia, and restoration of normal circulating blood volume. Because of the risks associated with both chronic catecholamine excess and hypertension, preoperative cardiac evaluation is justified for medical optimization in all patients who undergo surgical intervention. Perioperative antihypertensives are mandatory for all patients with catecholamine-secreting tumors before the initiation of anesthesia to reduce intraoperative hemodynamic instability and avoid wide swings in blood pressure and heart rate.

Alpha-adrenergic antagonists are the first-line agents because of their ability to combat hypertension, reduce vascular resistance, and help restore normal blood volume. In preparation for operative resection, α blockade should begin 1 to 2 weeks before the planned surgical date. The standard initial regimen is phenoxybenzamine 10 mg twice daily. The dose can be increased by 10 to 20 mg every 3 days to a goal blood pressure of less than 130/80 mm Hg while sitting, orthostatic hypotension, and the sensation of a "stuffy nose." Numerous alternative regimens have been described, including selective α1-adrenergic antagonists or calcium channel blockers (Table 2). For patients with resistant hypertension, nitroprusside therapy may be added, but this medication is associated with a fourth-side-effect profile. Its use is often limited to refractory and metastatic disease. For patients with tachycardia, β-adrenergic antagonists should be added to control heart rate. However, β blockers are should be reserved until at least 2 days after the initiation of α blockade. β-Blockers should never be used in the absence of α-adrenergic antagonists because they would result in unopposed α-adrenergic catecholamine stimulation. The goal heart rate is 60 to 65 beats/min, and medications are titrated to symptoms. Chronically high catecholamine levels lead to vasoconstriction and an overall decrease in circulating blood volume. Three days after commencement of α blockade, a high-salt (3 g/day) diet is recommended to help restore circulating fluid volume. Normalization of circulating blood volume before surgery in PPGL patients reduces the hypotension associated with tumor removal.

Management of PPGL during pregnancy is particularly difficult and is associated with a 60% maternal mortality rate and up to a 50% fetal death rate. On diagnosis, α-adrenergic antagonists should be initiated immediately and elective third-trimester Cesarean section should be performed because vaginal delivery is contraindicated due to potentially catastrophic massive catecholaminic release. Combined adrenalectomy with Cesarean section versus early postpartum resection is generally preferred. Tumor removal should be avoided during the first trimester because of the high risk of miscarriage, but there is the possibility of adrenalectomy in the second trimester.

INTRAOPERATIVE MANAGEMENT

Preparation and excellent communication with the anesthesiologist are essential components of PPGL management during surgery. To augment volume restoration, 1 to 2 L of resuscitative fluids are given before surgery. Adequate IV access and arterial monitoring are required before administration of anesthesia. Multiple vasoactive medications should be prepared and available in anticipation of blood pressure lability. Alpha or calcium channel blockade should continue, although esmolol or sodium nitroprusside is used for intraoperative blood pressure swings. Ephinephrine and norepinephrine are drugs of choice for intraoperative hypotension. A particularly important communication point is at the ligation of the adrenal vein. The surgeon and anesthesiologist should communicate closely during this event to prepare for potential rapid and significant hypotension, which can be treated with vasopressors as needed.

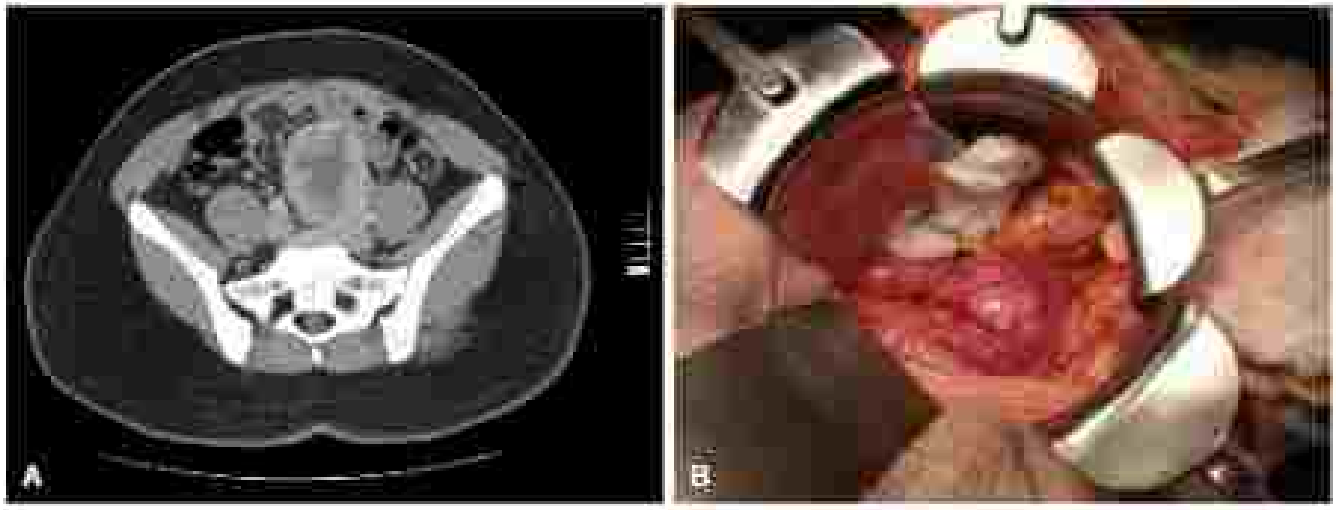

FIG. 1 (A) Paraganglioma in the aortic bifurcation, intravenous contrast-enhanced computed tomography shows heterogeneity and Hounsfield units greater than 10 with areas of necrosis. (B) Vessel anatomy of the IVC must be noted at the time of operation.

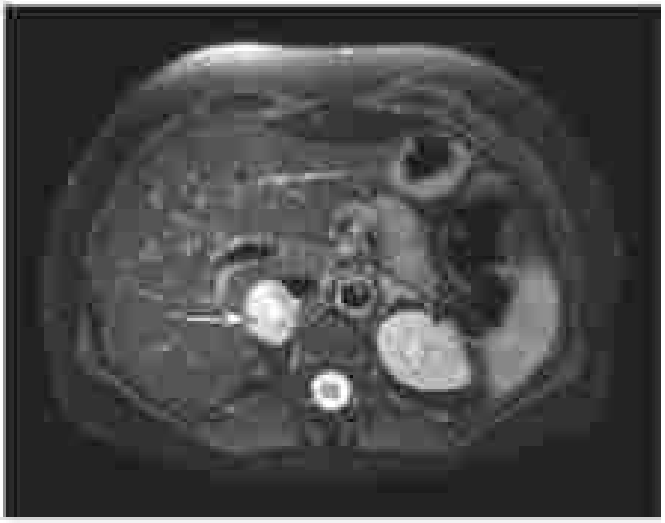

FIG. 2 Pheochromocytoma imaging of a right pheochromocytoma. 123-iodine imaging reveals a "right-hot" hypermetabolic appearance with heterogeneity.

TREATMENT AND SURGICAL APPROACH

Although medical management can be used to control symptoms, operative removal is the mainstay of treatment. Surgical resection for localized PPGL is the only curative treatment option, and operative debulking has a major role even in widely metastatic disease. Resection extent is based on disease locality, size, and potential for malignant or metastatic disease. Adrenalectomy is the standard resection for unilateral sporadic tumors localized to the adrenal gland. Subtotal adrenalectomy may have a role in sparing adrenal cortex for patients with bilateral pheochromocytomas and tumors associated with familial disease to avoid adrenal insufficiency and steroid dependence. When a cortex sparing procedure is planned, at least one third of a well-perfused cortex should be preserved. A multidisciplinary and multimodality therapeutic plan is required for malignant or metastatic disease.

Surgical removal of PPGL can be divided into transabdominal or retroperitoneal approaches. Within each category, laparoscopic, robotic, and open techniques may be used. Minimally invasive resection is the procedure of choice for most PPGLs and is feasible in the vast majority of patients. The minimally invasive approach results in decreased operative times, decreased blood loss, decreased need for blood transfusion, decreased analgesic requirements, shorter stays in the intensive care unit, shorter hospital stays, and faster return to work when compared with an open approach. Additionally, there are decreased surges in catecholamines during tumor manipulation with laparoscopic versus open adrenalectomy for pheochromocytoma. Open approaches are typically reserved for larger, locally advanced, malignant, or metastatic tumors, and intraoperative conversion from

TABLE 2 Preoperative Pharmacologic Management of PPGL

Nonselective α-adrenergic receptor antagonist	
Phenoxybenzamine	10 mg bid, increase by 10–20 mg every third day to goal
Selective α-adrenergic receptor antagonist	
Prazosin	1 mg, three times daily, increase to max 12 mg/day
Terazosin	2–10 mg/day
Doxazosin	1–16 mg/day
Calcium channel blocker	
Nifedipine	30–90 mg/day
Verapamil	180–540 mg/day
Nicardipine	60–120 mg/day
Amlodipine	10–20 mg/day
β-Adrenergic receptor antagonist[a]	
Atenolol	12.5–25 mg, 2–3 times daily
Metoprolol	25–50 mg, 2–4 times daily
Metoprolol XL	25–200 mg per day
Propranolol	20–80 mg, 1–3 times daily
Tyrosine hydroxylase inhibitor	
Metyrosine	250 mg, 4 times daily, increase 250–500 mg every third day to goal or maximum of 4 g/day

bid, two times daily; IVC, pheochromocytoma and paraganglioma.
[a]Labetalol and carvedilol are contraindicated due to ratio of α- to β-receptor antagonism.

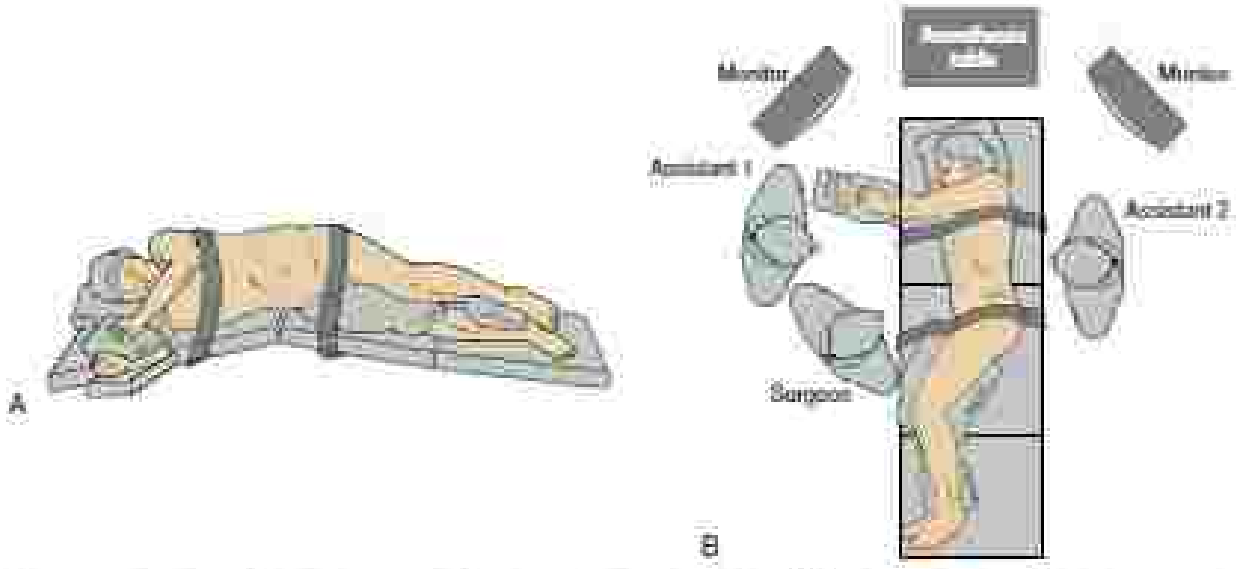

FIG. 3 Patient positioning for transabdominal laparoscopic adrenalectomy. (A) The patient is placed in lateral or mid-flank decubitus position with the table flexed to create a wide gap between the costal margin and the iliac crest. (B) Operative room setup and monitor placement.

FIG. 4 Right transabdominal adrenalectomy (single-site laparoscopic approach): port placement.

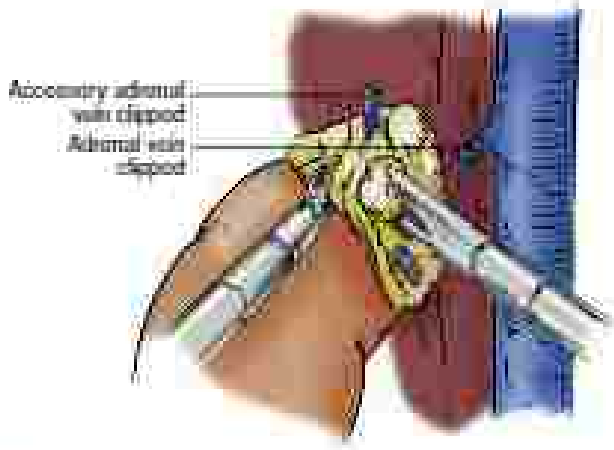

FIG. 5 (A) In a right-sided laparoscopic adrenalectomy, the liver is retracted to expose the gland. The lateral border of the inferior vena cava is dissected to encounter the short right adrenal vein. The accessory adrenal vein at the anterior border of the liver has the potential for significant bleeding.

a minimally invasive to open procedure may be required when malignancy or metastasis are suspected. Regardless of approach, complete tumor resection is a key component to outcomes of PPGL. The choice of operative approach ultimately depends on patient characteristics, anatomy and location of the tumor(s), sporadic versus hereditary nature of disease, and surgeon preference and comfort with each technique.

Transabdominal Laparoscopic Adrenalectomy

The transabdominal laparoscopic technique is the most commonly performed approach used for patients without obvious signs of malignancy or metastatic disease. Key technical maneuvers in any adrenalectomy for pheochromocytoma are minimal tumor manipulation and early control and division of the adrenal vein. The lateral decubitus position is used with the patient's hips rotated to expand the distance between the costal margin and the iliac crest (Fig. 3). After the peritoneal cavity is accessed, a 30-degree laparoscope is used. Port placement varies depending on the laterality of the tumor. A right adrenalectomy requires four trocars placed 2 cm inferior and parallel to the costal margin in the midclavicular line, and anterior axillary, mid-axillary, and posterior axillary lines (Fig. 4). Liver retraction is performed through the most medial port, then the lateral triangular ligament is divided to gain access to the right adrenal gland. The plane superior to the adrenal gland is dissected medially along the inferior border of the liver until the inferior vena cava (IVC) is encountered. During dissection of the lateral aspect of the IVC caudally from the liver, the short right adrenal vein will be identified draining directly into the IVC, where it is divided with clips or an energy device (Fig. 5). It is imperative to coordinate with the anesthesia team during this step. The arterial supply to the adrenal gland can be controlled with a vessel sealing device along its medial aspect, then the gland with the periadrenal fat can be circumferentially freed from surrounding tissue. Leaving the lateral attachments intact until near complete dissection facilitates exposure of the more important hilar structures. The position of the renal artery and vein must be

An inset highlights the abdomen in left, anteriorly, showing retroperitoneal pressure. Three ports are placed [illegible] on the middle axillary line, about at the tip of the twelfth rib. [illegible]

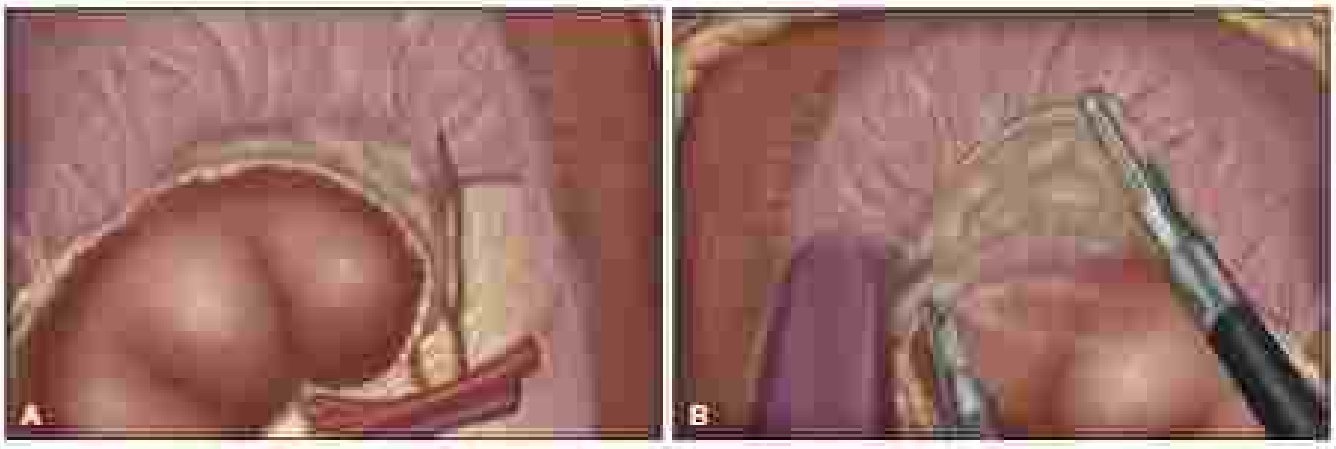

FIG. 9 *Local anatomy of retroperitoneoscopic adrenalectomy.* Posterior view of retroperitoneoscopic adrenalectomy. After the retroperitoneal dissection space is created, paraspinous muscles are swept medially and the peritoneum laterally prior to clearance of the superior pole of the kidney. The borders of the adrenal gland are appreciated, and the adrenal vein is divided before dissection of the gland from adjacent tissue. The left adrenal vein drains into the left renal vein (A), whereas the right adrenal vein drains into the IVC. (From Lobo DN, Scott-Coombes DM, Stanley MC, et al. Retroperitoneoscopic surgery with reference to laparoscopic surgery. Surg Endosc 2004;18:1412.)

placed inferiorly to the adrenal gland under direct vision so as not to injure the vena cava and artery. The adrenal vein is then identified and clipped with small vascular clips. The adrenal gland is then dissected free from the surrounding tissue, and the adrenal vein is divided between clips. Care must be taken to avoid injury to the adrenal vein, which can result in significant hemorrhage. Small accessory adrenal veins may be encountered and divided between clips. Because the adrenal gland is highly vascular, the adrenal vein should be divided before manipulation of the adrenal gland to avoid excessive release of catecholamines during surgery. After the adrenal vein is divided, the remainder of the adrenal gland is dissected free from the surrounding tissue. The retroperitoneum can be closed primarily, avoiding undue tension on the closure.

Open Approach

Open adrenalectomy procedures are used for large tumors, malignancies, or locally invasive tumors. The high recurrence rate after laparoscopic adrenalectomy for malignant tumors has led some surgeons to perform open adrenalectomy for malignant tumors. The adrenal gland is approached via a subcostal incision, a flank incision, or a thoracoabdominal incision. Open adrenalectomy is rarely performed for pheochromocytoma because of the risk of massive hemorrhage during manipulation of the tumor. Open adrenalectomy may be necessary for large tumors, tumors with local invasion, or tumors with vascular thrombus. Open adrenalectomy for pheochromocytoma should be performed with the same principles as laparoscopic adrenalectomy. Meticulous dissection of the adrenal vein before manipulation of the adrenal gland is essential. After the adrenal vein is ligated, the remainder of the adrenal gland is mobilized. Open adrenalectomy can be performed safely, avoiding undue release of catecholamines.

PERIOPERATIVE MANAGEMENT AND COMPLICATIONS

Morbidity and mortality rates for patients who are appropriately managed preoperatively and undergo elective laparoscopic surgery are low. In addition, patients are monitored in the intensive care unit for 24 hours and can be discharged on the second postoperative day. With adequate preoperative preparation, intraoperative pressure and resuscitation are rarely required for more than a few hours. Vital signs should be monitored frequently, and hemodynamic parameters and plasma levels should be monitored for 24 hours after operation. Most patients have an uneventful postoperative hospital course and are discharged on reduced dosages of antihypertensive drugs that can usually be withdrawn in most patients. Adrenal insufficiency is uncommon in patients who undergo unilateral adrenalectomy but should be expected in patients who undergo bilateral operations including cortical sparing techniques. Stress dose steroids with a rapid taper to oral corticosteroids may be implemented for patients at risk. Disease surveillance should commence for all patients who undergo surgical resection for PPGL, with perioperative serum or urinary metanephrine measurement approximately 2 to 6 weeks after removal to ensure biochemical cure. If preoperative metanephrines were normal, chromogranin A can be used as an alternative screening test for recurrence. When metanephrines remain elevated despite presumed surgical cure, imaging should be obtained 3 months after the operation. Follow-up is required for at least 10 years and should be lifelong if high risk for recurrence such as patients who are young, have a large or extraadrenal tumor, or have an associated genetic cause of the PPGL. Standard monitoring includes yearly screening for local or metastatic recurrence or new tumors with plasma or urinary metanephrines and imaging tests every 1 to 2 years.

RECURRENT, MALIGNANT, AND METASTATIC DISEASE

Up to 14% of PPGLs are malignant. Malignancy is more common in hereditary disease, paragangliomas, and tumors larger than 5 cm. There are no reliable histologic methods to differentiate benign and malignant in PPGLs. The diagnosis of malignancy in PPGL is based mainly on behavior and can be defined by the presence of metastatic disease. Additionally, there are multiple pathologic features and genetic tests that are used in an attempt to predict behavior. The Pheochromocytoma of the Adrenal gland Scaling System is one such scoring system that has been created to stratify patients using 12 features that include mitoses, necrosis, cellularity, and invasion.

A multidisciplinary approach should be taken to the treatment of recurrent, malignant, or metastatic PPGL. Functional imaging by PET/CT with novel radionuclides provides exceptional assessment of disease (Fig. 10). Complete surgical resection when possible is the optimal treatment modality and is associated with durable survival despite high accompanying recurrence rates. Metastatic options are rarely curative, with 5-year survival rates ranging from 40% to 60% depending on the site of metastasis. When an R0 or R1 resection is not feasible, tumor debulking may still be of benefit for symptom palliation and reduction of catecholamines. Combination systemic chemotherapy (cyclophosphamide, vincristine, dacarbazine),

FIG. 10 Functional imaging of a patient with recurrent metastatic pheochromocytoma. ^{68}Ga dotatate positron emission tomography/computed tomography has superior accuracy for metastatic disease as pictured by the extensive number of lesions identified.

[illegible] MIBG, targeted therapeutics, radiotherapy, radiofrequency ablation, cryoablation, and arterial embolization are options in the treatment metastatic disease with a focus on symptom relief and reducing tumor burden.

SUMMARY

PPGLs are rare catecholamine secreting tumors that can occur throughout the body and frequently lack the classic triad of paroxysmal headaches, palpitations, and sweating. They are associated with an increasingly recognized number of genetic mutations and hereditary testing should be considered in this patient population. The most useful diagnostic testing includes plasma or 24 hour urinary metanephrines, whereas CT and MRI are the most commonly used diagnostic imaging modalities. Surgical removal is the mainstay of treatment and can be performed via minimally invasive techniques with excellent results. Therapy for hereditary and metastatic disease requires a multidisciplinary approach.

[illegible]

MANAGEMENT OF THYROID NODULES

Jonathon O. Russell, MD [illegible]

BACKGROUND

Thyroid nodules are highly prevalent in the United States and are found in more than 50% of adults in some studies. Whereas a majority are benign, 5% to 15% may be malignant. Arguably due primarily to the increased use of medical imaging, the diagnosis of thyroid nodules and thyroid cancer has grown rapidly in recent decades, contrastingly, death from thyroid cancer remains rare and has increased only slightly during that same period.

Because a majority of thyroid nodules will be benign and a majority of malignant tumors will demonstrate indolent behavior, surgeons and clinicians must have a thorough understanding of the most appropriate diagnostic and treatment techniques. Any intervention must add value to that individual patient while minimizing harm. To that end, recent advancements in both the diagnosis and treatment of thyroid nodules focus primarily on reducing overtreatment and minimizing morbidity.

DIAGNOSIS

When a thyroid nodule has been identified, regardless of the method of identification, the diagnostic algorithm is clear and begins with thyroid function testing. In general, thyroid stimulating hormone and T4 are sufficient and will lead to a diagnosis of a euthyroid, hypothyroid, or hyperthyroid state. The next step is imaging. Hyperthyroid patients will infrequently have cancer, and scintigraphy is generally the next step. "Hot" nodules (those demonstrating increased activity on scintigraphy) will so rarely be malignant that further invasive diagnostic testing is not generally indicated. Cold nodules in the setting of hypothyroidism may require ultrasound scanning to determine whether further investigation is appropriate. For euthyroid and hypothyroid patients, however, ultrasound scanning is the most appropriate next step.

ULTRASONOGRAPHY

Because ultrasonography is noninvasive and inexpensive, does not expose patients to ionizing radiation, best characterizes thyroid nodules for consideration of biopsy, and is readily available, it is the next step in the diagnostic algorithm of hypothyroid or euthyroid patients with thyroid nodules. Both the size and characteristics of the nodule are important to determine the risk of a clinically relevant malignancy. In general, nodules less than 1 cm do not require fine needle

FIG. 10. Functional imaging of a patient with recurrent metastatic pheochromocytoma. ^{68}Ga-dotatate positron emission tomography/computed tomography has superior accuracy for metastatic disease as pictured by the extensive number of lesions identified.

[131]I-MIBG, targeted therapeutics, radiotherapy, radiofrequency ablation, cryoablation, and arterial embolization are options in the treatment metastatic disease with a focus on symptom relief and reducing tumor burden.

MANAGEMENT OF THYROID NODULES

Jonathon O. Russell, MD, and Ralph P. Tufano, MD, MBA

BACKGROUND

Thyroid nodules are highly prevalent in the United States and are found in more than 50% of adults in some studies. Whereas a majority are benign, 5% to 15% may be malignant. Arguably due primarily to the increased use of medical imaging, the diagnosis of thyroid nodules and thyroid cancer has grown rapidly in recent decades. Fortunately, death from thyroid cancer remains rare and has increased only slightly during that same period.

Because a majority of thyroid nodules will be benign and a majority of malignant tumors will demonstrate indolent behavior, surgeons and clinicians must have a thorough understanding of the most appropriate diagnostic and treatment techniques. Any intervention must add value to that individual patient while minimizing harm. To that end, recent advancements in both the diagnosis and treatment of thyroid nodules focus primarily on reducing overtreatment and minimizing morbidity.

DIAGNOSIS

When a thyroid nodule has been identified, regardless of the method of identification, the diagnostic algorithm is clear and begins with thyroid function testing. In general, thyroid stimulating hormone and T4 are sufficient and will lead to a diagnosis of a euthyroid, hypothyroid, or hyperthyroid state. The next step is imaging. Hyperthyroid patients will infrequently have cancer, and scintigraphy is generally the next step. "Hot" nodules (those demonstrating increased activity on scintigraphy) will as rarely be malignant that further invasive diagnostic testing is not generally indicated. Cold nodules in the setting of hypothyroidism may require ultrasound scanning to determine whether further investigation is appropriate. For euthyroid and hypothyroid patients, however, ultrasound scanning is the most appropriate next step.

ULTRASONOGRAPHY

Because ultrasonography is noninvasive and inexpensive, does not expose patients to ionizing radiation, best characterizes thyroid nodules for consideration of biopsy, and is readily available, it is the next step in the diagnostic algorithm of hypothyroid or euthyroid patients with thyroid nodules. Both the size and characteristics of the nodule are important to determine the risk of a clinically relevant malignancy. In general, nodules less than 1 cm do not require fine needle

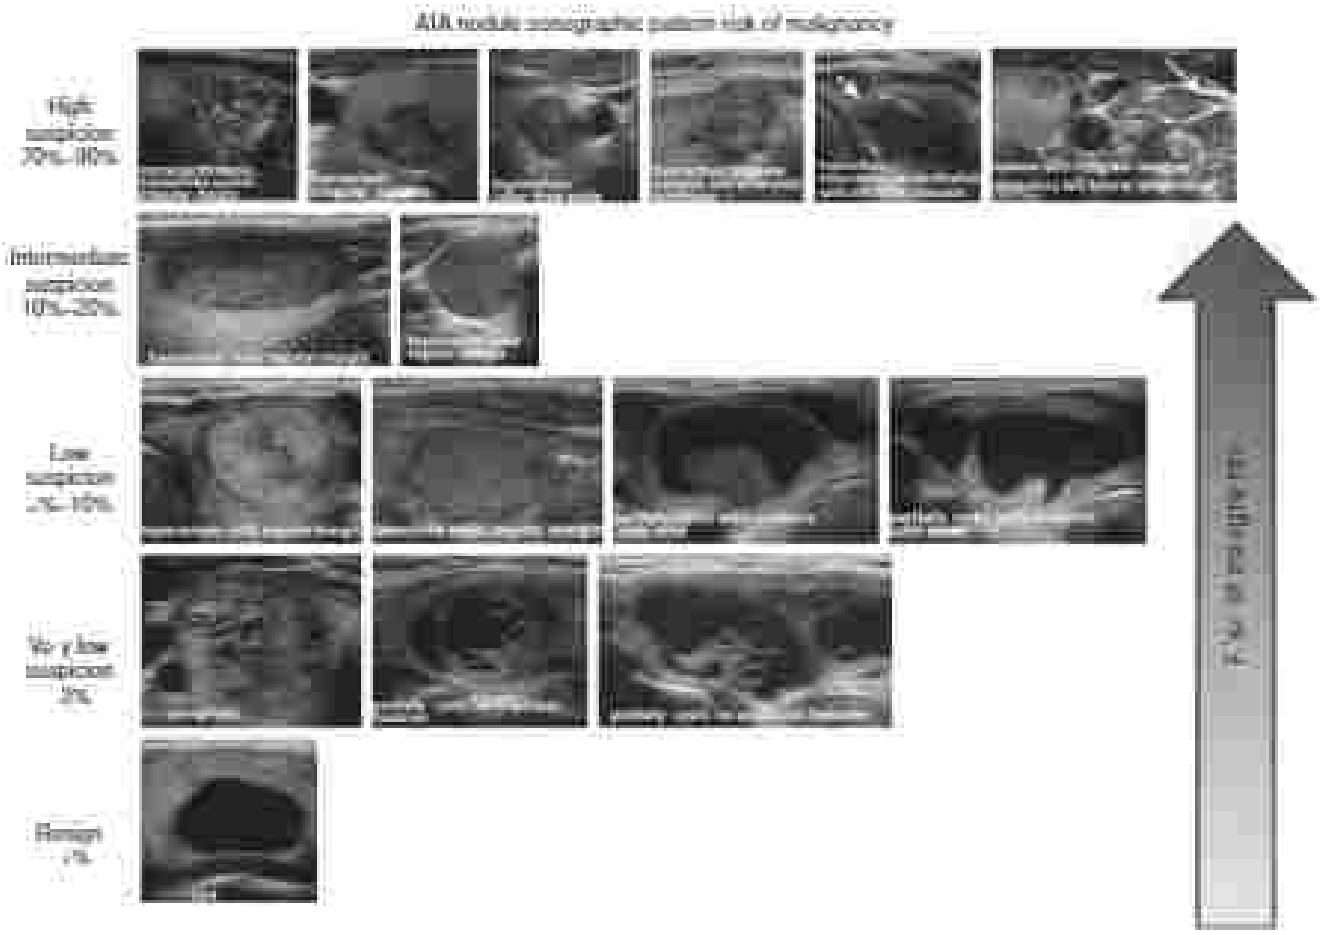

FIG. 1 Sonographic findings aid in risk stratification of thyroid nodules. [illegible]

aspiration (FNA), and only a repeat ultrasound should be scheduled in 6 to 24 months. For nodules more than 1 cm, however, certain high-risk features guide the necessity of more invasive diagnostic techniques (Fig. 1). Hypoechoic lesions, those with irregular borders, microcalcifications, and more are concerning signs of malignancy. Depending on a combination of such features, FNA may be warranted at size criteria between 1 to 2 cm. Both the American Thyroid Association and American College of Radiology have proposed classification systems that guide the timing of FNA in thyroid nodules.

FINE-NEEDLE ASPIRATION

For patients with nodules meeting criteria for biopsy, FNA is the next step in the diagnostic algorithm. The Bethesda Criteria represent a standard diagnostic criteria to be used by all cytopathologists in reporting FNA results. Table 1 demonstrates each of the six criteria, risks of malignancy, and recommended next steps.

MOLECULAR TESTING

As noted in Table 1, each FNA result is recognized as demonstrating only a probability of malignancy on final pathologic study. Historically, Bethesda III and IV lesions, due to their low but real risk of malignancy, were referred for diagnostic lobectomy. This led to a high rate of diagnostic surgery with benign final pathology. In the hopes of avoiding these unnecessary surgeries when otherwise clinically possible, patients and surgeons may opt to send additional FNA material for molecular testing. Such testing may increase or decrease the probability of malignancy, but each has limitations. Because of the expense and additional FNA passes required, it is our practice to limit molecular testing to those patients who are motivated to avoid surgery and do not have symptoms or other surgical indications. Because long-term follow-up will be required in this patient population, the explanation of these molecular tests and their limitations is a crucial responsibility for a modern thyroid surgeon.

NONINVASIVE FOLLICULAR THYROID NEOPLASM WITH PAPILLARY-LIKE NUCLEAR FEATURES

Since the release of the 2015 American Thyroid Association guidelines, an additional pathologic classification for some thyroid nodules has been created. Noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) represents a subset of thyroid nodules with almost no risk of metastatic spread, and it is therefore no longer considered a malignancy. The diagnosis requires a complete histopathologic review of the entire nodular capsule to ensure there is no invasion. This means that it is indistinguishable from other follicular lesions on FNA, and surgical intervention is therefore required to differentiate these lesions from well-differentiated thyroid cancers as of this writing. Because it is no longer considered malignant, some recent authors have demonstrated that the probabilities of malignancy noted in Table 1 are lower (because a subset of tumors previously defined as malignant are now considered benign). Some early reports suggest that this change in the classification of pathology has also affected the positive and negative predictive values of some of the molecular testing mentioned previously, because they were designed in an era where NIFTP was still considered a cancerous finding.

TABLE 1 2017 Bethesda System for Reporting Thyroid Cytopathology: Diagnostic Categories and Recommended Clinical Management

Diagnostic Category	Risk of Malignancy if NIFTP Is CA	Risk of Malignancy if NIFTP Is Not CA	Clinical Management
Nondiagnostic or unsatisfactory	5–10	5–10	Repeat FNA with ultrasound guidance
Benign	0–3	0–3	Clinical and sonographic follow up
Atypia of undetermined significance or follicular lesion of undetermined significance	6–18	10–30	Repeat FNA, molecular testing, or lobectomy
Follicular neoplasm or suspicious for a follicular neoplasm	10–40	25–40	Molecular testing, lobectomy
Suspicious for malignancy	45–60	50–75	Near total thyroidectomy or lobectomy[b]
Malignant	94–96	97–99	Near total thyroidectomy or lobectomy[c]

Modified from Baloch ZW, Cooper DS, Randolph GW, et al. Overview of diagnostic terminology and reporting. In: Ali SZ, Cibas ES, editors. The Bethesda System for Reporting Thyroid Cytopathology: Definitions, Criteria, and Explanatory Notes. New York: Springer; 2018.

CA, carcinoma; FNA, fine needle aspiration; NIFTP, noninvasive follicular thyroid neoplasm with papillary-like nuclear features.

[a] Actual management may depend on other factors (e.g., clinical, sonographic) besides the FNA interpretation.

[b] Some of these have recommended molecular analysis to assist the type of surgical procedure (lobectomy vs. total thyroidectomy).

[c] In the case of "Suspicious for metastatic tumor" or a "Malignant" interpretation indicating metastatic tumor rather than a primary thyroid malignancy, surgery may not be indicated.

TREATMENT RATIONALE

Treatment recommendations have trended toward less intervention in recent years because thyroid nodules are ubiquitous, most cytologically indeterminate nodules will ultimately return as benign on surgery, and even the few cancers are unlikely to cause death. As mentioned previously, FNA of subcentimeter nodules is discouraged during the diagnostic stage. During the treatment stage, lobectomy is now encouraged as a potential treatment for differentiated thyroid cancers if one or less in the appropriate clinical scenario. Prophylactic central neck dissection is generally discouraged for early stage differentiated thyroid cancers, except in specific situations and in the hands of high volume thyroid surgeons.

This last point deserves further consideration: to help a patient with a nodule that is unlikely to cause harm, the morbidity must be very low. High volume surgeons (variably defined, but generally more than 20 thyroidectomies per year) have superior outcomes. Any surgeon should constantly consider his or her own volume, outcomes, and adverse events. Additionally, at least in cases of cancer, completeness of resection is an important prophylaxis against long term complications. Radioactive iodine and other adjuncts do not compensate for inadequate surgery. The equipoise between the morbidity of the treatment and the disease process are considered repeatedly in this chapter.

OBSERVATION TRIALS

Given the above, some patients who are poor surgical candidates may instead be best served with watchful waiting. Taking this one step further, and based mainly on the Japanese experience with observation of papillary microcarcinomas (defined as 1 cm or less, most institutions have begun to offer active surveillance for some indeterminate and suspicious for malignancy thyroid nodules that are small (usually <1 cm) and meet other careful inclusion criteria but who would otherwise be surgical candidates. In most of these studies with long term follow up, 10% to 20% will ultimately progress to require surgery, but delayed surgery appears to be successful in early trials with no risk for decreased disease control. Although it remains to be seen how safe and effective this approach will be in a Western population, it clearly underscores the point that most thyroid nodules, even small thyroid cancers have a generally indolent clinical course. At this time, observing indigent or indeterminate lesions should be done as part of a multidisciplinary evaluation process requiring extensive patient education and engagement. Tumors that are near the recurrent laryngeal nerve, have radiographic evidence of aggression, or have other concerning features are generally not candidates for this approach.

SURGERY

Surgery remains the mainstay of treatment for most patients with symptomatic, cytologically indeterminate, or malignant thyroid nodules. In addition to the general risks of any surgical intervention, hypoparathyroidism and permanent vocal fold injury remain the chief concerns of thyroid surgeons. As above, both complications are less common among high volume surgeons and when completing lobectomy rather than total thyroidectomy.

Before surgery, confirmation of normal vocal fold mobility provides information that may alter the surgical plan, and we advocate preoperative laryngeal examination. Most high volume thyroid surgeons will use a nerve monitoring device for all thyroid surgery. Arguments against this are primarily financial. On the other hand, the potential to modify surgery intraoperatively and thus avoid a disastrous bilateral vocal fold palsy is a primary motivator for those who use the device. Additionally, intraoperative feedback of nerve health allows near instant technical modification that may help some surgeons avoid temporary vocal fold weakness.

Additional technology that is commonly used in thyroid surgery includes vessel sealing technologies of various types. Although the specific device may not be important, provided the appropriate technique and settings are used, thermal energy devices have become the norm among high volume thyroid surgeons. They have been demonstrated to have an excellent safety profile while decreasing operative times in most series.

Beyond these technological advancements, the surgical technique has changed little for more than 100 years. A transverse cervical incision is designed in a skin fold above the sternal notch. Flaps are raised, the linea alba (midline raphe) is identified and divided, and the strap muscles can be separated. The soft tissue is elevated off of the gland itself, and the trachea below and the larynx above are identified. In cases of malignancy, it is important that surgeons remove any pyramidal lobe, which may extend as high as the hyoid. This can be done by grasping the pyramidal lobe with a pickup and performing a fine hand dissection with electrocautery beginning superiorly, such that an inferiorly based pyramidal lobe pedicle is created. This maneuver also facilitates identification of the cricoid and removal of the Delphian lymph node, which then ensures clear visualization of the cricothyroid space laterally. We mobilize this tissue bluntly with an elevator and thus identify and preserve the external branch of the superior laryngeal nerve while simultaneously isolating the superior pole vessels (Fig. 2). The superior pole is then followed inferiorly to a point above the expected insertion of the recurrent laryngeal nerve (RLN).

FIG. 2. The external branch of the superior laryngeal nerve should be preserved; identification and dissection may facilitate this preservation.

FIG. 3. Blood supply to the inferior parathyroid gland may often arise from a superior vector and can be inadvertently sacrificed if not anticipated.

Once this has been completed, the RLN proper is identified. This can be completed either at the insertion or more proximally and inferior to the gland. We believe it most appropriate to then dissect the nerve off of the thyroid and to the laryngeal insertion to remove the maximum amount of thyroid tissue. In the process of this dissection, parathyroid glands must be reflected off the thyroid if not completed previously. It is our experience that the blood supply to the inferior parathyroid may come from a superior vector and may thus be inadvertently sacrificed without appropriate caution (Fig. 3). Both parathyroid glands will generally draw their blood supply from the inferior thyroid artery.

Once the RLN and parathyroid glands have been reflected away from the thyroid, the thyroid may be cautiously removed from the trachea with any number of techniques. We prefer some combination of electrocautery, thermal cautery, vessel sealants, or bipolar energy delivery. Functionality of the RLN is confirmed throughout with the intermittent application of a stimulus via a monopolar probe. Whereas hemostatic agents such as fibrin glue may be placed after confirming hemostasis, we generally do not find a surgical drain to be necessary. Lobectomy patients are generally discharged the same day, whereas total thyroidectomy patients generally merit monitoring of postoperative calcium levels, which may necessitate overnight observation. It has been demonstrated that, in the appropriately selected patient, same day discharge may be safe for both groups.

REMOTE ACCESS APPROACHES

One of the primary concerns for some patients is the position of a cervical incision in the mid neck, often the neck of a young female patient. Although not all patients find this problematic, it is clear that at least some patients prefer other alternatives. Kocher himself first adjusted the position of his incision to improve cosmesis by using a transverse rather than a vertical incision. Beginning near the early 2000s, there was a concerted interest in improving cosmesis further. Incisions shrank and various sites for remote access were used, including the breast, axilla, and retroauricular positions. Surgical robotics were likewise used. Although all of these were found to be effective in Asian populations, they have not garnered broad acceptance in the Western Hemisphere.

More recently, however, we have demonstrated the safety and efficacy of the transoral endoscopic vestibular approach in a North American population. First demonstrated to be clinically effective by Anuwong, the technique is gaining popularity in rapid fashion because of the relatively small area of dissection required for the approach, bilateral access to the central necks, and a familiar vantage point. Briefly, the technique requires placement of 3 surgical ports via the lower oral vestibule (Fig. 4). Insufflation (CO_2) assists with flap elevation, and the case is then completed with standard laparoscopic instrumentation. With a safety profile and operative times similar to that of the traditional approach, we have found this technique to be ideal for selected patients without advanced thyroid cancer who are motivated to avoid a cervical incision (Fig. 5).

FIG. 4. Port placement during the transoral endoscopic vestibular approach to the thyroid.

FUTURE DIRECTIONS

Molecular testing has already decreased the need for diagnostic surgery in patients with behavior indeterminate nodules. Future efforts will become even more effective and may add prognostic information as well. This will ensure that only patients who will benefit from treatment receive treatment.

Additional approaches to treat thyroid nodules may also decrease the need for surgery. Image guided ablation techniques (such as radiofrequency ablation or ethanol injection) effectively reduce nodule size and symptoms in benign goiter. Others in the Far East are already using these approaches to manage small cancers primarily. Although such approaches remain to be validated in a Western population, the indolent behavior of these tumors and the ability to successfully manage these cancers in a delayed fashion make such techniques theoretically appealing. Furthermore and in the future, such approaches may appeal to patients who do not feel comfortable with watchful waiting for small thyroid cancers.

FIG 3 (A) Preoperative and (B) 1 week postoperative appearance of a male after removal of a 4-cm benign thyroid goiter.

CONCLUSION

Thyroid nodules and differentiated thyroid cancer are extremely common but rarely cause death. A simple diagnostic algorithm with thyroid function testing followed by ultrasound scanning and FNA is appropriate in most situations. Treatment should add personal value by minimizing morbidity and improving long-term outcomes. Novel technologies, approaches, and techniques all promise to redefine our approach to thyroid nodules in the immediate future.

NONTOXIC GOITER

Matthew A. Nobis, MD, and Gerard M. Doherty, MD

Goiter is a nonspecific term referring to any enlargement of the thyroid gland. However, in common use, it mainly denotes benign causes of thyroid enlargement, such as toxic multinodular goiter, diffuse toxic goiter (Graves disease), or nontoxic multinodular goiter. Although malignant enlargement of the thyroid gland can technically be considered a goiter, it is usually referred to as a mass or nodule.

Nontoxic goiter is a benign condition even though some specimens may contain small incidental cancers (up to 20% contain microcarcinomas). The predominant process and the decision making are based on the benign enlargement and resulting symptoms (e.g., dysphagia, dyspnea, or neck pressure). In some areas of the world, nontoxic goiters are endemic because of iodine deficiency, although public health efforts have reduced this somewhat.

PATHOGENESIS

A nontoxic multinodular goiter is defined as an enlargement of the thyroid gland containing follicles that are morphologically and functionally altered. The pathogenesis is multifactorial and can include iodine deficiency, goitrogens such as bamboo shoots, maize, and sweet potatoes, growth factors, and dyshormonogenesis. A family history of nontoxic goiter could implicate the environment, diet, or dyshormonogenesis as causes. Aside from severe iodine deficiency, the cause in an individual is typically not evident, nor does it often influence management.

CLINICAL FEATURES

Nontoxic goiters may remain asymptomatic, or they may give rise to compressive features such as dyspnea, dysphagia, or venous congestion/discomfort with certain movements. A change in the voice can occur from direct pressure on the larynx, or from stretching of the laryngeal nerves. Direct effects on the nerve causing paresis of the ipsilateral vocal fold are uncommon from benign goiter because nerve paresis is much more commonly associated with malignant infiltration of the nerve. Sudden changes in the goiter, as from hemorrhage into a nodule, can cause transient, intermittent, or permanent hoarseness. Thyroidectomy can often assuage voice changes due to direct pressure on the larynx, but the benefits for overt uncommon changes due to effects on the nerve are less consistent.

On physical examination, the size of the gland, the features of diffuse enlargement or nodularity, tracheal deviation, extension of the gland below the sternum or clavicular heads, or high up into the neck near the angle of the mandible are all important for treatment planning. Many large goiters are not palpable by physical examination, particularly if they have a predominant substernal or posterior component (Fig. 1). Associated lymphadenopathy should raise suspicion of malignancy.

FIG 3 (A) Preoperative and (B) 1 week postoperative appearance of a male after removal of a 4-cm benign thyroid goiter.

CONCLUSION

Thyroid nodules and differentiated thyroid cancer are extremely common but rarely cause death. A simple diagnostic algorithm with thyroid function testing followed by ultrasound scanning and FNA is appropriate in most situations. Treatment should add personal value by minimizing morbidity and improving long-term outcomes. Novel technologies, approaches, and techniques all promise to redefine our approach to thyroid nodules in the immediate future.

NONTOXIC GOITER

Matthew A. Nobis, MD, and Gerard M. Doherty, MD

Goiter is a nonspecific term referring to any enlargement of the thyroid gland. However, in common use, it mainly denotes benign causes of thyroid enlargement, such as toxic multinodular goiter, diffuse toxic goiter (Graves' disease), or nontoxic multinodular goiter. Although malignant enlargement of the thyroid gland can technically be considered a goiter, it is usually referred to as a mass or nodule.

Nontoxic goiter is a benign condition even though some specimens may contain small incidental cancers (up to 20% contain microcarcinomas). The predominant process and the decision making are based on the benign enlargement and resulting symptoms (e.g., dysphagia, dyspnea, or neck pressure). In some areas of the world, nontoxic goiters are endemic because of iodine deficiency, although public health efforts have reduced this somewhat.

PATHOGENESIS

A nontoxic multinodular goiter is defined as an enlargement of the thyroid gland containing follicles that are morphologically and functionally altered. The pathogenesis is multifactorial and can include iodine deficiency, goitrogens such as bamboo shoots, maize, and sweet potatoes, growth factors, and dyshormonogenesis. A family history of nontoxic goiter could implicate the environment, diet, or dyshormonogenesis as causes. Aside from severe iodine deficiency, the cause in an individual is typically not evident, nor does it often influence management.

CLINICAL FEATURES

Nontoxic goiters may remain asymptomatic, or they may give rise to compressive features such as dyspnea, dysphagia, or stridor (aggravated/manifest with certain movements). A change in the voice can occur from direct pressure on the larynx, or from stretching of the laryngeal nerves. Direct effects on the nerve causing paresis of the ipsilateral vocal fold are uncommon from benign goiter because nerve paresis is much more commonly associated with malignant infiltration of the nerve. Sudden changes in the goiter, as from hemorrhage into a nodule, can cause transient, intermittent, or permanent hoarseness. Thyroidectomy can often assuage voice changes due to direct pressure on the larynx, but the benefits for overt uncommon changes due to effects on the nerve are less consistent.

On physical examination, the size of the gland, the features of diffuse enlargement or nodularity, tracheal deviation, extension of the gland below the sternum or clavicular heads, or high up into the neck near the angle of the mandible are all important for treatment planning. Many large goiters are not palpable by physical examination, particularly if they have a predominant substernal or posterior component (Fig. 1). Associated lymphadenopathy should raise suspicion of malignancy.

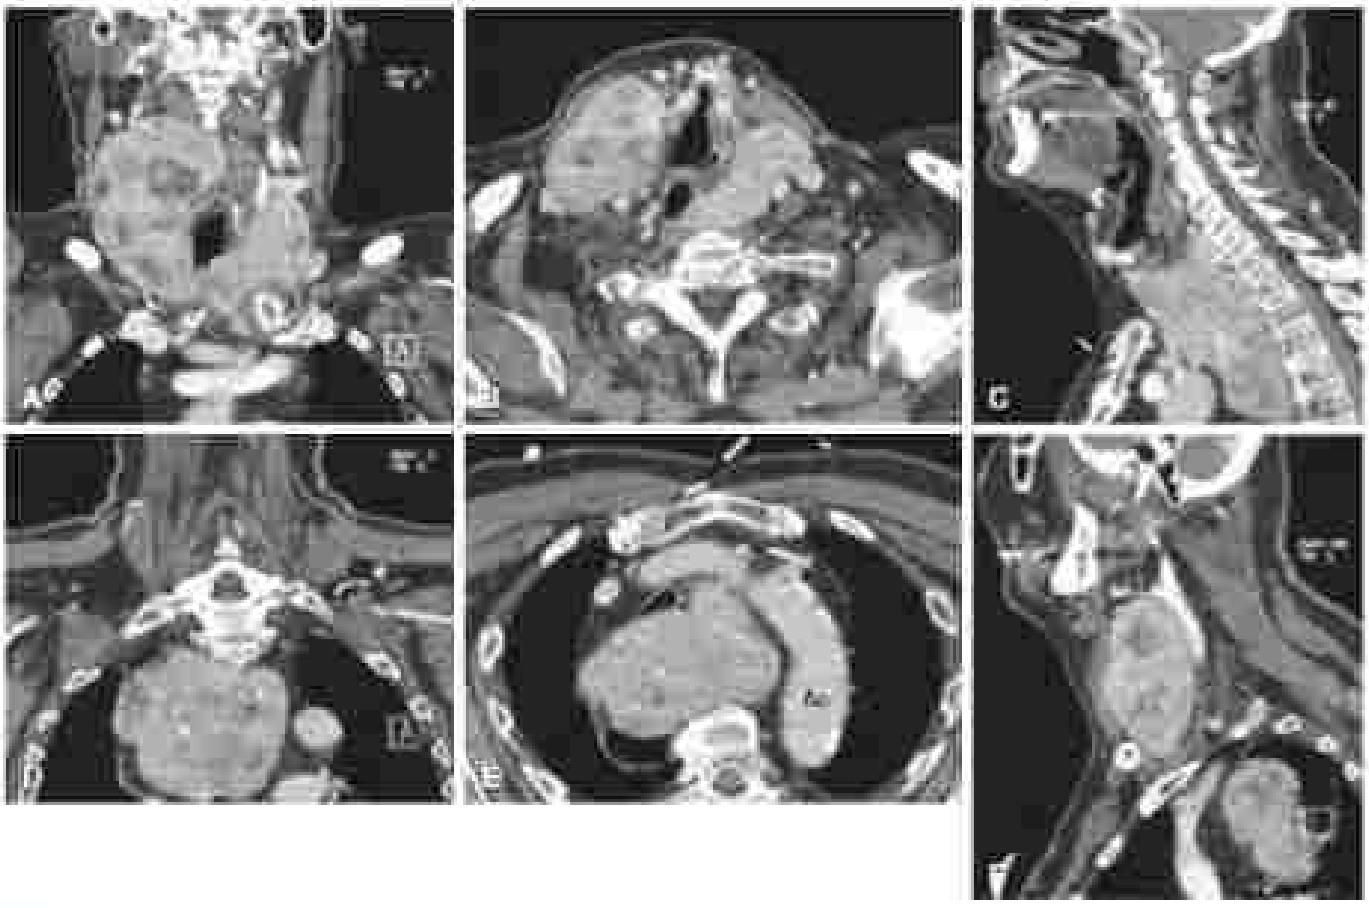

FIG. 1 An 82-year-old man with a palpable right thyroid mass. The patient presented with a large palpable right neck mass. Cross-sectional imaging revealed a heterogeneous infiltrating multinodular goiter (A–B) with a thalassemia left thyroid lobe (C–D). Note that the retrosternal component is below the arch of the aorta (*), and has grown along the prevertebral fascia (C). The right upper pole has displaced the course of the right common carotid artery (*). This patient required thoracotomy to deliver the mediastinal component of the gland safely.

EVALUATION

Thyroid-stimulating hormone (TSH), free T_4, and T_3 levels should be assessed to identify subclinical or overt thyrotoxicosis, hypothyroidism, or a euthyroid state. Fine needle aspiration should be performed with ultrasound guidance for any suspicious thyroid nodule. Ultrasound features that raise the risk of malignancy include hypoechogenicity, microcalcifications, hypervascularity, and solid components of complex (cystic and solid) nodules, as well as regional lymphadenopathy.

Plain chest films can demonstrate tracheal deviation, mediastinal and intrathoracic extension, airway compression, and gross calcifications. However, cross-sectional imaging such as computed tomography (CT) or magnetic resonance imaging (MR) is more informative for these findings. In particular, evaluating the extent of airway compression, the precise geometry of goiter position in the chest, and any associated lymphadenopathy that might indicate a clinically significant malignant component, is much more effective with CT or MR.

Radioiodine scans, pulmonary function tests, flow volume loops and barium swallow studies may each be useful in specific situations but are not typically necessary in the era of accurate cross-sectional imaging.

Preoperative assessment of vocal fold movement should be considered for each patient. Deliberate voice assessment is mandatory, and fiberoptic laryngoscopy should be considered for patients with any voice alteration or any prior neck or chest operation that places the vagus or recurrent laryngeal nerves at risk. We find that it is useful to assess for respiratory stridor, which can be associated with severe narrowing of the tracheal lumen (Fig. 2).

INDICATIONS FOR TREATMENT

Nontoxic goiter that causes local discomfort, such as tightness, or a choking sensation especially with certain movements, or that has caused mechanical partial obstruction of the upper aerodigestive tract should be considered for treatment. Substernal extension of the goiter into the chest, even in the absence of symptoms, should be considered a relative indication for treatment, as further enlargement of this intrathoracic component can lead to the need for a more disruptive operation to resect it in the future. Cosmetic issues rarely are isolated concerns or indications for therapy, as most patients with goiter of sufficient size to be bothersome are also associated with other symptoms.

TREATMENT MODALITIES

TSH suppression therapy with thyroxine has little role in the management of an established goiter. Prospective trials have failed to demonstrate a benefit for management of multinodular goiter. The side effects of TSH suppression, including bone density loss and atrial arrhythmias, negate the theoretical value, particularly in the elderly patients for whom nonoperative therapy might be most attractive.

Radioactive ablamentation can cause goiter size reduction of 40% to 60% within 2 years, decreasing compressive symptoms. Complications include radiation thyroiditis and hypothyroidism, as well

FIG. 2. A 68-year-old woman with an incidental goiter found during workup for dyspnea. On physical examination, the patient had an obvious, at a palpable thyroid mass, but she had little respiratory symptom. A, computed tomography scan revealed a large, right-sided substernal thyroid with tracheal deviation to the left (A), as well as severe narrowing at the lumen of the tracheal (B).

as a temporary enlargement of the gland, which may be important in some clinical situations. Recent experience with the use of exogenous TSH administration to increase the efficiency of radioiodine administration to patients with limited iodine uptake shows some improvement over radioiodine alone. These approaches may be useful for patients who have comorbidities that affect the safety of operative management, but these same comorbidities must be considered if the patient becomes temporarily hyperthyroid from treatment or as the time course of correction of the local pressure symptoms of the goiter is extended.

Surgical management is the mainstay of treatment for symptomatic, nontoxic goiter and is generally well tolerated, even in patients with limited physiologic reserve. The operation should typically be a bilateral procedure, removing all, or nearly all, of both thyroid lobes, in addition to any substernal extension. The operation is nearly always limited to a cervical incision, with median sternotomy or posterolateral thoracotomy being necessary only very rarely in previously unoperated patients. In experienced centers, complication rates are low (<2%) with techniques that include careful hemostasis and liberal parathyroid autotransplantation. For patients with significant airway compression or deviation, securing the airway can be the most critical part of the operation and may require conscious fiberoptic intubation under topical anesthesia to begin the procedure.

The thyroid gland should be exposed by a sufficient incision, although many thyroid operations can be done through very limited incisions, the geometry of the large multinodular goiter often requires long incisions to expose and remove the gland safely. Suprasternal flaps improve the exposure of the limits of the gland, especially superiorly for glands with upper poles that extend high in the neck. The strap muscles can be separated in the midline, or divided, near the upper pole, as necessary to expose the thyroid gland. In almost all cases, division of the sternothyroid muscle at the thyroid cartilage is sufficient for this exposure, but the sternohyoid can be divided as well if necessary. The larger the cervical portion of the gland, especially the upper poles, the more likely it is that transverse division of the sternothyroid and sternohyoid muscles will be helpful.

We find it helpful to divide the isthmus early in the case, as this provides a useful anterior landmark, particularly in cases where tracheal deviation distorts the typical course of the trachea and larynx. We then begin the dissection on the side of the larger lobe if the goiter is asymmetric. This ensures that the patient will have the most benefit in case the procedure has to be confined to a unilateral procedure (e.g., intraoperative recurrent laryngeal nerve [RLN] injury).

The upper pole of the gland is isolated by first separating the lateral aspect of the upper portion of the thyroid gland from the carotid sheath. If recurrent nerve monitoring is used, then the sheath is opened and the vagus nerve stimulated to establish baseline electromyography (EMG) function. The plane between the larynx and the upper pole of the thyroid gland is then opened, exposing the superior thyroid artery. The external branch of the superior laryngeal nerve (EBSLN) can be identified during some operations by direct inspection or by nerve monitor stimulation, keeping in mind that many EBSLNs run in an intramuscular course. Positive confirmation of the nerve can be determined by seeing a symmetric wave in both the anterior and posterior segments of the ipsilateral cricothyroid muscle in response to nerve stimulation. However, in any case, the delicate fascia over the cricothyroid muscle should be kept intact because the nerve is deep to this. Because the plane is followed superiorly, the EBSLN should stay medial and superior to the upper pole of the thyroid and its vessels. The upper pole vessels can then be divided safely using any number of hemostatic strategies, including ligatures, clips, and powered dissection tools. The branches of the superior thyroid artery should be individually controlled immediately adjacent to the thyroid parenchyma to minimize the risk to the EBSLN.

Once the upper pole is fully mobilized, the thyroid is partially rotated anteriorly and medially to continue dissecting the lateral portion of the thyroid gland. The middle thyroid vein, if present, is divided, and the thyroid separated from the carotid sheath along its entire extent. The dissection can then be carried posteriorly into the paratracheal space. The ability to rotate the thyroid gland may be limited by a large substernal component. The decision of whether to proceed with the dissection of the tracheoesophageal groove, recurrent laryngeal nerve and parathyroid glands first preferred, or whether to dissect the substernal portion of the goiter in order to create the necessary mobility, is dictated by the geometry of the particular patient and goiter. A large substernal component with a narrow thoracic inlet can create severe compression of the goiter and significant hemorrhage from the capsular veins of the gland. Delivery of the substernal component (either transcervically or by sternotomy) will often relieve this compression and allow a more hemostatic dissection.

The tracheoesophageal groove is dissected to identify the RLN. We try to identify the RLN as low in the neck as possible, because

this is the area where the nerve is least tethered to surrounding structures, and least likely to be stretched during dissection and identification. The nerve is identified by its appearance, anatomic course, and by stimulation if nerve monitoring is used; however, stimulation alone is not sufficient to identify the RLN. In particular, the absence of an EMG signal does not prove that a stimulated structure is not the RLN. Although intraoperative nerve monitoring is used by many experienced thyroid surgeons as an intraoperative adjunct, large trials have failed to show a benefit to patients as measured by RLN injury rates. The use of intraoperative nerve monitoring is a reasonable adjunct at the discretion of the surgeon but is not a standard of care.

Once the recurrent nerve is identified, it can be separated from the posterior aspect of the thyroid gland, and the intrathoracic portion can be safely delivered into the wound. The arterial supply to the thyroid gutter comes entirely from branches in the neck; there is no intrathoracic arterial supply to be concerned with (with the exception of the rare thyroid ima, which can arise from the innominate artery or the aorta). The main risk, then, is traction on the RLN as the substernal or paraesophageal intrathoracic portion of the goiter is delivered into the cervical wound by blunt dissection and gentle traction.

An important note of caution: in posteriorly displaced goiters with a component that extends inferiorly along the esophagus, especially on the right, the RLN may pass anterior to some portion of the goiter and may appear to be buried within the thyroid parenchyma because it has been trapped between nodules. This configuration makes the RLN especially vulnerable to stretch injury if this possibility is not recognized and anticipated early in the dissection.

Once the nerve is identified and the inferior portion of the thyroid gland mobilized, the RLN is traced up to its insertion into the larynx under the inferior border of the cricopharyngeus muscle. The small branches of the inferior thyroid artery are divided along the parenchymal surface of the gland, with the RLN always in view and protected. The parathyroid glands typically become evident during this portion of the dissection. Their blood supply from the inferior thyroid artery should be preserved if possible. If not, then the glands should be removed and grafted into the sternocleidomastoid muscle. As the dissection approaches the insertion of the RLN into the larynx, the RLN becomes progressively more fixed by surrounding tissues, including branches of the inferior thyroid artery, the fascial attachments of the thyroid gland to the trachea, and the insertion itself. Great care is necessary to dissect the thyroid gland safely away from the RLN without directly injuring or stretching the RLN. Once the RLN is fully separated from the thyroid gland, then the final attachments of the thyroid gland to the trachea can be divided. If intraoperative nerve monitoring was used, then the EMG signal with vagus nerve stimulation should be assessed at the completion of the dissection.

The process is then repeated on the opposite side. If there has been difficulty with the dissection on the initial side, then the contralateral procedure may be modified to reduce the risk of complications. For example, if the RLN lost function as documented by intraoperative nerve monitoring, then the contralateral RLN dissection may be modified to leave the RLN segment near the laryngeal insertion undisturbed by leaving a portion of the thyroid lobe in place in that position.

Devitalized parathyroid tissue should be cut into small (1–2 mm) pieces and grafted into small pockets in the sternocleidomastoid muscle. It is best to close each pocket with a suture to hold the graft in place while it develops a blood supply over the ensuing 6–12 weeks. It is not necessary to attempt to mark the site with permanent sutures or clips as subsequent exploration to remove these remnants is extremely rare, and best guided by ultrasound if necessary.

Meticulous hemostasis is important, because bleeding in the confined space of the neck can compress the airway. The strap muscles are reapproximated in some fashion, depending on how they were opened or divided, but the closure should not be occlusive. We routinely leave a large gap at the inferior aspect of the strap muscles to allow decompression if a postoperative hematoma should occur. The platysma muscle is reapproximated to align the skin edges and remove tension from the wound. The skin is closed according to the preference of the surgeon; one popular preference is to approximate the skin edges with a running 3-0 polypropylene pullout subcuticular suture, followed by skin glue. The suture is removed after the glue is dry (about 2 minutes). This provides a cosmetic closure that requires no further attention until after the glue peels away at about postoperative day 14.

POSTOPERATIVE CARE

In our practice, patients remain hospitalized overnight after removal of a nontoxic goiter to manage their limited pain and to monitor them for neck hematoma or hypocalcemia. All patients are managed with oral calcium supplement: Calcium citrate 950 mg by mouth four times daily) and escalcitol 0.25 μg by mouth daily beginning immediately after the operation. If they are symptomatic with numbness or tingling or if their calcium on the morning after surgery is below 8 mg/dL, then the dose is doubled. If their symptoms persist, either before or after discharge, or if there is special concern about the immediate parathyroid function, for example if two or more parathyroid glands were grafted, then we will consider keeping the patient for further observation or facilitating calcium laboratory draws within a few days of discharge.

Postoperative voice assessment is mandatory in all patients. Most patients have some immediate voice changes, but these nearly all resolve within 2 weeks of operation. Laryngoscopy to document vocal cord motion should be performed for all patients with significant voice changes that persist beyond 2 weeks, and for all patients who have a change in their intraoperative nerve monitoring findings during the procedure, if that adjunct has been used. Although some have advocated for more broad use of laryngoscopy before and after surgery, there is no evidence that this changes patient outcomes, and we most experienced surgeons focus this effort in a more selective way.

MANAGEMENT OF THYROIDITIS

Mustapha El Lakis, MD, Douglas Wiseman, MD, and Elac von Kobadow, MD

Thyroiditis is an inflammatory process of the thyroid gland that may manifest with or without goiter formation and with gradual loss of thyroid function and episodes of hyperthyroidism. It includes a diverse group of disorders that can be clinically categorized as painful or painless thyroiditis (Table 1). Thyroiditis is most commonly asymptomatic but may be associated with a wide range of symptoms related to mass effect, hypothyroidism, or hyperthyroidism (Box 1). The inflammatory processes that cause acute illness with severe pain are (1) subacute thyroiditis, (2) acute suppurative thyroiditis, (3) radiation-induced thyroiditis, and (4) trauma-induced thyroiditis. On the other hand, thyroiditis in which there is usually no pain or tenderness includes (1) Hashimoto's thyroiditis, (2) postpartum thyroiditis, (3) drug-induced thyroiditis, and (4) Riedel's thyroiditis. Medical therapy remains the mainstay of the management of thyroiditis, but surgical treatment is warranted in certain circumstances (Table 2).

PAINLESS THYROIDITIS

Hashimoto's Thyroiditis

Hashimoto's thyroiditis, or chronic autoimmune thyroiditis, is the most common type of thyroiditis and cause of hypothyroidism in iodine sufficient areas of the world. The condition is named from a 1912 pathology report by Hakaru Hashimoto, who described four female patients with goiter and intense lymphocytic infiltration of the thyroid by stroma lymphomatosa. The prevalence of Hashimoto's thyroiditis varies depending on the criteria used for diagnosis. Autopsy studies demonstrate that 40% to 45% of women and 20% of men in the United States and the United Kingdom have focal thyroiditis.

Hashimoto's thyroiditis results from autoimmune-mediated destruction of the thyroid gland, which can manifest with different phenotypes, including hypothyroidism, however, many patients can have normal thyroid function. It can present with or without a goiter or, sometimes, with atrophic autoimmune thyroiditis. The cause of Hashimoto's disease is poorly understood, although a combination of environmental and genetic factors has been attributed to its development. The amount of iodine intake parallels the prevalence of Hashimoto's thyroiditis. Similarly, drugs containing high amounts of iodine, such as amiodarone, often precipitate autoimmune thyroiditis, although a variety of mechanisms has been suggested. In recent years, genetic susceptibility has been established for this disorder based on several observations: it clusters in families, the concordance rate in monozygotic twins is 30% to 40%, it is more common in patients with Down syndrome and Turner syndrome, and it has an association with human leukocyte antigen allele DR3.

Hashimoto's thyroiditis, like other autoimmune disorders, is more common in women (a male to female ratio of 1:7) between the ages of 30 and 50 years. Most patients are symptom free and present with a relatively small and firm granular thyroid. Some patients present with an enlarging diffuse goiter that causes compressive symptoms such as fullness, neck pressure, dysphagia, dyspnea, hoarseness, cough, or a choking sensation. Hypothyroidism is the characteristic functional abnormality; however, the inflammatory process that occurs early in the course may cause thyroid follicular disruption and thyroid hormone release, leading to transient hyperthyroidism referred to as Hashitoxicosis. Ophthalmopathy may occur rarely in patients with Hashimoto's thyroiditis. Furthermore, thyroid lymphoma has been associated with Hashimoto's thyroiditis, with up to 80% of patients with thyroid lymphoma having Hashimoto's thyroiditis. Most thyroid lymphomas are of the non-Hodgkin B cell type and tend to occur in older female patients.

On physical examination, patients with Hashimoto's thyroiditis have a nontender, diffusely firm, or lumpy thyroid gland. Associated thyroid nodules are usually benign Hürthle cell nodules. When Hashimoto's thyroiditis is suspected clinically, thyroid ultrasound scanning is indicated. Ultrasound features can vary depending on the severity and the phase of disease. The classical finding is a diffusely enlarged gland with heterogeneous echotexture (Fig. 1). The biochemical workup should include measurement of antimicrosomal antibody, antithyroglobulin antibody titers, thyroid peroxidase antibodies, and serum thyroid stimulating hormone (TSH) levels. Almost all patients have elevated antimicrosomal antibodies (>90%) and less often, antithyroglobulin antibodies (20% to 30%) and TSH receptor blocking antibodies (10%). All thyroid nodules should be evaluated according to their ultrasound features (see the chapter on management of thyroid nodules). Enlarged lymph nodes may be present, but they are usually benign and reactive. A rapidly enlarging goiter should raise suspicion of lymphoma and warrants a fine-needle aspiration (FNA) biopsy with flow cytometry analysis.

In patients with hypothyroidism, treatment consists of thyroid hormone replacement—which may result in a decrease in goiter size—with a goal of normal TSH levels. The management of patients with subclinical hypothyroidism (normal T_4 and elevated TSH) is controversial. All patients are followed up long term for the potential development of hypothyroidism, thyroid enlargement, compressive symptoms, or lymphoma. Surgery is indicated in patients with a dominant nodule that is or may be malignant, goiters causing compressive symptoms, or cosmetic concerns. Thyroidectomy for thyroiditis may be challenging because of the obliteration of tissue planes from inflammation/fibrosis, and a stiff thyroid gland may result in excessive traction on the recurrent laryngeal nerves when mobilizing the gland. Some series for thyroidectomy in patients with Hashimoto's thyroiditis have higher complication rates than thyroidectomy for differentiated thyroid carcinoma.

Histologically, the thyroid gland can be atrophic, or it can be diffusely enlarged (25–250 g) with an intact capsule and a potentially observable prominent pyramidal lobe. Grossly, the cut surface shows a pale, grayish tan nodular gland, and histologic examination reveals an extensive lymphocytic infiltrate with germinal center formation (Fig. 2). Thyroid follicles are smaller than normal and contain reduced amounts of colloid. The follicles are lined by Hürthle or Askanazy cells, which are characterized by abundant eosinophilic and granular cytoplasm. In addition, fibrosis may be increased but does not extend beyond the capsule.

Postpartum Thyroiditis

Postpartum thyroiditis is considered a variant of Hashimoto's thyroiditis; it is a destructive thyroiditis induced by an autoimmune mechanism within 1 year of parturition. Postpartum thyroiditis can also occur after spontaneous or induced abortion. It usually presents in one of three ways: transient hyperthyroidism, transient hypothyroidism, or transient hyperthyroidism followed by hypothyroidism and recovery. Its prevalence ranges from 1% to 17%, and its incidence is increased in women with type 1 diabetes mellitus, women with a prior history of postpartum thyroiditis, and women with positive antithyroid peroxidase antibodies. Postpartum thyroiditis is self-limited, and most women recover within 1 year postpartum; however, it increases the risk for development of permanent hypothyroidism within 5 to 12 years in up to 45% of patients.

TABLE 1 Types of Thyroiditis

Disorder	Cause
PAINLESS THYROIDITIS	
Hashimoto's thyroiditis	Autoimmune thyroiditis
Postpartum thyroiditis	Postpartum exacerbation
Riedel's thyroiditis	Fibrous thyroiditis
Drug-induced thyroiditis	Amiodarone, tyrosine kinase inhibitors, interferon α, checkpoint inhibitor immunotherapy, lithium
PAINFUL THYROIDITIS	
Subacute thyroiditis	Viral infection
Acute suppurative thyroiditis	Bacterial infection (*Staphylococcus aureus*, *Streptococcus pyogenes*)
Radioiodine-induced thyroiditis	Iodine-131 treatment
Trauma-induced thyroiditis	Vigorous palpation or trauma

BOX 1 Symptoms Associated with Thyroiditis

Mass Effect
- Neck pressure
- Dysphagia
- Dyspnea
- Hoarseness
- Cough

Hypothyroidism
- Fatigue
- Constipation
- Depression, mood swings
- Cold intolerance
- Weight gain

Hyperthyroidism
- Hair loss
- Palpitations
- Tremors
- Heat intolerance
- Weight loss
- Sweating
- Anxiety, nervousness
- Depression, mood swings

Patients are usually seen with the acute onset of the thyrotoxic phase, which typically occurs 2 to 8 weeks after delivery and lasts for a few months until the thyroid hormone stores have been depleted. This phase is characterized by moderate thyroid enlargement and is followed by a euthyroid phase, which can last for a few months, then by a hypothyroid phase with symptomatic hypothyroidism, which can last for up to 1 year. Unlike in Graves' disease, patients' thyroid stimulating immunoglobulin levels are within the normal range. However, patients have elevated antimicrosomal and antithyroglobulin antibody titers. Ultrasound examination of the thyroid gland reveals diffuse hypoechogenicity, which resolves with resolution of the thyroiditis.

Patients are monitored with serial thyroid function tests to determine their clinical progression through the various phases. Antithyroid drugs and radioiodine therapy are not effective for treatment of thyrotoxicosis, because the thyrotoxicosis occurs as a result of increased release of thyroid hormone stores, not as a result of increased synthesis of thyroid hormones. However, β-blocker therapy may be used for symptoms of thyrotoxicosis. Thyroid hormone replacement is initiated in the hypothyroid phase, but it should eventually be discontinued to determine a patient's transition to the recovery phase.

TABLE 2 Indications for Thyroid Surgery

Condition	Indication
Hashimoto's thyroiditis	Suspicion of malignancy or malignant thyroid nodule Local compressive symptoms Cosmetic concern
Postpartum thyroiditis	Not indicated
Drug-induced thyroiditis	Thyrotoxicosis refractory to medical treatment
Riedel's thyroiditis	Tracheostomy for decompression and diagnosis
Subacute thyroiditis	Thyrotoxicosis refractory to medical treatment
Acute suppurative thyroiditis	Refractory to percutaneous drainage and antibiotics
Radioiodine-induced thyroiditis	Not indicated
Trauma-induced thyroiditis	Not indicated

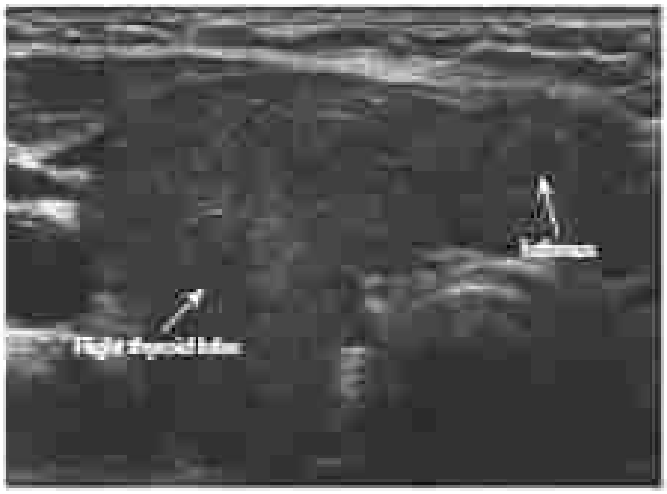

FIG. 1 Transverse ultrasound image showing right thyroid lobe and isthmus in a patient with chronic lymphocytic thyroiditis. The thyroid gland has diffuse and heterogeneous hypoechogenicity.

Drug-Induced Thyroiditis

Patients receiving interferon alpha, amiodarone, interleukin 2, lithium, tyrosine kinase inhibitors, or checkpoint inhibitor immunotherapy may develop painless thyroiditis. Hypothyroidism and hyperthyroidism are potential toxicities of interferon α therapy. Up to 10% of patients may develop either Hashimoto's thyroiditis or Graves' disease. The risk for development of a thyroid abnormality increases when serum antithyroid antibody concentrations are elevated before initiation of the drug. Patients with hepatitis C infection are also at an increased risk. When symptoms are severe, interferon α is discontinued.

FIG. 1. Left thyroid lobe in a patient with chronic lymphocytic thyroiditis that required a left thyroid lobectomy and isthmusectomy for an inconclusive fine-needle aspiration biopsy that on cytologic examination showed a Hürthle cell neoplasm. Grossly the thyroid lobe was pale and firm.

Amiodarone, a class III antiarrhythmic drug, is associated with both hypothyroidism and hyperthyroidism due to its high iodine content and its direct toxic effect on the thyroid. With every 200 mg of amiodarone, 9 mg of inorganic iodine is released into the systemic circulation, which significantly exceeds the recommended amount of 0.3 mg/day. Amiodarone-induced thyrotoxicosis (AIT) occurs in 2% to 5% of patients on chronic amiodarone therapy and is more common in patients with underlying Hashimoto's thyroiditis. AIT is classified into two types. Type I occurs as a result of an iodine-induced increase in thyroid hormone synthesis, especially in patients with a preexisting multinodular goiter. Type II is secondary to a direct toxic effect on the thyroid gland, causing thyroiditis and inflammatory-induced destruction of follicular epithelial cells. It is often followed by transient hypothyroidism. In the absence of life-threatening arrhythmias, amiodarone may be discontinued. However, because of its high lipid solubility and half-life of about 100 days, plasma levels of amiodarone decrease very slowly. The management of AIT consists of high-dose prednisone (40–60 mg/d). β-Blockers may be used for thyrotoxic symptoms, but they must be used with caution because, in combination with amiodarone, they may cause bradycardia and chest arrest. Potassium perchlorate, which inhibits iodine uptake and release by the thyroid gland, has also been used to treat AIT, often in combination with a thionamide agent. Patients with type II AIT who respond to medical therapy, including discontinuation of amiodarone, may develop transient or less commonly, permanent hypothyroidism requiring thyroid hormone replacement. Rarely in patients with persistent AIT despite medical therapy, near total or total thyroidectomy is indicated.

Tyrosine kinase inhibitors (most frequently sunitinib) sometimes include hypothyroidism—which can occur in up to 39% of patients—and to a lesser extent, thyrotoxicosis, possibly from destructive thyroiditis. TSH should be determined before initiation of the drug and at least every three months thereafter. Hypothyroidism is managed by thyroid hormone replacement; however, drug discontinuation or dosage reduction is typically unnecessary.

Riedel's Thyroiditis

Riedel's thyroiditis, also known as *Riedel struma* or *invasive fibrous thyroiditis*, is an extremely rare condition with a prevalence of 0.05% or less of surgical thyroid diseases. It was originally described in 1896 by Bernhard Riedel as a "specific inflammation of mysterious solitary producing an iron hard tumefaction of the thyroid." It is characterized by a replacement of the thyroid gland with dense fibrous tissue that extends beyond its capsule and involves the perithyroidal soft tissue. In contrast to other inflammatory conditions, extrathyroidal extension of the fibrosis may result in hypoparathyroidism, hoarseness, and compression of the trachea. Riedel's thyroiditis can occur with other fibrotic conditions affecting the retroperitoneum, mediastinum, lungs, lacrimal and parotid glands, bile ducts, and orbits, suggesting that it may be a primary fibrotic disorder. No etiologic relationship to drugs or other autoimmune diseases has been identified.

Patients present with slowly growing, painless goiters manifesting with neck pressure, dysphagia, or hoarseness from mass effect and the involvement of the esophagus and recurrent laryngeal nerves, respectively. Patients can also have symptoms related to hypothyroidism and hypoparathyroidism. On physical examination, one or both of their lobes are enlarged. Furthermore, the gland is "stony" hard, nontender, and adherent to the adjacent soft tissue and muscles.

Like other thyroid conditions, the diagnostic armamentarium should include screening thyroid function tests, and an ultrasound of the neck. Serum calcium, phosphorus, and parathyroid hormone levels help identify hypoparathyroidism. Ultrasound examination typically demonstrates diffuse hypoechogenicity, reduced vascularity throughout the entire thyroid gland, and the absence of demarcation between the thyroid gland and other surrounding structures. The extent of the fibrosis is best defined by computed tomography or magnetic resonance imaging. FNA biopsy is often inadequate, but when successful, it demonstrates a paucity of follicular epithelial cells and extensive fibrotic change. Sometimes these cytologic findings cannot be distinguished from the fibrotic change that occurs in patients with poorly differentiated or anaplastic thyroid cancer; consequently, the definitive diagnosis is confirmed by open thyroid biopsy, which also helps to exclude carcinoma.

Untreated, Riedel's thyroiditis usually progresses slowly and may stabilize or even regress spontaneously. Surgery may be indicated. The aim is to decompress the trachea by an isthmusectomy and to make a tissue diagnosis. More extensive surgery can be dangerous because of the loss of normal tissue planes, which is associated with a higher risk of injury to important structures (recurrent laryngeal nerves, parathyroid glands, and carotid arteries). Hypothyroidism is managed by thyroid hormone replacement, and hypoparathyroidism by calcium and calcitriol. High-dose corticosteroids reduce goiter size and are important in relieving compressive symptoms. Tamoxifen has also been shown to reduce goiter size and relieve compressive symptoms. More recently, some success has been reported with combined prednisone and mycophenolate mofetil therapy in a patient with disease that was resistant to prednisone and tamoxifen.

PAINFUL THYROIDITIS

Subacute Thyroiditis

Subacute thyroiditis is also known as subacute granulomatous thyroiditis, de Quervain's thyroiditis, subacute nonsuppurative thyroiditis, giant cell thyroiditis, and painful thyroiditis. It is a self-limited inflammatory condition of the thyroid gland presumed to be caused by a viral infection. It affects women between 30 and 40 years of age more often than males (a ratio of 3 to 5:1). The condition is characterized by a sudden or gradual onset of unilateral or bilateral neck pain that may radiate to the jaw, ear, and upper chest. In some cases, the pain is so severe that the patient cannot tolerate palpation of the neck or tight-fitting clothing. Pain can be exacerbated by coughing or turning the head. Fever, fatigue, malaise, anorexia, and myalgia are common. On physical examination, patients have an enlarged, firm, and tender thyroid gland, particularly in the acute phase. The overlying skin may be erythematous if the inflammation is severe.

Patients usually present with thyrotoxicosis followed by euthyroidism, hypothyroidism, and, ultimately, restoration of normal thyroid function. Fifteen percent of patients may develop permanent hypothyroidism. The thyrotoxic phase pathophysiology is similar to

other destruction-induced thyroiditis. Hyperthyroidism symptoms are usually mild and transient and last until the thyroid hormones are depleted. Each phase typically lasts 2 to 8 weeks. Some patients may progress directly from the hyperthyroid phase to the recovery phase, without the intervening hypothyroid phase. Up to 4% of patients develop recurrent disease. This condition is typically diagnosed clinically. In the early stages of the illness, TSH is suppressed (typically <0.1 mIU/L), whereas free T_4 and free T_3 levels are elevated. Thyroid antibody titers (antithyroglobulin, antimicrosomal, and TSH receptor antibody) are also elevated in 10% to 20% of patients. Inflammatory serum markers, such as erythrocyte sedimentation rate (ESR), are typically elevated (ESR >100 mm/h), and a normal ESR rules out active subacute thyroiditis. Leukocytosis and elevated C-reactive protein may also be present. Radioiodine imaging shows low uptake (typically <1%–3%), which helps to confirm the diagnosis. Ultrasound examination and FNA or core needle biopsy are rarely necessary, especially in patients with a tender thyroid. The sonographic features in a patient with subacute thyroiditis are a heterogeneous hypoechoic gland with a diffuse decrease in vascularity, unlike Graves' disease, which manifests with an enhanced flow on Doppler scanning. However, fine-needle biopsy may be useful to differentiate subacute thyroiditis from suppurative thyroiditis. Typical cytologic features include neutrophils, lymphocytes, histiocytes, and giant cells.

The condition is self-limited. Patients complaining of severe pain will benefit from nonsteroidal antiinflammatory drugs. For refractory severe neck pain or persistent pain after 2 to 3 days of nonsteroidal antiinflammatory therapy, prednisone (40 mg/d) is indicated. Hyperadrenergic symptoms may require short-term β-blocker therapy; however, thionamides are not indicated. Thyroid hormone replacement may be needed in the hypothyroid phase if patients are symptomatic. Therapy should be withdrawn and the patient reevaluated after a months. Iodine-131 therapy is not indicated, nor is it effective because radioiodine uptake in patients with subacute thyroiditis is suppressed. Thyroidectomy is reserved for the rare patient who has a prolonged course that is unresponsive to medical treatment.

Acute Suppurative Thyroiditis

Acute suppurative thyroiditis is a rare condition that manifests with a neck abscess, sudden onset of neck pain, and tenderness. Pain is usually unilateral and is accompanied by fever, chills, and other systemic symptoms and signs of infection. Most patients have a unilateral fluctuant neck mass. The condition is caused by gram-positive or gram-negative organisms, with Staphylococcus and Streptococcus species being the most commonly reported bacterial agents. Fungal, mycobacterial, and parasitic agents have been reported in immunocompromised patients. The thyroid gland is very well vascularized and has a capsule and extensive lymphatic drainage, which makes it resistant to infections. Therefore acute suppurative thyroiditis often occurs in immunocompromised or elderly frail patients. Infectious agents most commonly reach the thyroid gland via hematogenous spread, but they can also do so through lymphatic spread, direct extension, such as via esophageal perforation, or neck trauma. Acute suppurative thyroiditis in children is usually secondary to direct extension from a pyriform sinus fistula.

Thyroid function in patients with acute suppurative thyroiditis is usually normal, but thyrotoxicosis may be present. Thyroid ultrasound scans can differentiate between subacute thyroiditis (diffuse heterogeneity and low intensity vascular flow) and suppurative thyroiditis (abscess), as can FNA biopsy (multinucleated giant cell granulomas in subacute thyroiditis versus purulent collection in suppurative thyroiditis).

Acute suppurative thyroiditis is treated by empiric intravenous antibiotics and abscess drainage, the latter of which can be achieved via ultrasound guidance. Infrequently, surgical drainage or removal of the thyroid gland is required in patients who do not respond to percutaneous drainage and systemic antibiotic therapy.

Radioiodine-Induced Thyroiditis

Less than 1% of patients treated with radioactive iodine develop thyroiditis. It typically manifests with thyroid pain and tenderness 5 to 10 days after therapy, which can be due to radiation-induced injury and necrosis of thyroid follicular cells and associated inflammation. The neck pain and tenderness are usually mild and spontaneously subside in a few days to 1 week. There also may be transient exacerbation of hyperthyroidism, unless hormone stores were first depleted with thionamide therapy in cases of Graves' disease. Nonsteroidal antiinflammatory drugs are usually sufficient for analgesia, but prednisone may be required in severe cases.

Trauma-Induced Thyroiditis

Thyroiditis has been reported secondary to vigorous physical examination, thyroid biopsy, neck surgery (parathyroid surgery), or trauma (seat belt). Similar to other causes, it manifests by transient neck pain and tenderness, as well as transient hyperthyroidism. It usually requires no intervention and is self-limited.

Management of Hyperthyroidism

Tracy S. Wang, MD, MPH, FACS, and Julie Ann Sosa, MD, MBA, FACS

Hyperthyroidism is a common condition, with an estimated prevalence of 1% to 3% in the United States. It is diagnosed more frequently in women and represents a form of thyrotoxicosis, a term that refers to the clinical state of having excess thyroid hormone, which can have multiple causes. The thyroid is regulated by production of thyroid-stimulating hormone (TSH) by the pituitary gland, which in turn stimulates secretion of thyroxine (T_4) and triiodothyronine (T_3), the active form of thyroid hormone). T_3 and T_4 secretion prompts a negative feedback loop to the pituitary to regulate TSH secretion. Hyperthyroidism is specifically defined as a disorder in which excess thyroid hormone is produced and secreted by the thyroid gland. The most common cause of hyperthyroidism is Graves' disease, followed by a toxic multinodular goiter or a toxic thyroid nodule (toxic adenoma).

Management of hyperthyroidism includes medical management with antithyroid medications, radioactive iodine (RAI) therapy, or thyroidectomy (thyroid lobectomy or total thyroidectomy based on underlying disease). The choice of therapy is dependent on the cause of the hyperthyroidism, clinical features, patient values, and preferences with respect to logistics of each treatment option, risks and benefits, potential side effects, and costs. If surgery is chosen, consideration should be given to availability of a high-volume thyroid surgeon to minimize risks of recurrent laryngeal nerve injury, hypoparathyroidism, or both.

other destruction-induced thyroiditis. Hyperthyroidism symptoms are usually mild and transient and last until the thyroid hormones are depleted. Each phase typically lasts 2 to 8 weeks. Some patients may progress directly from the hyperthyroid phase to the recovery phase, without the intervening hypothyroid phase. Up to 4% of patients develop recurrent disease. This condition is typically diagnosed clinically. In the early stages of the illness, TSH is suppressed (typically <0.1 mIU/L), whereas free T_4 and free T_3 levels are elevated. Management of Hyperthyroidism

Tracy S. Wang, MD, MPH, FACS, and Julie Ann Sosa, MD, MA, FACS

Hyperthyroidism is a common condition, with an estimated prevalence of 1% to 3% in the United States. It is diagnosed more frequently in women and represents a form of thyrotoxicosis, a term that refers to the clinical state of having excess thyroid hormone, which can have multiple causes. The thyroid is regulated by production of thyroid-stimulating hormone (TSH) by the pituitary gland, which in turn stimulates secretion of thyroxine (T_4) and triiodothyronine (T_3), the active form of thyroid hormone). T_3 and T_4 secretion prompts a negative feedback loop to the pituitary to regulate TSH secretion. Hyperthyroidism is specifically defined as a disorder in which excess thyroid hormone is produced and secreted by the thyroid gland. The most common cause of hyperthyroidism is Graves' disease, followed by a toxic multinodular goiter or a toxic thyroid nodule (toxic adenoma).

Management of hyperthyroidism includes medical management with antithyroid medications, radioactive iodine (RAI) therapy, or thyroidectomy (thyroid lobectomy or total thyroidectomy based on underlying disease). The choice of therapy is dependent on the cause of the hyperthyroidism, clinical features, patient values, and preferences with respect to logistics of each treatment option, risks and benefits, potential side effects, and costs. If surgery is chosen, consideration should be given to availability of a high-volume thyroid surgeon to minimize risks of recurrent laryngeal nerve injury, hypoparathyroidism, or both.

TABLE 1 Signs and Symptoms Associated with Thyrotoxicosis

	Signs	Symptoms
General		Weight loss despite increased appetite, heat intolerance, sweating
Cardiovascular	Tachycardia, hypertension, arrhythmia (atrial fibrillation)	Palpitations
Pulmonary	Tachypnea	Dyspnea
Gastrointestinal		Diarrhea, nausea, vomiting
Reproductive	Changes in menstrual cycle	
Ocular	Proptosis, eyelid retraction, periorbital edema	Diplopia, blurry vision, retro-orbital pain, irritated eyes
Dermatologic	Warm and moist ("clammy") skin	
Neuromuscular	Tremor, hyperactivity, hyperreflexia	Tremor, nervousness, anxiety, fatigue, weakness, disturbed sleep, poor concentration

INITIAL EVALUATION AND MANAGEMENT

Hyperthyroidism may be overt or subclinical; overt hyperthyroidism is characterized by low serum TSH levels and high levels of both T3 and T4; in contrast, subclinical hyperthyroidism is defined by the presence of low serum TSH levels and normal T3 and T4 levels. Patients with subclinical hyperthyroidism are often symptom free, in contrast to those with overt hyperthyroidism, in which symptoms may manifest across a spectrum of target organs, including the cardiovascular, pulmonary, gastrointestinal, reproductive, ocular, dermatologic, and neuromuscular systems (Table 1).

In patients with suspected hyperthyroidism, serum TSH should be measured first, because it has the highest sensitivity and specificity in the diagnosis of thyroid dysfunction. If the TSH is low, serum T3 and T4 levels (free or total) should be obtained to differentiate between subclinical and overt hyperthyroidism. Once the diagnosis is established, the cause should be determined; current American Thyroid Association (ATA) guidelines recommend the following diagnostic strategies, depending on available expertise and resources: (1) measurement of thyroid receptor antibodies (TRAb), (2) determination of RAI uptake (RAIU), or (3) measurement of thyroidal blood flow on ultrasonography (Fig. 1). TRAb levels above the normal range are diagnostic for Graves' disease. The ratio of total T3 to total T4 can be useful in determining the cause of thyrotoxicosis, because T3 will be more elevated in hyperthyroidism, whereas T4 is more elevated in thyrotoxicosis caused by thyroiditis.

In patients with hyperthyroidism, thyroid ultrasonography should be performed in patients who have nonfunctioning or hypofunctioning nodules identified on RAIU scans (if performed) or on physical examination; routine ultrasonography is otherwise not recommended. The evaluation of a thyroid nodule with fine needle aspiration (FNA) biopsy should be guided by existing guidelines for the management of thyroid nodules in euthyroid individuals; thyroid nodules that are functional on radioiodine uptake scans need not undergo FNA.

Although the long-term management of hyperthyroidism can take many routes, initial treatment should be focused on controlling the signs and symptoms of hyperthyroidism. The initial management of all patients with symptomatic thyrotoxicosis should include β-adrenergic blockade, particularly in elderly patients and patients with resting heart rates greater than 90 beats/min or coexistent cardiovascular disease. These include a nonselective β-adrenergic receptor blocker such as propranolol (10–40 mg, 3–4 times a day) or those with relative β-1 selectivity, such as atenolol (25–100 mg, 1–2 times daily) or metoprolol (25–50 mg, 2–3 times daily). β-Adrenergic drugs are generally contraindicated in patients with asthma, given that there is insufficient β-1 selectivity at the recommended doses; they also should be used cautiously in patients with congestive heart failure, bradyarrhythmias, and Raynaud's disease. For patients who do not tolerate β-adrenergic agents, calcium channel blockers have been shown to affect rate control.

Thyroid storm (thyrotoxic crisis) is a rare condition that occurs in 1% to 5% of patients admitted to a hospital for thyrotoxicosis and is associated with a high (up to 25%) risk of death. Development of thyroid storm is not dependent on serum TSH levels, and the pathogenesis is not well understood; it can be triggered by cessation of antithyroid medications, acute illness, trauma, or stress. The diagnosis is clinical, and a scoring system to assess the severity of the crisis has been proposed; based on temperature, central nervous system manifestations (none, mild agitation, delirium/psychosis, or progression to seizures/coma), gastrointestinal-hepatic dysfunction (none, diarrhea or nausea/vomiting, or unexplained jaundice), cardiovascular dysfunction (presence of tachycardia, congestive heart failure, and atrial fibrillation), and any precipitating factors. Treatment is supportive and a multidisciplinary approach to management, including definitive therapy with RAI or thyroidectomy, is recommended. Thyroid storm also can be precipitated by manipulation of the thyroid during surgery, particularly in patients who are not biochemically euthyroid before surgery.

MANAGEMENT OF GRAVES' DISEASE

Graves' disease is an autoimmune disease caused by antibodies to the TSH receptor on thyroid follicular cells, resulting in excess production of thyroid hormone. Treatment options for Graves' disease include antithyroid medications, RAI therapy, or thyroidectomy; choice of therapy should incorporate the patient's specific clinical scenario and preference (Table 2). In the United States, RAI has been a preferred modality of treatment by physicians, although the trend has been to reduce use of RAI in favor of antithyroid medications; in a 2011 survey of clinical endocrinologists, 60% selected RAI as their primary therapy for uncomplicated Graves' disease, compared with 20% 30 years earlier. However, in Europe, Latin America, and Japan, there has been greater physician preference for antithyroid medications as first-line therapy.

Antithyroid Medications

Antithyroid medications include the thionamides, which include methimazole (MMI) and propylthiouracil (PTU), both inhibit thyroid hormone synthesis, with PTU having the additional benefit of blocking peripheral conversion of T4 to T3. MMI is favored as first-line therapy in nearly all patients, except during the first trimester of pregnancy and for the treatment of thyroid storm, given the association of PTU with fulminant hepatic failure and death. Use of PTU is reserved for specific indications, such as during the first trimester

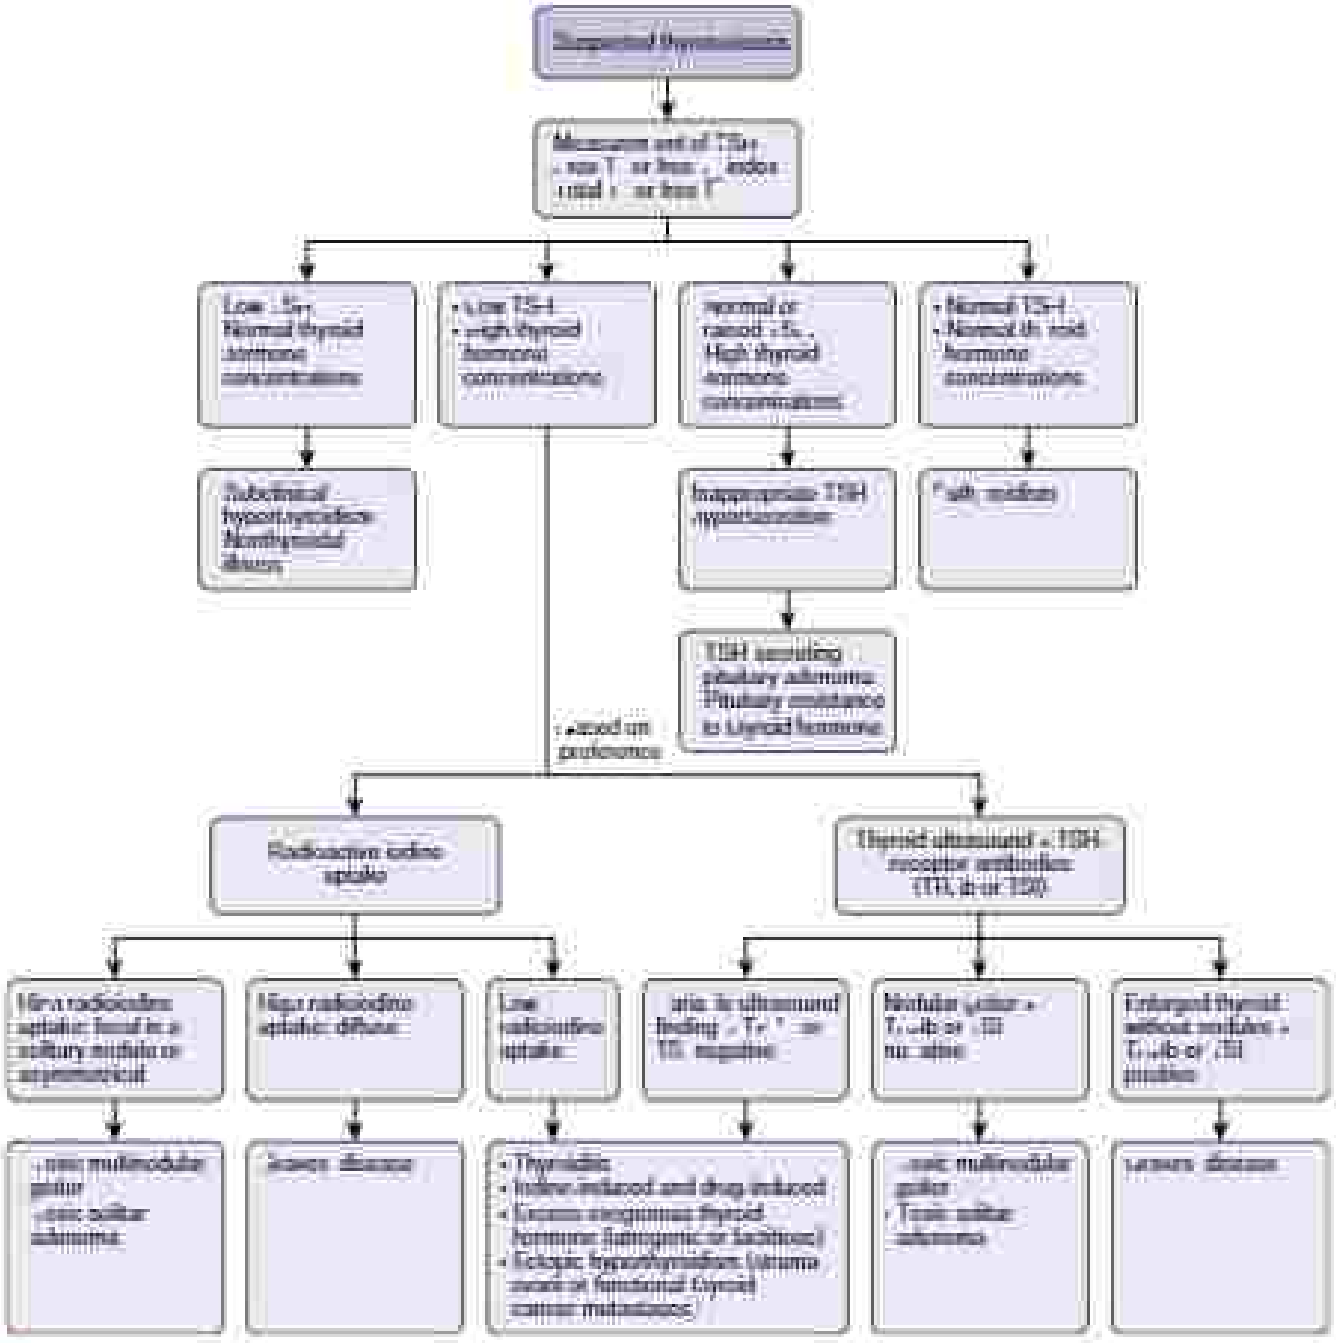

FIG. 1. Algorithm for assessment of thyroid acute. ... ...ethoxythyroxine. ... types are bot... T... H-receptor antibodies. ...SH thyroid stimulating hormone. ...T thyroid stimulating immunoglobulins. (From ... [illegible])

of pregnancy, given the potential teratogenic effects of MMI. Antithyroid medications can be used either as the primary treatment for Graves' disease or as pretreatment for patients undergoing RAI or thyroidectomy. If being used as primary treatment, patients should be treated for 12 to 18 months, because results of a randomized clinical trial found that remission rates are not improved after more than 18 months of treatment.

After completion of initial therapy, the medications can be tapered or discontinued among patients where TRAb levels have normalized, based on the clinical symptoms. Remission is defined as biochemical euthyroidism more than 12 months after discontinuation of therapy; relapse rates are 20% to 30% over 3 to 5 years of follow-up. In patients who relapse, definitive therapy with RAI or thyroidectomy should be considered. Side effects of antithyroid medications include the risk of agranulocytosis, which is dose related with methimazole and almost always occurs within the first 90 days of treatment. MMI-induced hepatotoxicity is usually cholestatic, in contrast to the hepatocellular injury associated with PTU, which can lead to fulminant hepatic failure. Milder side effects of antithyroid medications include development of a pruritic rash, arthralgias, abdominal pain, nausea, fatigue, and pharyngitis.

RAI Therapy

The goal of RAI therapy is to render the patient hypothyroid. RAI is incorporated into thyroid hormone, causing ionizing damage to thyroid follicular cells and destruction of the gland. RAI treatment can cause a transient exacerbation of hyperthyroidism, therefore

TABLE 2 Clinical Situations that Favor a Particular Modality as Treatment for Graves' Hyperthyroidism

Clinical Situations	RAI	ATD	Surgery
Pregnancy[a]		Preferred, use caution	Acceptable, use caution
Comorbidities with increased surgical risk and/or limited life expectancy	Preferred	Acceptable	Contraindicated

consideration should be given to initiation of antithyroid medications and/or β-adrenergic blockade in symptom-free patients who may be at risk of complications from worsening thyrotoxicosis (the elderly or patients with cardiovascular or pulmonary disease). Antithyroid medications should be stopped 2 to 3 days before RAI therapy and restarted 3 days later, to allow for RAI incorporation into the thyroid. Most patients will develop hypothyroidism 2 to 3 months after a single dose of 12 to 15 mCi of RAI. Patients should have initial assessment of TSH, total T3, and free T4 1 to 2 months after therapy; biochemical monitoring should occur every 4 to 6 weeks for 6 months or until the patient is hypothyroid and stable on thyroid hormone replacement. Consideration for repeat therapy should not be considered for at least 6 months after initial treatment.

RAI is contraindicated during pregnancy, lactation, for coexisting thyroid cancer/suspicion of thyroid cancer, and among individuals unable to comply with radiation safety guidelines. Assuming a dose of 10 to 15 mCi, these precautions include that the patient sleep alone for 3 to 6 days (15–18 days in the case of a pregnant partner), and to keep a distance of 3 feet from adults and 6 feet from pregnant women and children during the day. RAI also should be used with caution among women planning a pregnancy within the first 4 to 6 months after treatment.

The presence of mild Graves' orbitopathy is also a relative contraindication to use of RAI, because RAI can worsen orbitopathy, compared with antithyroid medications or thyroidectomy, particularly in patients with other risk factors for worsening disease, such as use of tobacco. If patients have no risk factors for worsening of eye disease, RAI therapy is considered equally acceptable. Patients with mild orbitopathy may benefit from corticosteroid prophylaxis, but RAI should not be used in patients with active and moderate to severe Graves' orbitopathy. Other side effects of RAI include transient worsening of thyrotoxicosis, risks of secondary malignancy, and potential anterior neck pain from radiation thyroiditis, sialadenitis, and dry mouth.

Surgery

Indications for Surgery

Despite the safety and effectiveness of antithyroid medications and RAI for the long-term treatment of hyperthyroidism secondary to Graves' disease, there may be circumstances that warrant a patient preference for surgery. Indications for surgery include women planning a pregnancy in less than 6 months; patients with other indications for cervical surgery (presence of large thyroid nodules ≥4 cm, or large goiters with compressive symptoms of dysphagia, dysphagia, or voice changes, suspicion of or documented thyroid malignancy, or concurrent primary hyperparathyroidism requiring parathyroidectomy); relatively low uptake of RAI, persistent disease despite previous treatment with antithyroid medications or RAI, and patients with moderate to severe Graves' orbitopathy. Contraindications to surgery include severe patient comorbidities such as cardiopulmonary disease, end-stage cancer, or other disorders that may shorten the patient's life expectancy or place the patient at an increased risk for operative morbidity and death.

Surgery as First-Line Treatment for Graves' Disease

Several studies have compared the different treatment options for Graves' disease with respect to rates of recurrent hyperthyroidism. A recent systematic review and meta-analysis of eight studies (one

randomized controlled trial and seven comparative cohort studies) included 1402 patients (667 on antithyroid medications, 214 RAI patients, and 419 surgical patients) with Graves' hyperthyroidism. There was a higher relapse rate with antithyroid medications compared with RAI (odds ratio [OR], 4.25; 95% confidence interval [CI], 2.48 to 6.67; $P < .01$) and surgery (OR, 9.09; 95% CI, 4.65 to 19.23; $P < .01$). There was no difference in relapse rates between RAI and surgery (OR, 1.53; 95% CI, 0.61 to 3.65; $P = .34$), although patients in the surgical arm underwent both subtotal and total thyroidectomy.

A separate systematic review of the published literature between 2001 and 2011 included 14,246 patients who underwent either surgery (subtotal [3158, 22%] or total [1308, 10%] thyroidectomy) or RAI (9690, 68%). Overall, any thyroid surgery was favored over any dose of RAI for definitive treatment of Graves' disease, and total thyroidectomy was favored over subtotal thyroidectomy (OR, 40.37; 95% CI, 15.0 to 108.44; $P < .001$). Persistent or recurrent hyperthyroidism was present in 2080 (21%) patients who received a single dose of RAI, 330 (10%) patients after subtotal thyroidectomy, and 4 (0.3%) patients after total thyroidectomy.

A cost effectiveness analysis has suggested that (total) thyroidectomy also may be more cost effective than RAI or lifelong use of antithyroid medications in patients who have previously been treated with 18 months of antithyroid medications and have failed to achieve a euthyroid state. In this study, the decision model assumed that 52% of patients would fail initial therapy; these patients were then assigned to either additional treatment with antithyroid medications, RAI, or total thyroidectomy. In the base case of a 36 year old patient with uncomplicated Graves' disease, total thyroidectomy was the most effective (associated with highest quality of life, measured by quality-adjusted life years) and most cost effective. RAI was less costly, but also was associated with the lowest quality of life. These findings were robust as long as the cost of total thyroidectomy remained less than $19,300 (2007 USD), after which antithyroid medications became more cost effective.

Other studies have focused on the outcomes after thyroidectomy. A recent study of 99 patients with hyperthyroidism has suggested that earlier intervention may allow for faster biochemical recovery and improved postoperative management of thyroid function levels and therefore patient quality of life. In this study, patients were divided into two groups: the early therapy group did not undergo previous therapy except for use of antithyroid medications to achieve euthyroidism before surgery, and the delayed therapy group had at least one trial of antithyroid medications, previous RAI, or previous thyroidectomy. Patients in the early therapy group had a quicker biochemical recovery, as measured by the mean duration to reach a normal TSH (121 vs 240 days; $P = .007$) and free T4 (91 vs 183 days; $P = .015$). There may also be long term benefits of thyroidectomy with respect to extrathyroidal manifestations of Graves' disease. A recent study of patients younger than 40 years with hyperthyroidism studied patients who underwent surgery (n = 122) or treatment with antithyroid medications (n = 42) and found that 96% of surgical patients had significant improvement in cardiovascular dysfunction, compared with 79% of patients treated with medications alone, suggesting that total thyroidectomy was a preferred choice of treatment for patients with hyperthyroid cardiac dysfunction. A study of 10,992 hyperthyroid patients in the Swedish national registry compared 10,250 patients treated with RAI and 742 patients treated with surgery between 1986 and 2000. The hazard ratio (HR) for all cause mortality was 0.82 (95% CI, 0.71 to 0.96) for patients who underwent surgery versus RAI; this was in large part secondary to the decrease in cardiovascular related deaths: (HR, 1.70; 95% CI, 0.53 to 0.91), as compared with cancer-related death (HR, 1.04; 95% CI, 0.80 to 1.36) or death from other causes (HR, 0.78; 95% CI, 0.59 to 1.04).

Extent of Surgery

Current recommendations from the American Thyroid Association for the management of hyperthyroidism state that "If surgery is chosen as the primary therapy for Graves' disease, near total or total thyroidectomy is the procedure of choice." In contrast to near total/total thyroidectomy, subtotal thyroidectomy involves preservation of remnant of the thyroid (typically the tubercle of Zuckerkandl), which can extend posteriorly behind the recurrent laryngeal nerve and encircles the anterolateral portion of the trachea) to preserve both the integrity of the recurrent laryngeal nerve as it enters the cricothyroid muscle and the blood supply to the superior parathyroid gland. However, leaving a remnant of thyroid increases the risk of persistent or recurrent hyperthyroidism, and near total/total thyroidectomy has been shown to have acceptably low rates of morbidity when performed by high volume thyroid surgeons. Total thyroidectomy remains the favored surgical option for patients with Graves' disease.

Multiple studies have supported recommending total thyroidectomy as the procedure of choice. In a randomized clinical trial of 288 patients who underwent subtotal or total thyroidectomy for Graves' disease, 191 had 5 years of follow-up: 85 underwent subtotal thyroidectomy, and 56 underwent total thyroidectomy. Overall, recurrent hyperthyroidism occurred in nine (9%) patients after subtotal thyroidectomy and no patients after total thyroidectomy ($P = .002$). There was no difference in rates of transient or permanent hypoparathyroidism or recurrent laryngeal nerve injury. Feinet al performed a meta analysis of total thyroidectomy versus subtotal thyroidectomy including 23 studies (14 randomized controlled trials and 9 nonrandomized comparative studies) and 3242 patients. Overall, recurrent hyperthyroidism was less frequent in the total thyroidectomy group (2 of 1665; 0.1%) than in the subtotal thyroidectomy group (127 of 1577; 8.0%; OR, 0.16; 95% CI, 0.06 to 0.38; $P < .0001$); these findings remained true for both the randomized controlled trials (OR, 0.15; 95% CI, 0.05 to 0.43; $P = .0005$) and the comparative studies (OR, 0.09; 95% CI, 0.02 to 0.38; $P = .0006$). There was no difference in rates of permanent recurrent laryngeal nerve injury between the two groups (OR, 0.91; 95% CI, 0.41 to 2.02; $P = .82$), although rates of both temporary (OR = 2.78; 95% CI, 2.04 to 3.5e; $P < .00001$) and permanent (OR, 2.01; 95% CI, 1.38 to 3.35; $P = .005$) hypoparathyroidism were higher in the total thyroidectomy group. However, when only the randomized controlled trials were included in the analysis, there was no longer a difference in rates of permanent hypoparathyroidism (OR, 2.32; 95% CI, 0.73 to 7.38; $P = .15$).

Preoperative Management:

Patients should be euthyroid before undergoing thyroidectomy for Graves' disease. In addition to antithyroid medications and use of β-adrenergic blockade, use of potassium iodide in the immediate preoperative period has been advocated, to use originated from the observation by Plummer that its use decreased the risk of thyroid storm during thyroidectomy in an era in which thionamides and β-blockers were not available. Studies have shown a reduction in gland vascularity after administration of potassium iodide, and since surgical studies have demonstrated that this reduction in gland vascularity allows for an easier technical procedure. Attie et al. randomly assigned 56 patients to preoperative treatment with Lugol's solution or to no treatment. They found that patients who took Lugol's solution had lower mean blood flow (74.7 vs 128.62 mL/min; $P = .0001$) and blood loss (54.6 vs 108.5; $P = .0001$) than patients who did not, although other clinical variables were not studied.

However, other studies have shown that use of potassium iodide does not influence surgical outcomes in all settings. Single institution retrospective studies have suggested that use of preoperative potassium iodide did not affect outcomes from thyroidectomy (blood loss, operative time, or rates of transient/permanent hypoparathyroidism or recurrent laryngeal nerve injury). However, these studies examined outcomes by high volume thyroid surgeons, and it remains unclear whether these data are applicable if surgery is performed by low-volume thyroid surgeons, given the established relationship between surgeon volume and patient outcomes. Current ATA guidelines state that "a potassium iodide containing preparation should be given in the immediate preoperative period", although this is a "strong recommendation," it is based on "low quality evidence." If given, it can

TABLE 3 Clinical Situations That Favor a Particular Modality as Treatment for Toxic Multinodular Goiter or Toxic Adenoma

Clinical Situations	RAI	ATD	Surgery
TMNG			
Pregnancy*	Contraindicated	Preferred, use caution	Acceptable, use caution
Advanced age, comorbidities with increased surgical risk and/or limited life expectancy	Preferred	Acceptable	Contraindicated
Patients with previously operated or externally irradiated necks	Preferred	Acceptable	Use caution
Lack of access to a high-volume thyroid surgeon	Preferred	Acceptable	Use caution
Symptoms or signs of compression within the neck	Acceptable	†	Preferred
Thyroid malignancy confirmed or suspected	Contraindicated	†	Preferred
Large goiter/nodule	Acceptable	†	Preferred
Goiter/nodule with substernal or retrosternal extension	Acceptable	†	Preferred
Coexisting hyperparathyroidism requiring surgery	†	–	Preferred

*Not women considering a pregnancy within 6 months.
†Not first-line therapy but may be acceptable depending on the clinical circumstances.
ATD, antithyroid drugs; RAI, radioactive iodine; TMNG, toxic multinodular goiter.
From Ross DS, Burch HB, Cooper DS, et al. 2016 American Thyroid Association guidelines for diagnosis and management of hyperthyroidism and other causes of thyrotoxicosis. *Thyroid*. 2016;26:1343–1421.

be given as either potassium iodide (SSKI 50 mg iodide/drop; 1 to 2 drops three times daily) or Lugol's solution (5% elemental iodine and 10% potassium iodide; 8 mg iodide/drop; 5 to 7 drops three times daily) for 7 to 10 days before surgery. Potassium iodine should not be given to patients with thyroid nodular disease.

MANAGEMENT OF TOXIC THYROID NODULES/TOXIC MULTINODULAR GOITER

Hyperthyroidism secondary to the presence of a toxic multinodular goiter or toxic thyroid nodule/adenoma can be differentiated from Graves' disease by the pattern of uptake on radioactive iodine imaging (if performed; Fig. 1) or by the presence of normal levels of TRAb or thyroid stimulating immunoglobulins. The primary modalities of treatment are RAI therapy and thyroidectomy, with a goal of rapid and durable elimination of hyperthyroidism. Treatment with antithyroid medications would require long-term (possibly lifelong) treatment and should be considered only in select instances, such as for patients with advanced age, limited life expectancy, and/or comorbidities that would increase the risk of morbidity at the time of surgery. Considerations with respect to choice of RAI or thyroidectomy are not dissimilar to those influencing the decision in patients with Graves' disease (Table 3).

In contrast to patients with hyperthyroidism secondary to Graves' disease, not all patients with a toxic thyroid nodule/multinodular goiter will require pretreatment with antithyroid medications (preferentially methimazole, unless there is a contraindication). Current ATA guidelines recommend that any patient who would be at increased risk for the potential complications of a persistent hyperthyroid state (e.g., the elderly, patients with cardiovascular disease) be pretreated with antithyroid medications, with consideration of β-blockade for symptom-free patients at risk for complications due to hyperthyroidism. However, younger/middle-aged patients may only require β-blockade for symptomatic hyperthyroidism.

It is critically important that patients with a toxic thyroid nodule/goiter undergo cervical ultrasonography before surgery. Nonfunctioning nodules on radionuclide scintigraphy or nodules with suspicious characteristics on ultrasonography should be managed with FNA biopsy, according to current evidence-based guidelines. For patients with a toxic multinodular goiter, near-total/total thyroidectomy is recommended; for patients with a toxic thyroid nodule/adenoma, ipsilateral thyroid lobectomy may be performed for single nodules if the contralateral thyroid lobe is unremarkable on ultrasonography.

In certain patients, alternative therapies may be considered for patients with a toxic thyroid nodule/goiter for whom the standard treatment options are not appropriate, contraindicated, refused by the patient, or for whom expertise in other procedures is available. These alternative therapies may include ethanol ablation, radiofrequency ablation, or high-intensity focused ultrasonography (HIFU). HIFU is a type of thermal ablation that delivers energy in the form of ultrasound waves extracorporeally to a targeted area beneath the skin; the effects on benign tissues occurs via a thermal effect and by acoustic cavitation. Recent studies have examined the efficacy and safety of HIFU in patients with benign thyroid nodules, toxic thyroid nodules, and persistent Graves' disease. Although initial studies are promising in select patients and when performed by experienced clinicians, there remain questions with respect to patient pain, risk of recurrent laryngeal nerve injury, and long-term outcomes of this technique.

TECHNICAL CONSIDERATIONS OF THYROIDECTOMY

Thyroidectomy for hyperthyroidism can be challenging because of the hypervascularity of the gland; from a technical perspective, this can make identification of the parathyroid glands and recurrent laryngeal nerves more difficult, although a standard approach to thyroidectomy can be useful. A few technical aspects that should be considered during thyroidectomy include the following:

- Although extensive is important, particularly for patients with benign disease, the emphasis should be on safe visualization of key structures. Therefore the incision length should be made with careful consideration of gland size and the likely hypervascularity of the gland.
- It is often helpful to ligate the superior thyroid vessels first; there are often engorged in patients with hyperthyroidism, and early ligation can facilitate mobilization of the superior pole of the thyroid. This can be done with silk ties or with vessel-sealing devices, but one should be mindful that the maximum vessel size for many devices is 7 mm.

- The recurrent laryngeal nerve typically lies within the tracheoesophageal groove. Its course can be more variable on the right, and it can lie anterior or posterior to the inferior thyroid artery. In rare cases, a nonrecurrent laryngeal nerve can be present (typically on the right side); surgeons can be alerted to this by aberrant vascular anatomy if a computed tomography scan of the neck was obtained.
- The blood supply to both the superior and inferior parathyroid glands are derived from the inferior thyroid artery. The inferior gland can be more variable in location, and dissection close to the thyroid gland provides the safest plane to avoid inadvertent devascularization of the parathyroid glands.

Intraoperative recurrent laryngeal nerve monitoring is increasingly used during thyroidectomy, although visualization of the nerve remains the gold standard. During surgery, the vocal fold response to nerve stimulation can be measured by an electrode system incorporated in the endotracheal tube, which is positioned at the level of the vocal cords. Auditory or visual electromyographic signals can be obtained from the vagus or recurrent laryngeal nerve by intermittent stimulation using a handheld probe during thyroidectomy and at the time of visualization of the nerve or when dissection is occurring close to the nerve, depending on the system used. Changes in the pattern of the signals may hint at possible nerve irritation and dysfunction. Routine use of intraoperative nerve monitoring has not been shown to decrease rates of recurrent laryngeal nerve injury, and, if a surgeon chooses to incorporate it into his/her practice, routine use allows for familiarity with the system and ability to troubleshoot the technology by all who are involved in the surgical procedure, including the surgeons, anesthesiologists, and nurses.

POSTOPERATIVE MANAGEMENT

Management of Thyroid Function

After total thyroidectomy for either Graves' disease or a toxic multinodular goiter, potassium iodide–containing preparations should be discontinued, and β-blockade can be tapered in patients for whom they are used solely for management of symptoms of hyperthyroidism (rather than preexisting hypertension). Thyroid hormone replacement should be initiated at a dose appropriate to the patient's weight (typically 0.8 μg/lb or 1.5–1.7 μg/kg) and age (typically lower doses in the elderly). TSH levels should be measured 6 to 8 weeks after surgery and then every 1 to 2 months until levels are stable, followed by annual assessment. After lobectomy for a toxic thyroid nodule, TSH and free T4 levels should be obtained 4 to 6 weeks after surgery; thyroid hormone supplementation should be started if there is a persistent rise in TSH levels. Long-term thyroid hormone supplementation may be required in 15% to 30% of patients after thyroid lobectomy.

Complications of Thyroidectomy

The most common complications of thyroidectomy include transient or permanent recurrent laryngeal nerve injury and postoperative hypocalcemia/hypoparathyroidism. Both are uncommon (1% to 2% in the hands of experienced thyroid surgeons) but can have a significant effect on the patient's quality of life. Patients who elect to undergo thyroidectomy should have a preoperative voice evaluation, based on any subjective voice changes perceived by the patient and the surgeon's objective assessment of voice quality. Formal vocal cord evaluation should be obtained for any patient with subjective findings of voice change and any patient with previous anterior neck surgery (e.g., parathyroidectomy, thyroidectomy, carotid endarterectomy, or cervical fusion via the anterior approach) or mediastinal/thoracic surgery that places the vagus nerve at risk. Evaluation can include indirect or direct laryngoscopy, videostroboscopy, or transcutaneous vocal cord ultrasonography. Recurrent laryngeal nerve injury can be transient or permanent; subjective changes in voice quality should prompt referral to a voice specialist for evaluation and management.

During thyroidectomy, manipulation, devascularization, or unintentional resection of the parathyroid glands can result in transient or permanent hypoparathyroidism and associated hypocalcemia. Following total thyroidectomy, the goal is to prevent the development of symptomatic hypocalcemia in patients at risk for hypoparathyroidism, although the optimal algorithm remains unclear; options include routine oral calcium supplementation or selective supplementation, based on serum calcium or parathyroid hormone (PTH) levels. Evaluation of calcium/PTH levels and supplementation is not required for patients after thyroid lobectomy.

SPECIAL CONSIDERATIONS

Graves' Disease in Children

Graves' disease is the most common cause of hyperthyroidism in children. Although antithyroid medications, RAI, and thyroidectomy remain treatment options, the choice of initial treatment may vary based on the patient' age, clinical status, and patient/parent values and preferences; particularly for pediatric patients, the availability of a high-volume thyroid or pediatric surgeon is critical, given the possibility of life-long hypoparathyroidism or recurrent laryngeal nerve injury. If antithyroid medications are chosen, MMI therapy for 1 to 2 years is considered appropriate initial management, although it is important to recognize that most pediatric patients will not have durable remission on medication alone. MMI should be used and use of PTU avoided because of the risk of hepatotoxicity.

In patients who are not in remission after initial MMI therapy, consideration for RAI or surgery should be given. The goal of RAI therapy is to reduce hyperthyroidism to a single treatment, either as an estimated or fixed dose; smaller doses aimed at euthyroidism result in higher rates of persistent/recurrent hyperthyroidism and exposure of residual thyroid tissue to multiple doses of radiation that may lead to increased risk to the development of thyroid neoplasms. Long-term studies have not yet shown definitively there to be an increased risk of thyroid or nonthyroid malignancies; however, given the theoretical risk, RAI therapy is generally avoided in children younger than 5 years.

For patients younger than 5 years, surgery is the preferred treatment when definitive therapy is required and surgery can be performed by a high-volume surgeon. Surgery is also preferred in patients with large thyroid glands (>80 g), when response to RAI may be poor, and for those who are nonadherent or nonresponsive to antithyroid medications. If chosen, total or near-total thyroidectomy should be performed. Particularly in pediatric patients, access to a high-volume thyroid surgeon is critically important; current ATA guidelines on the management of pediatric thyroid nodular disease recommend that pediatric thyroid surgery be performed in a hospital with the full spectrum of pediatric specialty care.

Graves' Disease in Pregnancy

The diagnosis of hyperthyroidism in pregnancy can be challenging, because normal pregnancy leads to changes in thyroid physiology that results in altered thyroid function testing that mimics biochemical hyperthyroidism but does not require treatment. The diagnosis is made with serum TSH values and either total T3 and T4 levels, but reference ranges should increase to 1.5 times above that of the nonpregnant range by the second/third trimester or be trimester specific. If overt hyperthyroidism is diagnosed during pregnancy, treatment with antithyroid medications should be initiated. PTU should be used during the first trimester, given the teratogenic effects associated with MMI, including aplasia cutis, choanal/esophageal and other intestinal atresia, abdominal wall abnormalities (e.g., omphalocele), and eye, heart, and urinary tract malformations. PTU associated birth defects have been reported but appear to be less severe than those related to use of MMI. MMI can be used after the first trimester. RAI therapy is contraindicated during pregnancy.

Surgery as definitive therapy should be considered by patients considering starting families and who require high doses of antithyroid medications for euthyroidism, making spontaneous remission less likely. Surgery for patients diagnosed during pregnancy should be reserved only for those patients for whom medical management is not successful or those who have a contraindication to antithyroid medications. If performed, surgery during the first and third trimesters should be avoided, given the risks for fetal development and premature labor, respectively.

Amiodarone-Induced Thyrotoxicosis

Amiodarone is an iodine-rich antiarrhythmic drug that can result in amiodarone-induced thyrotoxicosis (AIT) or amiodarone-induced hypothyroidism in 15% to 20% of patients. AIT may develop at any point during amiodarone treatment, even several months after cessation, secondary to its long half-life (up to 100 days) and storage in fat tissues within the body. There are two forms of AIT, although both forms may occur in a single patient: type 1 develops in patients with underlying thyroid disease (iodine-induced hyperthyroidism), and type 2 develops in patients without underlying thyroid disease (destructive thyroiditis). Thyroid ultrasonography is helpful because it identifies the presence of thyroid nodules and the vascularity of the gland; type 2 AIT is characterized by hypervascularity, whereas type 1 AIT is associated with increased vascularity and blood flow velocity. Thyroid 131I uptake scans can also be useful, as uptake is very low in patients with type 2 AIT but may be normal or high in type 1 AIT.

For patients with type 1 AIT, the preferred treatment strategy is medical (thionamides), although spontaneous remission is unlikely because of the high levels of iodine present. Therefore higher doses of thionamides may be needed, and definitive therapy with surgery may be required, particularly given the risks of ongoing thyrotoxicosis in patients with underlying cardiac disease. Type 2 AIT may be self-limited, given that the destructive thyroiditis is caused by the amiodarone. It is best treated with glucocorticoids, at an initial dose of 0.5 to 0.7 mg/kg per day, with an initial course of 3 months. ILAI is not feasible in patients with either type of AIT because of the high iodine levels in the thyroid.

Surgical Management of Thyroid Cancer

Jessica B. Shonk, MD, and James D. Perrier, MD, PhD

Surgery is the standard of care for management of most thyroid malignancies, and oncologic thyroid surgery, including resection of thyroid nodules suspicious for primary malignancy, is an important area of surgical expertise. The American Cancer Society estimated diagnosis of 56,870 new thyroid cancer cases in the United States in 2017, with 2010 thyroid cancer–related deaths expected that year. Most thyroid cancers occur in women (42,470 expected cases in 2017), with approximately equal mortality rates between the sexes. Thyroid cancer incidence in the United States has increased dramatically over the last four decades, rising from 4.9 per 100,000 individuals in 1975 to 14.3 per 100,000 in 2009. This increase is primarily due to rising incidence of the papillary thyroid cancer (PTC) subtype, and in particular, the fraction of newly diagnosed PTCs represented by small tumors (e.g., less than 1 cm in maximum dimension) has increased significantly. In light of this latter finding, previous expert consensus opinion attributed increasing thyroid cancer rates to expanded surveillance and improved diagnostic sensitivity. However, in the more than 30 years since introduction of ultrasonography into clinical practice (the most sensitive tool for thyroid structural assessment), thyroid cancer rates have continued to rise, suggesting that the increasing thyroid cancer incidence rate is not fully explained by a corresponding increase in the use and sensitivity of diagnostic technology. Finally, although PTC incidence has risen dramatically, as have corresponding rates of thyroid surgery, the overall thyroid cancer–related mortality rate in the United States over the last 4 decades has remained stable at 0.5 deaths per 100,000 individuals. This finding implies that many thyroid cancers will not ultimately result in death, regardless of whether such cancers are resected or otherwise treated. The role of this finding on surgical decision-making for thyroid cancer is under active investigation.

Preoperative Workup

Optimal thyroid cancer management is multidisciplinary, involving endocrinologists, radiologists, pathologists, and surgeons. Thyroid cancer diagnosis begins with discovery of a thyroid nodule, defined as an intraparenchymal lesion that is radiologically discrete from surrounding thyroid tissue. Palpable thyroid nodule incidence in euthyroid postprandial areas is approximately 4.8% in women and 1.5% in men between the ages of 30 and 60 years. This translates into an annual incidence of 0.09% and a lifetime risk for thyroid nodule development of 10%. Not all thyroid nodules are palpable, however, and incidental thyroid nodule discovery (so-called incidentalomas) during unrelated imaging is common. A thyroid incidentaloma will be identified in roughly one of every six neck computed tomography (CT) scans and 19% to 68% of neck ultrasound examinations results will reveal a thyroid nodule. Seven percent to 15% of thyroid nodules will be malignant. Indications for oncologic thyroid surgery are classified into three general categories: (1) diagnosis and treatment of thyroid nodules for which primary malignancy is suspected, (2) treatment of a known or recurrent thyroid cancer, and (3) prophylactic surgery for patients harboring gene mutations associated with high risk of thyroid cancer development. Thyroid cancer subtypes for which surgery is indicated include differentiated thyroid cancer (DTC, which includes the PTC and follicular subtypes), poorly differentiated thyroid cancer (PDTC), medullary thyroid cancer (MTC), and, in some cases, anaplastic thyroid cancer (ATC).

Malignancy workup for a thyroid nodule begins with a detailed history and physical examination. This includes assessment for familial thyroid cancer history, history of ionizing radiation exposure (especially during childhood), and signs/symptoms of hypothyroidism or hyperthyroidism. In addition, evaluation for evidence of rapidly progressive disease, including rapid nodule growth or rapid development of compressive/invasive symptoms (including hoarseness, dysphagia, or neck pain), is critical to early recognition of ATC, whereas careful physical examination of the bilateral central and lateral neck fields is crucial for nodal metastasis disease detection (Fig. 1). Familial thyroid cancer accounts for 5% to 10% of cases, and

Surgery as definitive therapy should be considered by patients considering starting families and who require high doses of antithyroid medications for euthyroidism, making spontaneous remission less likely. Surgery for patients diagnosed during pregnancy should be reserved only for those patients for whom medical management is not successful or those who have a contraindication to antithyroid medications. If performed, surgery during the first and third trimesters should be avoided, given the risks for fetal development and premature labor, respectively.

Amiodarone-Induced Thyrotoxicosis

Amiodarone is an iodine-rich antiarrhythmic drug that can result in amiodarone-induced thyrotoxicosis (AIT) or amiodarone-induced hypothyroidism in 15% to 20% of patients. AIT may develop at any point during amiodarone treatment, even several months after cessation, secondary to its long half-life (up to 100 days) and storage in fat tissues within the body. There are two forms of AIT, although both forms may occur in a single patient: type 1 develops in patients with underlying thyroid disease (iodine-induced hyperthyroidism), and type 2 develops in patients without underlying thyroid disease (destructive thyroiditis). Thyroid ultrasonography is helpful because it identifies the presence of thyroid nodules and the vascularity of the gland; type 2 AIT is characterized by hypervascularity, whereas type 1 AIT is associated with increased vascularity and blood flow velocity. Thyroid ^{123}I uptake scans can also be useful, as uptake is very low in patients with type 2 AIT but may be normal or high in type 1 AIT.

For patients with type 1 AIT, the preferred treatment strategy is medical (thionamides), although spontaneous remission is unlikely because of the high levels of iodine present. Therefore higher doses of thionamides may be needed, and definitive therapy with surgery may be required, particularly given the risks of ongoing thyrotoxicosis in patients with underlying cardiac disease. Type 2 AIT may be self-limited, given that the destructive thyroiditis is caused by the amiodarone. It is best treated with glucocorticoids, at an initial dose of 0.5 to 0.7 mg/kg per day, with an initial course of 3 months. Surgical Management of Thyroid Cancer

Jessica B. Shonk, MD, and James D. Prescott, MD, PhD

Surgery is the standard of care for management of most thyroid malignancies, and oncologic thyroid surgery, including resection of thyroid nodules suspicious for primary malignancy, is an important area of surgical expertise. The American Cancer Society estimated diagnosis of 56,870 new thyroid cancer cases in the United States in 2017, with 2010 thyroid cancer–related deaths expected that year. Most thyroid cancers occur in women (42,670 expected cases in 2017), with approximately equal mortality rates between the sexes. Thyroid cancer incidence in the United States has increased dramatically over the last four decades, rising from 4.9 per 100,000 individuals in 1975 to 14.3 per 100,000 in 2009. This increase is primarily due to rising incidence of the papillary thyroid cancer (PTC) subtype, and in particular, the fraction of newly diagnosed PTCs represented by small tumors (e.g., less than 1 cm in maximum dimension) has increased significantly. In light of this latter finding, previous expert consensus opinion attributed increasing thyroid cancer rates to expanded surveillance and improved diagnostic sensitivity. However, in the more than 30 years since introduction of ultrasonography into clinical practice (the most sensitive tool for thyroid structural assessment), thyroid cancer rates have continued to rise, suggesting that the increasing thyroid cancer incidence rate is not fully explained by a corresponding increase in the use and sensitivity of diagnostic technology. Finally, although PTC incidence has risen dramatically, as have corresponding rates of thyroid surgery, the overall thyroid cancer–related mortality rate in the United States over the last 4 decades has remained stable at 0.5 deaths per 100,000 individuals. This finding implies that many thyroid cancers will not ultimately result in death, regardless of whether such cancers are resected or otherwise treated. The role of this finding on surgical decision-making for thyroid cancer is under active investigation.

Preoperative Workup

Optimal thyroid cancer management is multidisciplinary, involving endocrinologists, radiologists, pathologists, and surgeons. Thyroid cancer diagnosis begins with discovery of a thyroid nodule, defined as an intraparenchymal lesion that is radiologically discrete from surrounding thyroid tissue. Palpable thyroid nodule incidence in adults without prior thyroid disease is approximately 4.8% in women and 1.5% in men between the ages of 30 and 60 years. This translates into an annual incidence of 0.09% and a lifetime risk for thyroid nodule development of 10%. Not all thyroid nodules are palpable, however, and incidental thyroid nodule discovery (so-called incidentalomas) during unrelated imaging is common. A thyroid incidentaloma will be identified in roughly one of every six neck computed tomography (CT) scans and 19% to 68% of neck ultrasound examinations results will reveal a thyroid nodule. Seven percent to 15% of thyroid nodules will be malignant. Indications for oncologic thyroid surgery are classified into three general categories: (1) diagnosis and treatment of thyroid nodules for which primary malignancy is suspected, (2) treatment of a known or recurrent thyroid cancer, and (3) prophylactic surgery for patients harboring gene mutations associated with high risk of thyroid cancer development. Thyroid cancer subtypes for which surgery is indicated include differentiated thyroid cancer (DTC, which includes the PTC and follicular subtypes), poorly differentiated thyroid cancer (PDTC), medullary thyroid cancer (MTC), and, in some cases, anaplastic thyroid cancer (ATC).

Malignancy workup for a thyroid nodule begins with a detailed history and physical examination. This includes assessment for familial thyroid cancer history, history of ionizing radiation exposure (especially during childhood), and signs/symptoms of hypothyroidism or hyperthyroidism. In addition, evaluation for evidence of rapidly progressive disease, including rapid nodule growth or rapid development of compressive/invasive symptoms (including hoarseness, dysphagia, or neck pain), is critical to early recognition of ATC, whereas careful physical examination of the bilateral central and lateral neck fields is crucial for nodal metastasis disease detection (Fig. 1). Familial thyroid cancer accounts for 5% to 10% of cases, and

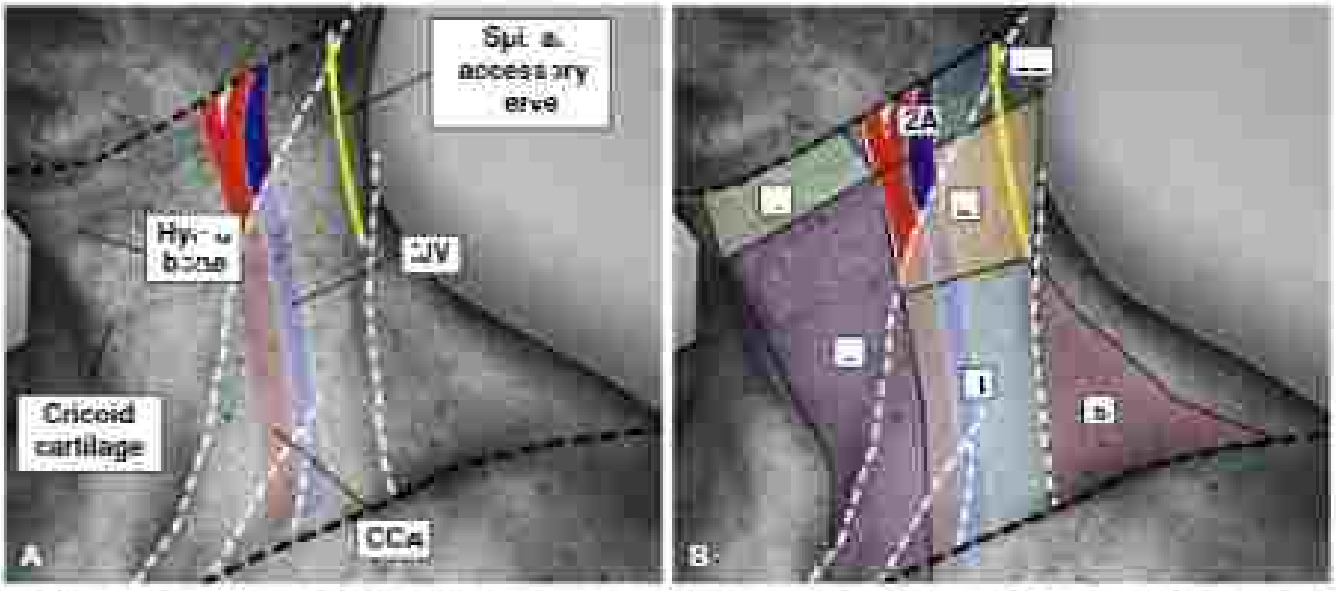

FIG. 1. Neck level team organization. (A) The left neck is shown. Important landmarks include the sternocleidomastoid muscle (SCM, white dashed line), the clavicle and lower border of the mandible (*not labeled*). (B) The common carotid artery (CCA), the internal jugular vein (IJV), the hyoid bone, the thyroid cartilage, and the spinal accessory nerve. (B) Nodal compartments. The boundary of the central (*level 6*) and lateral (*level 2–5*) nodal compartments, in which thyroid cancer may metastasize, are shown. Level 6: superior: hyoid bone, inferior: innominate artery, medial: tracheal midline, lateral: CCA. Level 2A: superior: inferior mandibular border/inferior hyoid bone, medial: spinal accessory nerve, lateral: posterior SCM border. Level 2B: superior: hyoid bone, inferior: cricoid cartilage, medial: CCA, lateral: posterior SCM border. Level 4: superior: cricoid cartilage, inferior: clavicle, medial: CCA, lateral: posterior SCM border. Level 5: superior: skull base, inferior: clavicle, medial: posterior SCM border, lateral: trapezius muscle.

patients with a first-degree relative diagnosed with DTC or MTC are at increased risk of thyroid cancer development. In addition, patients having known or suspected family history of gene mutations associated with thyroid malignancy will have increased thyroid cancer risk. These include mutations in the *PTEN* gene (Cowden's/*PTEN* syndrome), the *TSHR*-*ARMS* gene (Carney complex), the *APC* gene (familial adenomatous polyposis), and the *RET* gene (multiple endocrine neoplasia 2A and 2B). Exposure to ionizing radiation, especially during childhood, is also an important thyroid cancer risk factor. The risk of PTC development among children chronically exposed to fallout after the Chernobyl nuclear disaster, for example, is approximately nineteenfold higher than that of comparable unexposed populations. Thyroid function also influences thyroid cancer risk. Hypothyroidism not only confers an increased risk of disease development but is also associated with a more advanced cancer stage at the time of diagnosis. Hyperfunctional/hot thyroid nodules, in contrast, are associated with very low thyroid cancer risk (e.g., <2%). Physical examination findings suggestive of thyroid malignancy include hard nodule characteristics, fixed nodules, and palpable cervical adenopathy.

Thyroid Nodule Malignancy Assessment: Thyroid Function and Imaging

All thyroid nodule patients should undergo thyroid function assessment, which, for most patients, requires only serum thyroid-stimulating hormone (TSH) level testing. A suppressed serum TSH level indicates hyperthyroidism and should prompt radioiodine uptake scanning. Radioiodine avid (hyperfunctional/hot) nodules are associated with very low malignancy risk and do not merit additional workup for cancer. Otherwise, all thyroid nodules should undergo high-resolution Doppler ultrasonography (US), which is the most sensitive method for assessing thyroid malignancy risk. Other imaging modalities, including positron emission tomography (PET) scanning, CT, and magnetic resonance imaging, generally do not play a role in the initial workup for thyroid malignancy. Thyroid nodule US features concerning for malignancy have been well described, and high-risk findings (>90% specificity) include microcalcifications, hypervascularity, taller than wide shape, irregular nodule borders, and extrathyroidal nodule extension. Similarly, nodule US features reassuring for benign disease have also been defined, including spongiform character and purely cystic composition.

The cervical nodal basins in which thyroid cancer may preferentially metastasize (including levels 2A, 2B, 3, 4, 5 and 6, Fig. 1) should also be assessed by US when a potentially malignant thyroid nodule is discovered. Lymph node US features suggestive of metastasis include microcalcifications, loss of the normal nodal fatty hilum, cortical thickening, cystic composition, rounded shape, associated hypervascularity and hyperechogenicity. One or more of these US features will be identified in 20% to 30% of DTC patients, for example, and may change the associated operative strategy in approximately 20% of such cases.

Thyroid Nodule Malignancy Assessment: Aspiration Biopsy

A formal diagnosis of (thyroid) cancer requires tissue analysis, and suspicious thyroid nodules should undergo US guided fine needle aspiration (FNA) biopsy. Specific guidelines informing which thyroid nodules warrant FNA have been published by several different professional organizations, including the American Thyroid Association and the American College of Radiology. In general, all solid thyroid nodules greater than 1 cm in maximum diameter having US findings suspicious for malignancy should undergo FNA, as should most solid nodules greater than 1.5 cm in maximum diameter lacking suspicious US features. In addition, any cervical lymph node demonstrating US features suspicious for metastasis should undergo US guided FNA.

Interpretation of thyroid FNA samples (cytology) can be challenging in cases of DTC because the cytologic diagnosis of DTC depends on the aggregate presence of individual cellular features associated with malignancy, some of which are, in themselves, pathognomonic

TABLE 1 Bethesda Criteria for Categorization of Indeterminate Thyroid Nodule Cytology, with Associated Predicted Malignancy Risk in Each Case

Bethesda Category	Thyroid Malignancy Risk
1. Nondiagnostic/unsatisfactory	Up to 20%
2. Benign	1%–3%
3. Atypia of undetermined significance	5%–15%
4. Follicular/Hürthle cell neoplasm	15%–30%
5. Suspicious for papillary thyroid cancer	60%–75%
6. Malignant	97%–99%

For this reason, thyroid FNA findings are stratified into one of six possible categories (known as the *Bethesda categories*) according to the associated relative malignancy risk (Table 1). The Bethesda 1 category represents nondiagnostic findings, whereas benign cytology falls into the Bethesda 2 group. Cells having malignant features, but for which definitive evidence of malignancy is absent, are classified as indeterminate and represent the Bethesda categories 3 to 5, atypia of undetermined significance/follicular lesion of undetermined significance (Bethesda 3), follicular neoplasm/suspicious for follicular neoplasm/suspicious for Hürthle cell neoplasm (Bethesda 4), and suspicious for papillary cancer (Bethesda 5), where each numerical increase in category designation is associated with an incremental increase in malignancy risk. The Bethesda 6 category is reserved for frankly malignant cytology. In contrast to DTC, cytologic identification of MTC, poorly differentiated thyroid cancer, and ATC tends to be more straightforward for the interpreting pathologist.

Approximately 25% of thyroid FNAs will be designated as Bethesda 3, 4, or 5. The risk of malignancy for these indeterminate cases may be further informed by aspirate genetic testing. In particular, mutations in the *BRAF* oncogene (most commonly the *BRAF*V600E mutation) confer 99% specificity for PTC, and the presence of this mutation should prompt thyroid surgery. Additional oncogenic driver mutations potentially characterizing DTC have also been described, and commercially available assays for these mutations have been developed. Other testing platforms comparing the genetic profile of aspirated thyroid samples against panels of mutations associated with thyroid cancer are also now commercially available. In general, the predictive values afforded by currently available genetic testing for the presence or absence of thyroid malignancy are imperfect. Most experts thus agree that the current value of such testing for clinical decision making in these cases is limited; cytologic assessment remains the gold standard in this regard. Nonetheless, the development of new genetic testing platforms, and the refinement of existing tests, for greater diagnostic accuracy among cytologically indeterminate thyroid nodules remains an area of intense interest and improved testing options are forthcoming.

Aspirate from suspicious cervical lymph nodes are, in general, readily assessed for metastasis because identification of thyroid epithelial cells in a lymph node represents metastatic disease. The sensitivity of nodal FNA may be increased by determining the associated level of the thyroid-specific protein, thyroglobulin (Tg), in the aspirate, and this testing should thus be routine. A nodal aspirate Tg value exceeding 33 ng/mL in a patient who has not undergone thyroidectomy is suggestive of metastasis and should prompt compartment-oriented neck dissection.

Thyroid Malignancy: Preoperative Testing and Preparation

Additional testing and optimization may be required before proceeding with surgery in cases of thyroid malignancy or suspected malignancy. Coexisting hyperthyroidism, if present, should be managed medically, and biochemical euthyroidism should be achieved using thionamide treatment before surgery (to minimize risk of intraoperative hyperthyroid crisis/thyroid storm). Serum calcium levels should also be assessed before surgery, and the presence of hypercalcemia should prompt blood parathyroid hormone level testing. Coexisting primary hyperparathyroidism should be assessed with parathyroidectomy concomitantly during thyroid surgery. Fine-cut CT scanning of the neck and upper chest, with intravenous (IV) contrast, should be performed in selected cases for which high-resolution anatomic imaging may direct operative planning. This includes cases for which locally invasive disease is suspected, including all suspected or confirmed cases of poorly differentiated and anaplastic cancer, cases for which nodal metastatic disease has been identified or is suspected (particularly when lateral neck nodal basins are involved), in reoperative/recurrent cases, and when substernal mediastinal disease extension is suspected. Preoperative voice change/hoarseness, evidence of thin liquid aspiration, or hemoptysis is suggestive of locally invasive disease and should prompt endoscopic assessment, including direct laryngoscopy, esophagoscopy, or both.

Blood calcitonin and carcinoembryonic antigen are biomarkers for MTC, and baseline levels for each should be established before surgery for patients diagnosed with MTC. In particular, marked elevation in blood calcitonin levels are suggestive of distant metastatic disease, and levels exceeding 400 pg/mL should prompt preoperative whole-body imaging, most commonly CT scanning with IV contrast and triple phase liver imaging. *RET* proto-oncogene assessment for mutations associated with MTC should be performed in the postnatal period for all children having family history of multiple endocrine neoplasia (MEN) type 2. Specific *RET* gene mutations correlate with MTC onset age, as well as relative disease aggressiveness, and thus direct the relative urgency of thyroid surgery. All patients diagnosed with MTC should be assessed for concomitant pheochromocytoma, either with plasma metanephrine and normetanephrine level testing or with 24 hour urine fractionated catecholamine level testing because these adrenal tumors may coexist in cases of MEN2. Pheochromocytomas are associated with potentially life-threatening intraoperative hypertensive crisis and should be resected, following appropriate perioperative α-blocker treatment, before proceeding with any invasive procedure (e.g., thyroidectomy). Finally, although the blood Tg level is an important marker for DTC recurrence after total thyroidectomy, this testing is neither sensitive nor specific preoperatively for thyroid cancer and thus should not be assessed before thyroidectomy.

THYROID SURGERY FOR MALIGNANCY OR SUSPECTED MALIGNANCY

Differentiated Thyroid Cancer

Thyroid surgery is indicated for most patients diagnosed with DTC. For symptom-free patients having unilateral DTC, the extent of thyroid surgery chosen depends primarily on the speculated need for postoperative radioactive iodine (RAI) treatment. Iodine is a primary component of thyroid hormone and the thyroid epithelium (including DTC, which is epithelium derived) is thus iodine avid. This thyroid-specific feature allows therapeutic targeting of DTC with radioiodine, and adjuvant RAI has been shown to improve disease outcomes under specific circumstances. These include DTC cases for which tumor diameter exceeds 4 cm, local invasion is identified, aggressive histologic findings are present (e.g., tall cell, columnar cell, and hobnail PTC variants), distant metastatic disease is identified, and, potentially, when cervical nodal metastasis is present. Under these circumstances, total thyroidectomy is required, as the presence of normal iodine and thyroid tissue (e.g., the contralateral thyroid lobe) likely decreases adjuvant RAI treatment efficacy. RAI treatment after total thyroidectomy for DTC may also facilitate disease recurrence monitoring because blood Tg levels in such cases should remain very low in the absence of recurrence.

The extent of thyroid surgery for unilateral DTC when adjuvant RAI is not indicated appears to play little, if any, role in long-term outcome. Limiting surgery to these cases to unilateral thyroid lobectomy affords several advantages. First, most of the patients who are euthyroid before surgery will remain euthyroid (up to 90%) if the contralateral thyroid lobe is left in situ, thus obviating need for obligate life long thyroid hormone replacement in most cases. Second, the risks of permanent postoperative hypoparathyroidism and of intraoperative bilateral recurrent laryngeal nerve (RLN) injury among patients undergoing thyroid lobectomy, relative to total thyroidectomy, are extremely low, if not completely obviated. The potential need for emergency management of life threatening postoperative expanding cervical hematoma after thyroid surgery is the primary reason for hospital admission after thyroidectomy. This risk is lower when surgery is limited to thyroid lobectomy and, as a result, some patients who undergo lobectomy are discharged on the day of surgery. In contrast, total thyroidectomy is frequently associated with overnight observation for hematoma development.

It is important to note that PTC is multifocal in approximately 20% to 30% of cases and that microscopic disease involving the lobe contralateral to an identified PTC may not be detectable by preoperative ultrasound. Thus patients undergoing thyroid lobectomy for identified unilateral PTC will require postoperative ultrasound surveillance of their remaining thyroid tissue. Associated development of new nodularity may require aspiration biopsy, and, if concern for malignancy is identified, completion thyroidectomy will be required. In addition, several DTC tumor features informing adjuvant RAI treatment decision making are only identifiable during formal postoperative surgical specimen analysis (e.g., aggressive histologic subtype, lymphatic invasion, and vascular invasion). Identification of such tumor features after thyroid lobectomy necessitates subsequent completion thyroidectomy, most commonly performed approximately 4 weeks after the index operation. Similarly, identification of new cervical nodal metastatic disease during surveillance after thyroid lobectomy for DTC necessitates completion thyroidectomy, as well as compartment-oriented neck dissection, followed by RAI administration. Total thyroidectomy is also generally recommended in cases of unilateral DTC when (1) benign contralateral thyroid nodularity is present, (2) concomitant Graves' disease or hyperthyroidism has been diagnosed, (3) preexisting comorbidities would preclude possible future completion thyroidectomy, (4) significant ionizing radiation exposure history is identified, especially during childhood, (5) a significant family history of thyroid cancer is identified, and (6) when the patient prefers total thyroidectomy.

Finally, recent prospective data have called into question the need for thyroidectomy among average risk patients diagnosed with isolated, small (≤1 cm) PTCs for which clinical and radiographic evidence of invasive or metastatic features are absent. Ongoing prospective serial monitoring studies involving such patients indicate that most of these cases will not progress, especially with increasing age at diagnosis (e.g., >40 years). Close serial observation for such PTCs by an experienced endocrinologist is thus a management option, especially among patients identified as high risk surgical candidates. Evidence for disease progression during follow up, namely primary tumor growth, development of multifocal disease or evidence of new metastatic nodal involvement, however should prompt surgery.

Identification of metastatic DTC involving cervical lymph nodes requires compartment oriented neck dissection at the time of total thyroidectomy (Fig. 1). It is important to note that metastatic disease involving the lateral neck (levels 2 to 5), without concomitant involvement of the ipsilateral central neck (level 6), is rare. Thus all DTC cases for which lateral neck nodal metastatic disease has been identified will require both ipsilateral lateral and central neck dissections, even when no clinical or radiographic evidence of central neck involvement is identified. In contrast, isolated metastatic DTC nodal involvement of the central neck, without concomitant lateral neck nodal disease, is common, and lateral neck dissection should be limited to cases for which associated metastatic disease is confirmed.

Occult nodal metastatic disease involving the ipsilateral central neck is common, and some experts thus recommend ipsilateral central neck dissection at the time of thyroidectomy for all cases of DTC, even when radiographic and clinical evidence of nodal metastasis absence is absent (prophylactic central neck dissection). Nonetheless, the impact of occult nodal metastatic central neck disease on DTC recurrence and disease specific survival, if any, appears to be minimal, and many surgeons therefore do not routinely perform prophylactic central neck dissection in these cases.

Nondiagnostic and Indeterminate FNA Biopsy Findings

Thyroid nodules for which aspiration biopsy findings are nondiagnostic (Bethesda I category) should undergo repeat biopsy. If this repeat testing remains nondiagnostic, thyroid surgery should be considered because thyroid malignancy may be present in up to 20% of such cases (Table 1). Indeterminate biopsy findings (Bethesda 2–5 categories) should also prompt referral for surgery, given associated malignancy rates between 5% and 75%, depending on the specific Bethesda category. The accuracy of intraoperative frozen section analysis for identification of thyroid malignancy in these cases is generally poor, and the extent of thyroid surgery selected (ipsilateral thyroid lobectomy versus total thyroidectomy) will thus depend on factors specific to the individual patient. Because at least some fraction of these nodules will be benign for each category, a lower threshold for limiting the extent of thyroid surgery (e.g., thyroid lobectomy only) should be used. Patients having indeterminate biopsy findings should be counseled carefully regarding the potential need for subsequent completion thyroidectomy should thyroid cancer requiring adjuvant RAI be identified during formal postoperative surgical specimen analysis. In general, thyroid lobectomy is recommended for average risk patients having indeterminate thyroid biopsy findings when the index nodule is less than 1 cm in maximal diameter and remains an option for nodules up to 4 cm in maximal diameter.

Medullary Thyroid Cancer

MTC is derived from the parafollicular C cells of the thyroid, which are neuroendocrine in origin and thus do not absorb iodine. RAI therefore plays no role in MTC management. All cases of MTC should be managed with total thyroidectomy. In addition, local nodal metastatic disease is relatively common for this tumor type, and bilateral central neck dissection (levels 6, Fig. 1) is indicated in all cases of MTC, even when preoperative workup is negative for suspicious adenopathy. Lateral neck dissection (levels 2 to 5) is formally indicated whenever associated nodal metastatic disease is discovered, generally by FNA of suspicious adenopathy identified before surgery. Prophylactic ipsilateral lateral neck dissection may be considered, especially when blood calcitonin levels are significantly elevated (e.g., >400 pg/mL), although the potential morbidity of this procedure must be carefully weighed against an unproven associated benefit. Finally, preoperative identification of distant metastatic disease in cases of MTC does not obviate need for total thyroidectomy and compartment oriented neck dissection. Although surgical cure is not possible in such cases, total thyroidectomy will prevent local disease progression, including development and progression of direct invasion into adjacent structures, including the RLN(s), the larynx, the esophagus and the trachea. Elevated calcitonin levels may also produce significant symptoms, including flushing, weight loss, and intractable diarrhea. Disease debulking by primary tumor resection and resection of cervical metastatic disease may thus produce significant symptomatic improvement (or prevent/delay symptom development) in some patients.

RET proto-oncogene mutations associated with familial MTC syndromes, most commonly MEN2A and MEN2B, have been

classified by the American Thyroid Association according to disease penetrance and relative aggressiveness: moderate risk mutations, high risk mutations, and highest risk mutations. Children carrying moderate risk mutations should be screened regularly for blood calcitonin elevation that, when present, should prompt total thyroidectomy. The presence of a high risk RET mutation is an indication for total thyroidectomy within the first 5 years of life, whereas prophylactic total thyroidectomy should be performed within the first year of life for the highest risk mutation category. Adults found to be RET gene mutation carriers but for whom both blood calcitonin level testing and thyroid ultrasonography results are normal should undergo annual blood calcitonin level reassessment, with total thyroidectomy and bilateral central neck dissection reserved for cases in which this level becomes elevated.

Anaplastic and Poorly Differentiated Thyroid Cancers

Thyroidectomy plays a limited role in the management of anaplastic thyroid cancer because surgery does not generally improve survival for this rare malignancy. Most anaplastic thyroid cancers are metastatic or unresectable at the time of diagnosis, and it is these two features that drive the very poor prognosis associated with this cancer. Surgery for anaplastic thyroid cancer should thus be limited to (1) patients for whom high-resolution CT, US, or PET scanning is negative for local and distant metastatic disease, as well as for locally invasive disease (and for whom surgical cure may thus be possible) and (2) patients requiring symptomatic palliation related to locally invasive disease. Anaplastic thyroid cancer is rapidly progressive, and surgery for the former group should be performed as soon as possible. The appropriate extent of surgery among these patients, however, remains an area of controversy. Anaplastic thyroid cancer cells are undifferentiated and do not absorb iodine. Thus radioiodine plays no management or adjuvant treatment role in these patients. In the absence of contralateral nodularity, ipsilateral thyroid lobectomy is therefore usually recommended to minimize potential operative risk. That being said, one or more concomitant foci of PTC will be identified in up to 20% of ATC cases and some experts thus recommend total thyroidectomy. All patients who undergo thyroid surgery for anaplastic cancer should be referred promptly for adjuvant oncologic care, including chemoradiation and long-term disease recurrence follow-up (during which clinically significant PTC among long-term survivors managed initially with thyroid lobectomy can be identified and appropriately treated). Palliative surgery for locally invasive anaplastic thyroid cancer should be limited to cases of anticipated impending airway compromise and generally involves placement of a tracheostomy tube. Debulking plays no significant role in treatment, as residual unresected tumor will rapidly regrow, often fungating from the surgical wound, and generally involves significant blood loss. Even in the context of tracheostomy, anaplastic tumors may still produce airway compromise because rapid tumor growth may occlude the tracheostomy tube.

The considerations informing surgical decision making for PDTC are similar to those arising when managing DTC. Relative to DTC, PDTC is more likely to present with distant metastatic disease and, although this malignancy is by definition less responsive to radioiodine therapy, most patients will undergo adjuvant radioiodine therapy. Total thyroidectomy is thus indicated for known or suspected cases of PDTC. PDTC is also more likely to be locally invasive at the time of diagnosis and en bloc resection of involved structures is indicated in such cases. As in the case for DTC, central neck dissection, with or without lateral neck dissection, should be performed when clinical or radiologic evidence of cervical nodal metastatic disease is identified. Such disease is more common in PDTC (up to 45%) relative to DTC. Routine prophylactic compartment-oriented neck dissection in for PDTC remains controversial because data linking this practice to improved disease outcomes remain scant.

Rare Thyroid Tumors

Rare tumor types involving the thyroid include primary thyroid lymphomas, teratomas, and metastatic disease of extrathyroidal origin. Biochemical studies and thyroid imaging will not distinguish these tumors from benign or malignant primary thyroid nodules, and diagnosis thus depends on tissue assessment. Aspiration biopsy in cases of thyroid lymphoma is frequently nondiagnostic, although specimens characterized by high lymphocyte content are suggestive of this pathology. Core needle biopsy, with immunohistochemical or flow cytometric analysis, is generally required for diagnosis confirmation. Aspiration biopsy in cases of thyroid teratoma is also generally nondiagnostic, although the morphologically unusual cells identified by cytologic assessment may prompt core needle biopsy, which may be diagnostic. Nonetheless, the diagnosis of thyroid teratoma is frequently made during formal surgical specimen analysis after thyroidectomy. Finally, metastatic disease involving the thyroid, most commonly renal cell carcinoma or melanoma, generally occurs in the context of established primary tumor history and is usually readily diagnosed through FNA.

Indications for resection of unusual thyroid tumors depends on the specific diagnosis suspected. Surgery does not play a role in the management of thyroid lymphoma, and these patients should be referred for chemotherapy. Thyroid lobectomy with en bloc resection of involved structures and ipsilateral central neck dissection is likely to afford the best long-term outcome among patients diagnosed with a thyroid teratoma, although the data informing surgical decision-making for these rare tumors are extremely limited. These patients should also be referred for postoperative adjuvant therapy, generally involving both external beam radiation and chemotherapy. Finally, the utility of thyroidectomy for metastatic disease involving the thyroid will be informed by (1) the prognosis associated with the originating primary malignancy and (2) local associated symptoms for which palliation may be considered. When indicated, thyroid surgery in these cases is generally limited to en bloc resection of the involved lobe only.

THYROIDECTOMY: TECHNICAL CONSIDERATIONS

Disease recurrence and survival rates for resectable thyroid cancers are directly related to completeness of resection and an R0 resection should thus be attempted whenever possible. The surgeon should therefore be prepared for possible en bloc resection of involved structures, most commonly the strap musculature, followed by the ipsilateral RLN, the trachea, the esophagus, the larynx and the ipsilateral internal jugular vein. Residual tumor should not be left in situ under the assumption that this tissue will be destroyed by adjuvant RAI therapy, which may not clear such disease. Careful intraoperative inspection and palpation of the central neck is also critical because this may identify metastatic nodal disease missed during preoperative ultrasound scanning. When resected, the RLN should be reconstructed by primary anastomosis of its unresected ends to minimize ipsilateral laryngeal muscle atrophy. An ansa cervicalis nerve graft may be used for this purpose if the RLN cannot be primarily reconstructed in a tension-free manner. Complete initial disease resection also minimizes risk of local/regional cervical recurrence, which often requires reoperative surgery. Reoperative neck surgery is often technically challenging because wound bed scarring after the index operation may obliterate local tissue planes and distort normal anatomic organization. Risk of injury to associated structures, including the ipsilateral RLN and parathyroid glands, is thus higher in reoperative cases.

As is the case for all thyroid surgery, meticulous intraoperative hemostasis must be maintained because even low volume postoperative bleeding may produce life-threatening airway compromise, requiring emergency evacuation. Intraoperative hemostatic control may be facilitated by use of commercially available vessel sealing energy devices, in addition to traditional electrocautery, suture tie,

and titanium clips. Identification of the ipsilateral RLN is required during thyroid surgery and, although nerve identification and functional assessment may be facilitated by use of nerve monitoring technology, this technology is not a surrogate for manual nerve exposure and dissection. Nonetheless, intraoperative nerve monitor signal loss from an otherwise intact RLN indicates nerve dysfunction and may prompt deferment of planned contralateral thyroid lobe resection. Comorbid oral RLN injury in this context results in bilateral vocal cord paralysis, with possible associated airway compromise. Last, the thyroid surface should be carefully scrutinized during dissection for adherent parathyroid glands, and, assuming no direct tumor involvement, such glands should be carefully mobilized away from the thyroid, with their native blood supplies preserved. Inadvertent intraoperative devascularization or resection of all four parathyroid glands will produce permanent hypoparathyroidism, with significant morbidity stemming from resultant hypocalcemia. Even when the parathyroid glands are carefully preserved, temporary postoperative hypocalcemia is common, and liberal calcium supplementation may be required temporarily in the immediate postoperative period after total thyroidectomy. Devascularized parathyroid glands should be autotransplanted, most commonly into the ipsilateral sternocleidomastoid muscle.

A number of alternative surgical approaches intended to avoid or minimize a cervical incision, and thus development of a potentially unsightly cervical scar, have been developed for thyroidectomy. These include endoscopic/robotic axillo-breast, facelift, and transoral approaches. Such approaches are intended to maximize postoperative cosmesis and may not afford equivalent oncologic outcomes relative to the traditional open approach, especially in cases of invasive or locally metastatic disease. Such alternative surgical approaches should thus be used with caution and, in general, only by surgeons with significant expertise in their use.

Primary Hyperparathyroidism

Kathryn E. Cosa, MD, and Tracy S. Wang, MD, MPH, FACS

Parathyroid glands are responsible for the synthesis and secretion of parathyroid hormone (PTH), which acts to increase serum calcium levels to achieve calcium homeostasis. PTH synthesis is tightly controlled by feedback mechanisms involving serum calcium and vitamin D levels. Primary hyperparathyroidism (PHPT) is the result of inappropriate PTH production by one or more abnormal parathyroid glands, leading to elevated serum calcium levels (Fig. 1).

Epidemiology

The prevalence of PHPT has increased over the last 30 years but remains underdiagnosed and undertreated. Currently, the prevalence of PHPT is estimated to be 0.86% of the general population, increasing to 1% in postmenopausal women. The incidence of PHPT appears to increase with age and is estimated to be two to three times higher in women. Autonomous parathyroid function may be secondary to adenoma(s), hyperplasia, or, rarely, parathyroid carcinoma. Approximately 80% of cases of PHPT results from a single gland adenoma, 10% to 15% of cases are secondary to four gland hyperplasia, and 4% are attributed to adenomatous expansion to two or three glands. Parathyroid carcinoma is responsible for approximately 1% of PHPT cases and generally is characterized by very high serum calcium and PTH levels.

Diagnosis and Evaluation

The diagnosis of PHPT is biochemical and is characterized by hypercalcemia with a high or inappropriately normal PTH level. The biochemical evaluation should include serum levels of total calcium, concurrent PTH, creatinine, and 25-hydroxyvitamin D. Elevated total calcium levels, representing biologically active calcium, are not required for the diagnosis of PHPT but may aid in the diagnosis of patients with normal serum calcium levels and suspected PHPT. A 24-hour urinary calcium level should be obtained to rule out familial hypocalciuric hypercalcemia (FHH), an autosomal dominant syndrome resulting from loss-of-function mutation in the calcium sensing receptor gene. A value less than 100 mg/24 h should raise suspicion for FHH, and a calcium/creatinine clearance ratio should be calculated [(24-hour Ca urine/Ca serum) divided by (24-hour creatinine urine/creatinine serum)]. A value of less than 0.01 is diagnostic for FHH whereas a ratio greater than 0.02 is diagnostic of PHPT. In patients with values in between 0.01 and 0.02, other causes of hypocalciuria should be evaluated, such as chronic kidney disease, increased age, and use of thiazide diuretics. Genetic testing may also be considered in these patients.

The clinical presentation of PHPT is heterogeneous and continues to evolve. A thorough preoperative evaluation should address objective manifestations of PHPT, including nephrolithiasis, osteoporosis, and fragility fractures. If not previously obtained, a bone mineral density test is recommended and should include the lumbar spine, hip, and distal one third of the radius. A complete history should address subjective symptoms of PHPT, which can range from mild to severe. These include neurocognitive complaints such as irritability, anxiety, depression, short-term memory deficits, and difficulty concentrating; constitutional symptoms, including fatigue and insomnia; gastrointestinal complaints such as dyspepsia, abdominal pain, and constipation; musculoskeletal symptoms, including muscle, bone, and joint pain; and genitourinary complaints such as polydipsia/polyuria. A careful family history is critical to the workup of PHPT because several familial syndromes are associated with this disease. These include multiple endocrine neoplasia (MEN) type 1, MEN type 2A, and hyperparathyroidism–jaw tumor syndrome. In patients in whom an inherited syndrome is suspected (patients <40 years and those with multigland hyperplasia), genetic counseling is recommended because the specific disease and mutation may impact timing and extent of surgery.

Indications for Surgery

Parathyroidectomy remains the only curative intervention for PHPT and should be considered in all symptomatic patients. In

and titanium clips. Identification of the ipsilateral RLN is required during thyroid surgery and, although nerve identification and functional assessment may be facilitated by use of nerve monitoring technology, this technology is not a surrogate for manual nerve exposure and dissection. Nonetheless, intraoperative nerve monitor signal loss from an otherwise intact RLN indicates nerve dysfunction and may prompt deferment of planned contralateral thyroid lobe resection. Comorbid vocal fold RLN injury in this context results in bilateral vocal cord paralysis, with possible associated airway compromise. Last, the thyroid surface should be carefully scrutinized during dissection for adherent parathyroid glands, and, assuming no direct tumor involvement, such glands should be carefully mobilized away from the thyroid, with their native blood supplies preserved. Inadvertent intraoperative devascularization or resection of all four parathyroid glands will produce permanent hypoparathyroidism, with significant morbidity stemming from resultant hypocalcemia. Even when the parathyroid glands are carefully preserved, temporary postoperative hypocalcemia is common, and liberal calcium supplementation may be required temporarily in the immediate postoperative period after total thyroidectomy. Devascularized parathyroid glands should be autotransplanted, most commonly into the ipsilateral sternocleidomastoid muscle.

A number of alternative surgical approaches intended to avoid or minimize a cervical incision, and thus development of a potentially unsightly cervical scar, have been developed for thyroidectomy. These include endoscopic/robotic axillo-breast, facelift, and transoral approaches. Such approaches are intended to maximize postoperative cosmesis and may not afford equivalent oncologic outcomes relative to the traditional open approach, especially in cases of invasive or locally metastatic disease. Such alternative surgical approaches should thus be used with caution and, in general, only by surgeons with significant expertise in their use.

Primary Hyperparathyroidism

Kathryn E. Cosa, MD, and Tracy S. Wang, MD, MPH, FACS

Parathyroid glands are responsible for the synthesis and secretion of parathyroid hormone (PTH), which acts to increase serum calcium levels to achieve calcium homeostasis. PTH synthesis is tightly controlled by feedback mechanisms involving serum calcium and vitamin D levels. Primary hyperparathyroidism (PHPT) is the result of inappropriate PTH production by one or more abnormal parathyroid glands, leading to elevated serum calcium levels (Fig. 1).

Epidemiology

The prevalence of PHPT has increased over the last 30 years but remains underdiagnosed and undertreated. Currently, the prevalence of PHPT is estimated to be 0.86% of the general population, increasing to 1% in postmenopausal women. The incidence of PHPT appears to increase with age and is estimated to be two to three times higher in women. Autonomous parathyroid function may be secondary to adenoma(s), hyperplasia, or, rarely, parathyroid carcinoma. Approximately 80% of cases of PHPT results from a single gland adenoma, 10% to 15% of cases are secondary to four gland hyperplasia, and 4% are attributed to adenomatous expansion to two or three glands. Parathyroid carcinoma is responsible for approximately 1% of PHPT cases and generally is characterized by very high serum calcium and PTH levels.

Diagnosis and Evaluation

The diagnosis of PHPT is biochemical and is characterized by hypercalcemia with a high or inappropriately normal PTH level. The biochemical evaluation should include serum levels of total calcium, concurrent PTH, creatinine, and 25-hydroxyvitamin D. Elevated total calcium levels, representing biologically active calcium, are not required for the diagnosis of PHPT but may aid in the diagnosis of patients with normal serum calcium levels and suspected PHPT. A 24-hour urinary calcium level should be obtained to rule out familial hypocalciuric hypercalcemia (FHH), an autosomal dominant syndrome resulting from loss-of-function mutation in the calcium sensing receptor gene. A value less than 100 mg/24 h should raise suspicion for FHH, and a calcium/creatinine clearance ratio should be calculated [(24-hour Ca urine/Ca serum) divided by (24-hour creatinine urine/creatinine serum)]. A value of less than 0.01 is diagnostic for FHH whereas a ratio greater than 0.02 is diagnostic of PHPT. In patients with values in between 0.01 and 0.02, other causes of hypocalciuria should be evaluated, such as chronic kidney disease, increased age, and use of thiazide diuretics. Genetic testing may also be considered in these patients.

The clinical presentation of PHPT is heterogeneous and continues to evolve. A thorough preoperative evaluation should address objective manifestations of PHPT, including nephrolithiasis, osteoporosis, and fragility fractures. If not previously obtained, a bone mineral density test is recommended and should include the lumbar spine, hip, and distal one third of the radius. A complete history should address subjective symptoms of PHPT, which can range from mild to severe. These include neurocognitive complaints such as irritability, anxiety, depression, short-term memory deficits, and difficulty concentrating; constitutional symptoms, including fatigue and insomnia; gastrointestinal complaints such as dyspepsia, abdominal pain, and constipation; musculoskeletal symptoms, including muscle, bone, and joint pain; and genitourinary complaints such as polydipsia/polyuria. A careful family history is critical to the workup of PHPT because several familial syndromes are associated with this disease. These include multiple endocrine neoplasia (MEN) type 1, MEN type 2A, and hyperparathyroidism–jaw tumor syndrome. In patients in whom an inherited syndrome is suspected (patients <40 years and those with multigland hyperplasia), genetic counseling is recommended because the specific disease and mutation may impact timing and extent of surgery.

Indications for Surgery

Parathyroidectomy remains the only curative intervention for PHPT and should be considered in all symptomatic patients. In

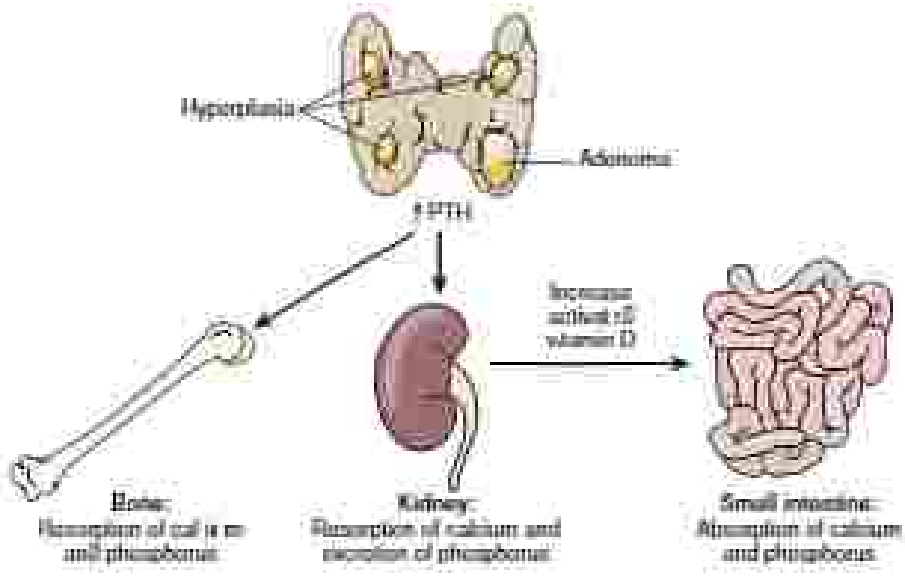

FIG. 1 Pathophysiology of primary hyperparathyroidism.

symptom free patients, both the American Association of Clinical Endocrinologists and the National Institutes of Health recommend parathyroidectomy when

- Serum calcium level is greater than 1 mg/dL above the normal laboratory range
- Presence of renal insufficiency, hypercalciuria, nephrolithiasis, or creatinine clearance less than 60 mL/min
- Presence of osteoporosis, vertebral compression fracture, or bone mineral density T-score of −2.5 or lower
- Patient younger than 50 years

Surgery in these patients should be considered even for patients without symptoms who are many asymptomatic patients may have mild symptoms that are difficult to identify. Patients with mild symptoms may benefit from surgery. Surgery is also recommended for patients who are unable to undergo regular follow-up. Surgery may be more cost-effective than medical management for some patients, especially those who are not operative candidates.

Localization

The majority of cases of PHPT are secondary to a solitary adenoma, which may be seen on single-dose imaging. Currently, the extent of our knowledge may not confirm a unilateral or bilateral disease, although it is usually possible to localize the lesion. The most common imaging modalities used to localize parathyroid adenomas are ultrasound (US), sestamibi scan, and four-dimensional computed tomography (4D-CT). Choice of imaging depends on availability and multidisciplinary skills, in addition to the clinical presentation by the patient and the surgeon.

Cervical Ultrasonography

Cervical US is often considered for all patients with PHPT, primarily to detect thyroid nodules, which are found in 40% of patients, and to identify concomitant thyroid pathology that can be addressed at the time of surgery. However, it is also a very operator-dependent study. However, it can still show parathyroid adenomas, which may be missed by clinical palpation. Patients with a thyroid ultrasound experience has a sensitivity of 76% to 94% and a specificity of 94% to 96%. Parathyroid adenomas appear as oval or round masses that are usually near the thyroid gland (Fig. 2).

Sestamibi Scanning

Sestamibi imaging is the most commonly performed nuclear medicine test used to localize parathyroid adenomas. There are multiple protocols available, such as dual-phase or subtraction techniques with single-photon emission CT (sestamibi SPECT) or dual-tracer subtraction (Fig. 3). The sensitivity and specificity of sestamibi SPECT are 80% to 90% and 97% to 98%, respectively. These localization studies are highly necessary for reoperative parathyroidectomy, minimally invasive surgery, and for patients who are unable to undergo neck exploration. Sestamibi scans may have a higher false-negative rate than US, but it may have further accuracy.

Four-Dimensional Computed Tomography

Four-dimensional CT is similar to traditional CT. The technique involves thin slices (0.5 mm) multiphasic CT scanning, with a fourth dimension consisting of contrast administration over time. Comparison between images obtained with three different phases allows differentiation of enlarged parathyroid glands from adjacent structures, including thyroid tissue and cervical lymph nodes (Fig. 4). Four-dimensional CT has a reported sensitivity and specificity of 85% and 99% for localization of disease and 66% and 89% for specific localization. Overall, the use of either 4D-CT or sestamibi SPECT improves accuracy and surgical success compared with US alone. The sensitivity of imaging studies is partially determined and all are operator variables by region and performance, per case. In general, more experienced providers achieve the best localization accuracy. The above-mentioned studies should be performed at high-volume centers when possible.

Preoperative Management

Most patients with PHPT should be maintained on 1000 to 1200 mg of calcium per day because low calcium intake can stimulate PTH secretion, resulting in worsening bone demineralization. Vitamin D deficiency is also common in PHPT, and patients with vitamin D deficiency (<20 ng/mL) should be supplemented. Multiple studies have shown it is not only safe but beneficial to supplement vitamin D to levels greater than 30 ng/mL to prevent increased bone loss.

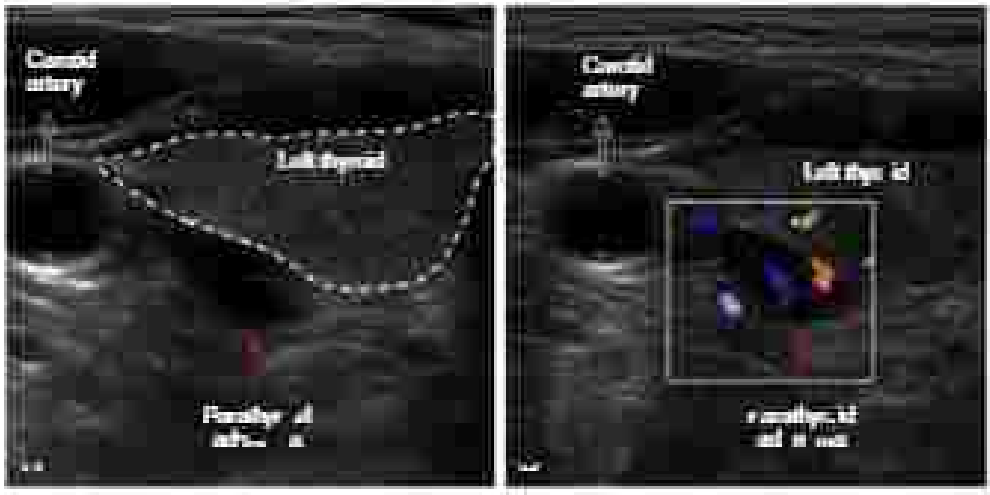

FIG. 3. Single-photon emission computed tomography acquisition obtained at 2 hours demonstrating increased uptake in a nodule of mass in the anterior upper mediastinum.

Severe hypercalcemia (>14 mg/dL) is rare in PHPT. However, patients who present to hypercalcemic crisis should be stabilized before surgery, and the possibility of parathyroid carcinoma should be considered. Stabilization begins with volume repletion using isotonic saline. Once adequately rehydrated, loop diuretics may be used to blunt calcium absorptive and proximal calciuresis. In refractory cases, calcitonin and bisphosphonates that inhibit bone resorption may be used. Once stabilized these patients should undergo parathyroidectomy.

Subjective assessment of vocal quality should be addressed before surgery. Patients with a history of prior operations involving either the vagus or recurrent laryngeal nerve should undergo preoperative vocal cord evaluation. Patients with subjective voice complaints should also be thoroughly evaluated for vocal cord function. Vocal cord evaluation can include direct or indirect laryngoscopy, videostroboscopy, or transcutaneous vocal cord ultrasonography.

INTRAOPERATIVE ADJUNCTS

Intraoperative Parathyroid Hormone Monitoring

Intraoperative PTH (IOPTH) monitoring allows for real time evaluation of parathyroid function. PTH has a short half life of 2 to 4 minutes, and therefore PTH levels should drop rapidly after successful excision of hyperfunctioning parathyroid tissue. Failure of the IOPTH level to decrease appropriately after excision of an enlarged parathyroid gland indicates the presence of additional disease and should prompt conversion to bilateral neck exploration.

Various IOPTH criteria exist to ensure cure. The Miami criterion protocol uses a greater than >50% IOPTH drop from the highest preexcision or postexcision measurement of IOPTH in a blood sample taken 10 minutes after resection of hyperfunctioning glands to confirm successful parathyroidectomy. Cure rates of 95% to 99% have been reported with this criterion. However, some studies have suggested that the Miami criteria are more likely to miss multigland disease with a sensitivity of only 80% for this pathology. This has led to the investigation of more stringent protocols, one of the most widely used is the [illegible] protocol. This protocol requires a greater than 60%-drop from the preexcision value at 10 minutes after resection of hyperfunctional glands and the 10 minute value should to be close to or within normal range to ensure successful parathyroidectomy. This protocol also has reported cure rates of 97% to 99%, with an improved sensitivity of 95% for multigland disease. However, surgeons should be aware that this protocol has been associated with an increased incidence of negative bilateral explorations ranging from 1% to 2%.

Surgeons should be aware of factors that can influence IOPTH results. Blood drawn from an ipsilateral central neck vein may have higher PTH levels than a peripheral sample and may take longer to decrease. It is also important to ensure samples are not diluted with intravenous fluids. Intravenous anesthetics (particularly propofol), or hemolysed, as these may lead to falsely low IOPTH levels.

Bilateral Internal Jugular Sampling or Localization

In patients with results showing preoperative imaging, or during a parathyroidectomy in which the abnormal parathyroid gland cannot be identified, IOPTH levels obtained from each internal jugular vein may help localize the location of an adenoma. Bilateral internal jugular vein IOPTH levels and a peripheral IOPTH level should be obtained in a close time proximity, a gradient of 5% to 10% is suggestive of lateralization to the side of the higher IOPTH level. This method was found to be more accurate for superior parathyroid glands, believed to be secondary to drainage patterns, because of this, samples should be obtained as low as possible on the internal jugular vein to ensure that the sample is obtained inferior to the site of venous drainage.

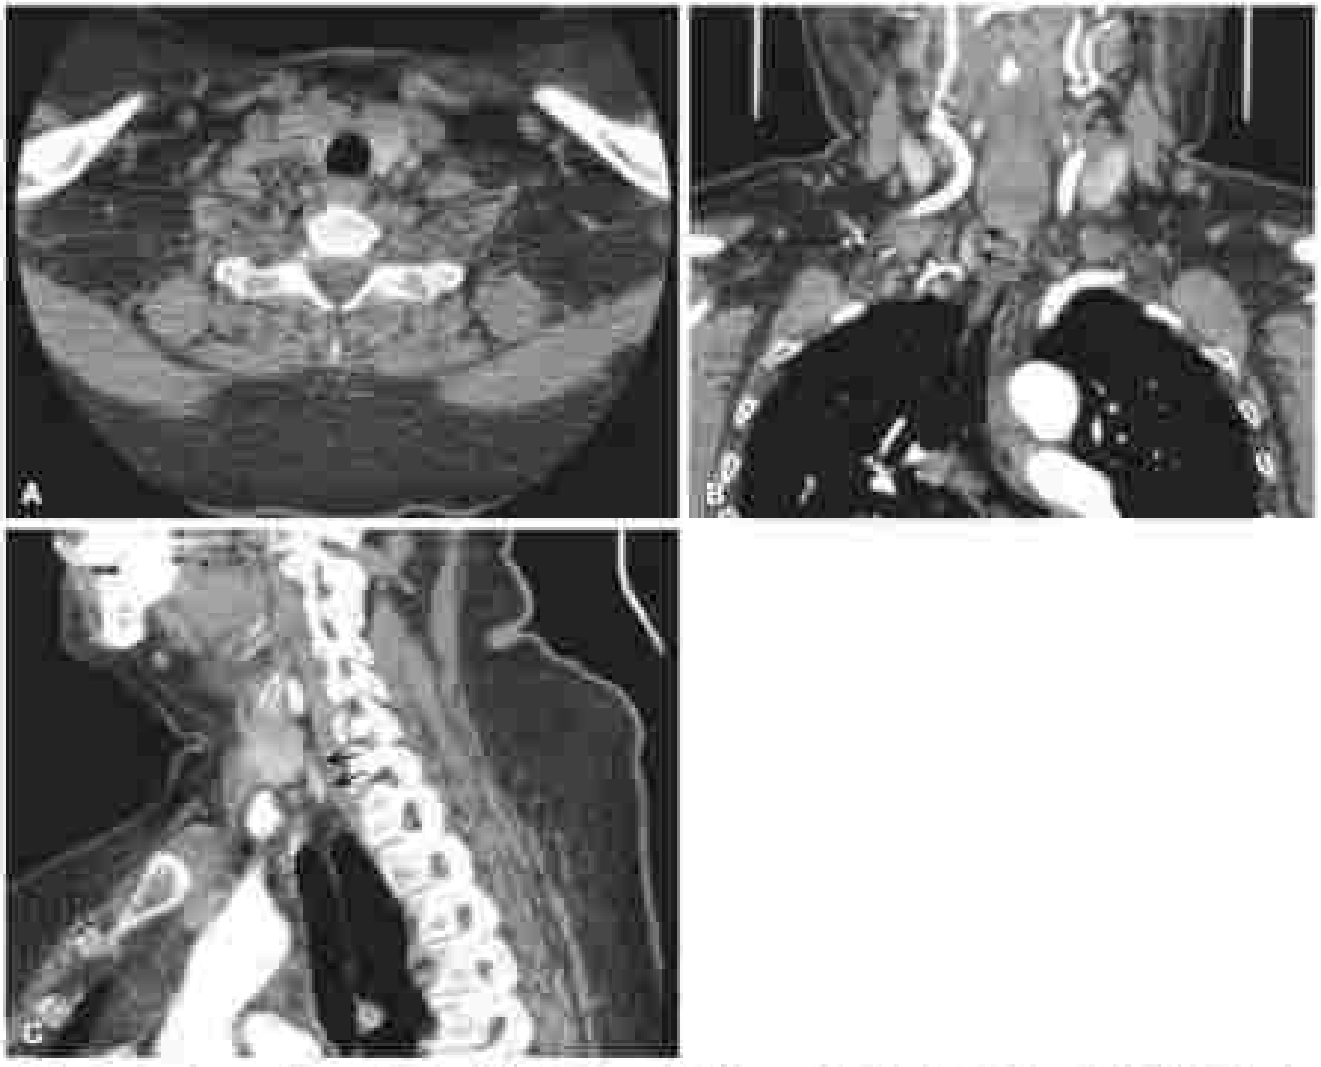

FIG. 4 Four-dimensional computed tomography scan with (A) axial, (B) coronal, and (C) sagittal multiplanar views during the arterial phase of an enlarged right inferior parathyroid adenoma.

Gamma Probe–Mediated Intraoperative Parathyroid Adenoma Localization

This technique is performed using technetium 99 m, the nuclear tracer used for metabolic scanning. Technetium 99 m is injected 1 to 2 hours before the operation. A handheld gamma probe is used to help guide the dissection. Once the gland is excised, ex vivo counts are obtained. This value is compared with the counts of the resection field, with a 20% drop in gamma emission indicating resection of an abnormal gland. This can be used as an adjunct with IOPTH monitoring or bilateral exploration. It has not been validated as an independent utility to identify or exclude multigland disease.

Gland Confirmation

Excision of abnormal parathyroid tissue is critical for successful parathyroidectomy. However, thyroid nodules or lymph nodes may be misidentified as parathyroid tissue during surgery. Traditionally, parathyroid tissue has been confirmed with intraoperative frozen section. However, at some institutions this may increase operative time and cost. In vivo aspiration using IOPTH is an accurate and inexpensive option to distinguish parathyroid tissue. In vivo aspiration of the gland is performed using a 25-gauge needle to aspirate the abnormal parathyroid (Fig. 5). The aspirate is then run with the serum IOPTH samples. An ex vivo aspirate IOPTH level of more than 1.5 times that of the baseline serum IOPTH level is consistent with parathyroid tissue with a 100% specificity and 98.3% accuracy.

PARATHYROIDECTOMY

Parathyroid Embryology and Anatomy

Surgeons' familiarity with parathyroid anatomy is critical to identify eutopic and ectopic parathyroid glands. Most patients have four parathyroid glands. However, up to 13% may have additional parathyroid tissue. Embryologically, the inferior and superior parathyroid glands are derived from the third and fourth pharyngeal pouch, respectively, secondary to embryologic descent, parathyroid gland location can be variable (Fig. 6). However, superior and inferior glands are symmetric 70% to 85% of the time. The superior parathyroid glands descend with the thyroid and are posterior to the recurrent laryngeal nerve. They can commonly be found near the cricothyroid junction and are associated with the posterolateral aspect of superior thyroid. The inferior parathyroid glands descend with the thymus and tend to be located in a more anterior plane. They are usually close to the inferior pole of the thyroid gland or within the thymofalyx ligament. Ectopic parathyroid glands can be found in a variety of locations related to their descent. The most common location is the thymus, but other locations include the tracheoesophageal groove, retroesophageal space, intrathyroidal, mediastinal or undescended in the carotid sheath (Fig. 7).

FIG. 5 Ex vivo parathyroid adenoma.

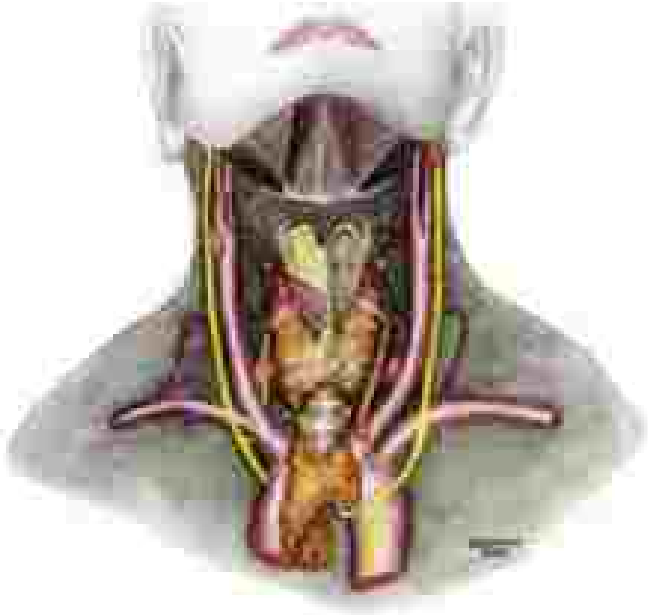

FIG. 6 Ectopic and complex parathyroid locations. (From White ML, [illegible] Radiographics. 1998;18(4):937–957.)

Minimally Invasive Parathyroidectomy

Minimally invasive, or "focused," parathyroidectomy (MIP) should be performed in patients when preoperative localization is successful and IOPTH monitoring is available because this improves the rate of cure, compared with relying on preoperative imaging alone. MIP is not recommended for patients when there is evidence of bilateral disease on preoperative imaging or evidence of familial hyperparathyroidism. MIP can be performed with the patient under general anesthesia or with superficial cervical plexus nerve blockade and local anesthesia. However, the latter requires a compliant patient and coordination between the surgical and anesthesia teams.

Before MIP, the surgeon should review the preoperative imaging and, if possible, have these available in the OR. Before intubation, a baseline serum PTH level is obtained to avoid a potential spike in the PTH level from manipulation of the neck with intubation or surgical prep. The patient is then positioned with the neck slightly extended, using a shoulder roll or inflatable cuff. A 2- to 4-cm transverse incision is made approximately one or two fingerbreadths above the sternal notch, in a preexisting skin crease, if possible. The platysma is divided with electrocautery, and subplatysmal flaps are raised. The midline raphe between the strap muscles is opened. The strap muscles are then taken off the thyroid and retracted laterally. At this point the thyroid is retracted medially to expose the targeted parathyroid gland.

If there is difficulty finding a suspected parathyroid adenoma, it is important to refer to the embryology and anatomy described above. When looking for a superior gland, it is important to evaluate the thyroid is elevated and medially rotated. This allows for adequate posterolateral exposure of the superior aspect of the gland. When looking for an inferior parathyroid gland, it is important to evaluate the preoperative imaging to determine inferior extent of the gland in relation to the inferior pole of the thyroid because this gland may be adherent to the pole or more inferiorly to the thymus ligament or thymus. Identification of the recurrent laryngeal nerve may also be beneficial because superior parathyroid glands are located posteriorly relative to the recurrent laryngeal nerve and superior to the inferior thyroid artery, whereas the inferior glands are generally anterior to the nerve and inferior to the inferior thyroid artery. It is also necessary to fully evaluate the thyroid capsule as the parathyroid gland may be located underneath.

Once the abnormal parathyroid gland is identified, it should be carefully dissected, taking care to avoid rupture of the capsule because this may lead to spillage and implantation, resulting in parathyromatosis. Once the gland is excised, it should be confirmed to be parathyroid tissue. This can be done with visual inspection accompanied by an appropriate decrease in IOPTH levels, intraoperative frozen section, or ex vivo operation with IOPTH level, as described above. Serum IOPTH levels are assessed immediately after excision of the

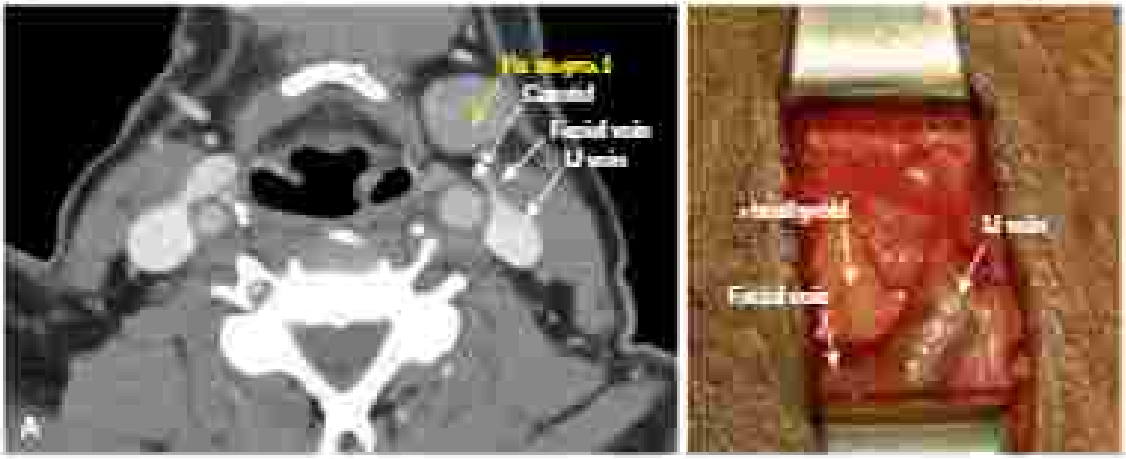

FIG. 7 Ectopic parathyroid adenoma located in the carotid sheath adjacent to the facial vein. (A) Four-dimensional computed tomography scan demonstrating an ectopic parathyroid adenoma located in the carotid sheath adjacent to the facial vein (F). (B) Operative view of the same patient with the ectopic parathyroid identified between the internal jugular and facial veins. J, Internal jugular.

abnormal gland (three now) and again 5 and 10 minutes after excision. The probability of cure is estimated using the protocol the surgeon is most familiar with as discussed above. Once the gland is excised and while awaiting IOPTH results, hemostasis is ensured. Any normal parathyroid glands identified during exploration are inspected for viability, and the anatomic integrity of the recurrent laryngeal nerve, if exposed, is verified. Hemostatic agents may be placed in the wound bed. The operation concludes with reapproximating the strap muscles and platysma using absorbable 3-0 suture. The skin is closed using a cosmetic technique the surgeon is most comfortable with.

Conversion from MIP to bilateral exploration is recommended when evidence of multigland disease is found, when an abnormal parathyroid cannot be found, or if there is failure of the IOPTH levels to drop appropriately per the surgeon's designated protocol, as discussed previously.

Bilateral Neck Exploration

Bilateral neck exploration may be the initial operative intervention planned when preoperative studies are discordant or nondiagnostic, if IOPTH monitoring is unavailable, when there is a high suspicion of multigland disease such as familial hyperparathyroidism, or by surgeon preference. As discussed previously, surgeon familiarity with parathyroid embryology and anatomy is critical for successful surgery. If bilateral exploration is performed for localized disease, it is recommended to identify this gland first. If performed for nonlocalized disease, initial dissection can be started on either side. During bilateral neck exploration, all four parathyroid glands should be identified before resection of any tissue. Normal parathyroid glands are typically 20 to 40 mg. They are soft and often associated with fat. These glands should be carefully preserved. If a single parathyroid adenoma is identified, it is resected, and the remaining normal parathyroid glands left in situ. If IOPTH is available, it can be used for confirmation of visual findings but is not mandatory when all glands are identified. If multiple abnormal parathyroid glands are identified subtotal parathyroidectomy is performed. Again only abnormal parathyroid glands should be excised, such as in the case of a double adenoma. In this situation IOPTH can be especially useful to confirm visual findings of this less frequently encountered pathology.

When tissue gland hyperplasia is present, a subtotal (3.5-gland) parathyroidectomy is generally the preferred approach. Leaving the remaining parathyroid tissue in situ improves parathyroid viability, decreases the risk of permanent hypoparathyroidism and avoids the need to wait for autotransplanted parathyroid tissue to function, as this may take 6 to 8 weeks or longer. The choice of which parathyroid to leave should be decided early to ensure remnant viability. The gland to be divided should be the most normal appearing and, ideally, be easily accessible in case reoperation is needed for recurrent disease. The volume of parathyroid gland being left in situ should approximate one to two times the volume of a normal parathyroid gland. Division can be performed by placing a large titanium hemoclip across the gland and then dividing distally. A permanent suture may be left on the remnant with long tails to facilitate easy identification if recurrent disease or reoperative neck surgery is necessary in the future.

In rare cases when a total parathyroidectomy is performed, autotransplantation of parathyroid tissue is required to avoid leaving the patient with permanent hypoparathyroidism. When performing a total parathyroidectomy with autotransplantation, the parathyroid tissue to be transplanted may be placed into the nondominant brachioradialis muscle rather than the sternocleidomastoid muscle. This avoids complications of reoperative neck surgery in the case of recurrent disease. Autotransplantation is performed by harvesting a volume of parathyroid tissue approximately equivalent to that of a normal parathyroid gland from the most normal-appearing gland resected. This tissue then is minced sharply into 1 mm fragments. The nondominant brachioradialis muscle then is exposed, and three or four pockets are made in the muscle bluntly using blunt dissection. Equal volumes of the prepared parathyroid are placed into each respective muscle pocket. The pockets are closed with nonabsorbable suture with the ends left long to facilitate future operative localization, if necessary. A hemoclip may be placed on each suture to allow subsequent radiographic localization.

If available, use of IOPTH monitoring should be considered during bilateral exploration because this may help confirm visualized findings, as well as aid in recognition of supernumerary parathyroid glands. It can also help with the decision for autotransplantation. If the IOPTH drops to values below normal range after a 3.5-gland subtotal parathyroidectomy, autotransplantation may be a consideration to avoid permanent hypoparathyroidism. Similarly, if IOPTH levels remain marginally elevated after subtotal parathyroidectomy, consideration can be given to additional resection of the remnant gland.

When no abnormal parathyroid glands are identified during bilateral exploration, thorough evaluation of ectopic locations should be performed. This includes thorough evaluation of the tracheoesophageal groove and retroesophageal space, opening the carotid sheath, and consideration of a cervical thymectomy or rarely ipsilateral thyroid lobectomy. Bilateral internal jugular sampling, as described above, may be helpful. If an abnormal parathyroid is not identified, normal parathyroid glands should be left in situ. Terminating at the time of initial surgery without preoperative consent is not recommended. We highly recommend calling in a colleague to take a look because two pairs of eyes are better than one.

Parathyroid Carcinoma

Parathyroid carcinoma is a rare cause of PHPT (approximately 1% of cases), and surgical resection remains the only curative option. This is best accomplished at the index operation. Before surgery, parathyroid carcinoma may be suggested by very high PTH and calcium levels. During surgery, parathyroid carcinoma should be suspected if the parathyroid appears white or gray and is firm, hypervascular, and densely adherent to surrounding structures.

These findings should prompt en bloc resection of surrounding structures to avoid damaging the tumor capsule because this can result in implantation of spilled tumor cells and incurable parathyromatosis. Resection may need to include thyroid tissue, muscle, strap, or the recurrent laryngeal nerve. However, radical resection of uninvolved tissue is unnecessary and results in increased morbidity and mortality rates. Prophylactic lymph node dissection is not recommended. In a recent study, only 6.9% of patients had lymph node metastases, and a second study demonstrated that lymph node status was not associated with disease-specific survival.

Immediate Postoperative Care

Patients should be monitored for postoperative complications, including hematoma and hypocalcemia. Postoperative supplementation with calcium or vitamin D should be considered. We use the following algorithm (Fig. 9). Signs and symptoms of hypocalcemia are paresthesias (usually perioral or involving the distal extremities), as well as muscle spasms. These symptoms can usually be managed with oral calcium and calcitriol. Severe hypocalcemia may present with tetany and seizures and require intravenous calcium gluconate supplementation. Outpatient parathyroidectomy may be performed in specific circumstances. However, an overnight stay may be appropriate in the setting of extensive dissection, subtotal parathyroidectomy, patients with social issues, or significant vitamin D deficiency.

Operative Complications Postoperative Outcomes

The primary complications associated with parathyroidectomy are recurrent laryngeal nerve injury and hypoparathyroidism. The overall complication rate is approximately 4% for bilateral neck exploration and between 1% and 3% for MIP. If transection of the recurrent laryngeal nerve is identified during surgery, a reinnervation

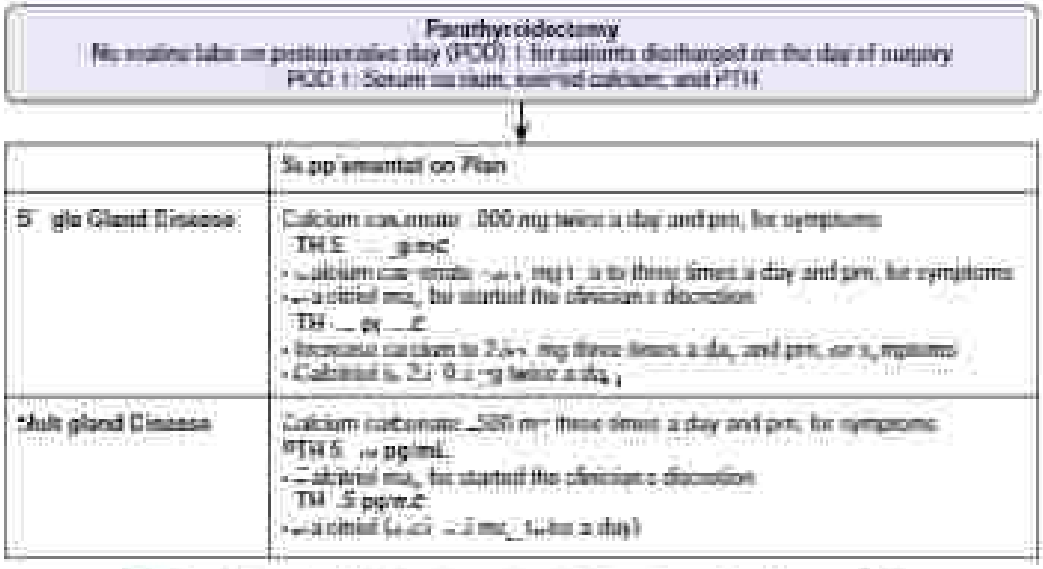

FIG. [illegible] serum and calcium supplementation algorithm after parathyroidectomy (PTX).

procedure should be attempted at that time. Temporary hypoparathyroidism is common after parathyroidectomy because the function of the remaining normal parathyroid tissue has been suppressed and often requires several days to regain function. Permanent hypoparathyroidism is rare and occurs when all parathyroid tissue is resected, inadvertently damaged, or if autotransplantation is unsuccessful.

After surgery, serum calcium and PTH levels should be checked 1 to 2 weeks after surgery to establish postoperative baseline levels and allow for weaning of any supplemental calcium, if appropriate. If serum calcium levels are normal after surgery but PTH levels are elevated, this is likely due to secondary hyperparathyroidism from vitamin D deficiency and will normalize with oral vitamin D supplementation. Prior studies have demonstrated that elevated PTH levels with normal calcium levels after parathyroidectomy are not associated with an increased risk of recurrence.

Surgical cure, defined as normal calcium homeostasis 6 months after parathyroidectomy, is achieved in greater than 95% of cases when bilateral exploration is required, with comparable results among patients undergoing MEP (cure rates as high as 98%). Approximately 2% of patients develop recurrent PHPT after initially curative surgery. Therefore blood testing should be repeated 6 months after surgery and then yearly. Long-term follow up by a multidisciplinary team including the surgeon is critical after parathyroidectomy. This ensures that surgeons are aware of their postoperative outcomes including rate of cure, permanent hypoparathyroidism, or persistent recurrent laryngeal nerve paralysis.

[illegible] Guidelines for the definitive management of PHPT. JAMA Surg. 2014;149(10):1013–1020.

Evaluation and Management of Persistent or Recurrent Primary Hyperparathyroidism

[illegible]

Remedial (revision, redo, reoperative) surgery for primary hyperparathyroidism (PHPT) has posed significant challenges that can be traced to the first cases in Austria and the United States. The earlier successful operation was performed by Felix Mandl in Vienna in 1925 for the street car conductor, Albert Ishmo, whose initial surgical cure was followed by recurrent disease, failed remedial surgery, and disease related death. In the United States, the merchant seaman Captain Charles Mansell underwent six unsuccessful explorations until his ectopic mediastinal parathyroid adenoma was resected at the Massachusetts General Hospital. In spite of a well performed operation, he died after surgery due to profound hypocalcemia and osteopenia resulting from retained nephrolithiasis. These tales cautionary illustrate the conundrums and dangers associated with remedial parathyroid surgery. Fig. 1 demonstrates the locations of ectopic and the most common ectopic sites of abnormal parathyroid glands in remedial cases and their relationship to the recurrent laryngeal nerves.

In this chapter I have summarized more than 30 years of experience based on the largest series of remedial parathyroid explorations. Persistent PHPT is defined by either (1) the absence of cure after an operation for PHPT or (2) apparent cure, followed by biochemical recurrence within 6 months. Recurrent PHPT is defined by an initial biochemical cure for at least 6 months, followed by recurrence

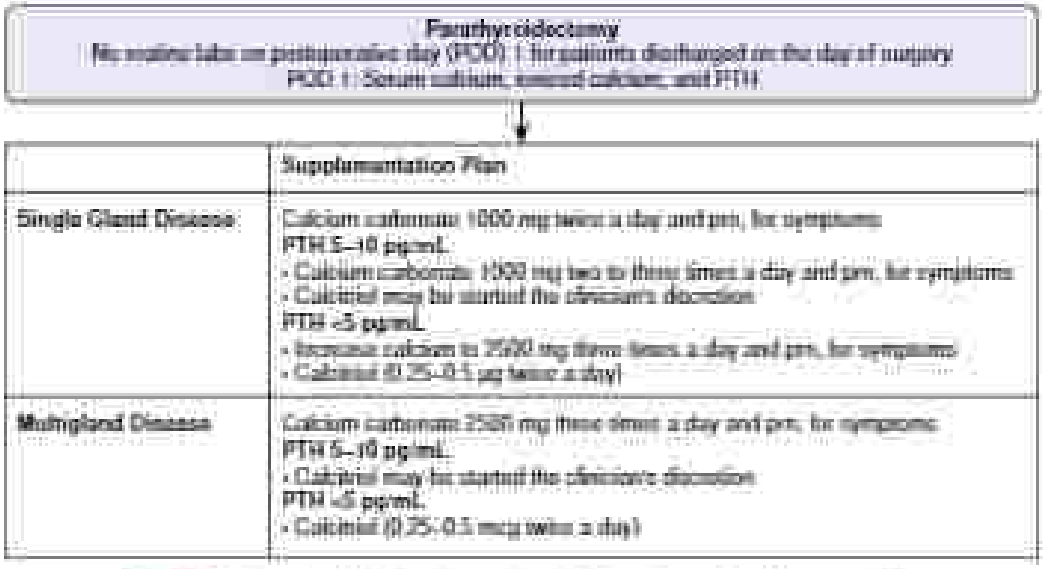

FIG. 4 Calcium and calcitriol supplementation algorithm after parathyroidectomy (PTH).

procedure should be attempted at that time. Temporary hypoparathyroidism is common after parathyroidectomy because the function of the remaining normal parathyroid tissue has been suppressed and often requires several days to regain function. Permanent hypoparathyroidism is rare and occurs when all parathyroid tissue is resected, inadvertently damaged, or if autotransplantation is unsuccessful.

After surgery, serum calcium and PTH levels should be checked 1 to 2 weeks after surgery to establish postoperative baseline levels and allow for weaning of any supplemental calcium, if appropriate. If serum calcium levels are normal after surgery but PTH levels are elevated, this is likely due to secondary hyperparathyroidism from vitamin D deficiency and will normalize with oral vitamin D supplementation. Prior studies have demonstrated that elevated PTH levels with normal calcium levels after parathyroidectomy are not associated with an increased risk of recurrence.

Surgical cure, defined as normal calcium homeostasis 6 months after parathyroidectomy, is achieved in greater than 95% of cases when bilateral exploration is required, with comparable results among patients undergoing MIP (cure rates as high as 98%). Approximately 2% of patients develop recurrent PHPT after initially curative surgery. Therefore blood testing should be repeated 6 months after surgery and then yearly. Long-term follow up by a multidisciplinary team including the surgeon is critical after parathyroidectomy. This ensures that surgeons are aware of their postoperative outcomes including rate of cure, permanent hypoparathyroidism, or persistent recurrent laryngeal nerve paralysis.

Evaluation and Management of Persistent or Recurrent Primary Hyperparathyroidism

Robert Udelsman, MD, MBA, FACS, FACE

Remedial operation, redo, reoperative surgery for primary hyperparathyroidism (PHPT) has posed significant challenges that can be traced to the first cases in Austria and the United States. The earliest successful operation was performed by Felix Mandl in Vienna in 1925 for the renal calculi disorder, Albers-Schönberg disease. Mandl's initial surgical cure was followed by recurrent disease, failed remedial surgery, and disease-related death. In the United States, the merchant seaman Captain Charles Mansell underwent six unsuccessful explorations until his ectopic mediastinal parathyroid adenoma was resected at the Massachusetts General Hospital. In spite of a well performed operation, he died after surgery due to profound hypocalcemia and osteopenia resulting from retained nephrolithiasis. These twelve cases illustrate the conundrums and dangers associated with remedial parathyroid surgery. Fig. 1 demonstrates the locations of ectopic and the most common ectopic sites of abnormal parathyroid glands in remedial cases and their relationship to the recurrent laryngeal nerves.

In this chapter I have summarized more than 30 years of experience based on the largest series of remedial parathyroid explorations. *Persistent PHPT* is defined by either (1) the absence of cure after an operation for PHPT or (2) apparent cure, followed by biochemical recurrence within 6 months. *Recurrent PHPT* is defined by an initial biochemical cure for at least 6 months, followed by recurrence.

FIG. 1 Location of ectopic (yellow) and ectopic (red) parathyroid tissue and their relationship to the recurrent laryngeal nerves (yellow). (From Wilhelmi SJ, Lee AK, Rosenthal RJ, et al. Evaluation and management of persistent and recurrent primary hyperparathyroidism: a practical approach to optimizing success and minimizing complications. *Ann Surg Oncol*. 2010;17:1–11.)

Although this interval is arbitrary, it distinguishes what in most cases is either an inadequate initial operation (persistent PHPT) from an adequate operation followed by progression of the underlying disease (recurrent PHPT).

DIFFICULTY OF REMEDIAL EXPLORATION

Reoperative parathyroid surgery is inherently more difficult for the following three reasons: (1) Reoperative neck and mediastinal anatomy is often distorted and fibrotic, resulting in disruption of normal tissue planes making identification and protection of critical structures including the recurrent laryngeal nerves and normal parathyroid glands difficult. (2) Critical information gleaned from previous operative and pathology reports is often insufficient, inaccurate, and occasionally misleading. (3) Alleged visualization of a normal parathyroid gland cannot be assumed to be accurate in the absence of histologic confirmation. (4) Even an experienced surgeon can inadvertently compromise the end artery blood supply to a normal parathyroid gland left in situ. (5) An inexperienced surgeon may misidentify upper and lower parathyroid glands, thereby contributing subsequent exploration. (6) Mislabeling of specimens, especially during prolonged exploration, is not infrequent. (7) Although pathologists can distinguish an enlarged from a normal parathyroid gland, they cannot accurately discriminate between a hyperplastic and an adenomatous parathyroid gland. (8) Preoperative localization in remedial cases is compromised due to scarring, altered revascularization, and anatomic distortion. (9) Underlying thyroid disease, such as nodular goiter or Hashimoto's thyroiditis, undermines imaging and exploration. The cumulative effects of these compromises result in decreased cure and increased complication rates in the remedial neck.

REMEDIAL NECK/MEDIASTINUM

Patients who have undergone previous parathyroid or thyroid surgery are defined as remedial cases. However, nonendocrine cervical or mediastinal procedures also pose similar challenges. These include patients who have undergone anterior cervical spinal procedures, carotid endarterectomy, transcervical thymectomy, and, in select cases, median sternotomy.

TEAM APPROACH

Patients with persistent or recurrent PHPT should be managed by an experienced team in an institution with sophisticated resources. The team includes endocrinologists, parathyroid surgeons, imaging experts, and pathologists. Furthermore, every patient with persistent or recurrent PHPT does not require exploration. Patients with mild asymptomatic disease, especially those with a limited lifespan, can be managed without surgery with or without a calcimimetic agent. Although there are no published guidelines defining indications for remedial parathyroid exploration, it is logical that the threshold for remedial surgery should be higher than for de novo cases. Accordingly, it is strongly recommended that all remedial cases be referred to an experienced team for evaluation and treatment recommendations.

CONFIRM THE DIAGNOSIS

It is critical to confirm the diagnosis in every patient who presents with persistent or recurrent PHPT. A subset may not have PHPT or have familial hypocalciuric hypercalcemia (FHH) and may not require intervention. Other causes of elevations of both serum parathyroid hormone (PTH) and calcium levels must be considered. These include mild secondary hyperparathyroidism due to renal insufficiency, gastrointestinal malabsorption, or vitamin D deficiency. In addition, a variety of medications, including lithium and thiazide diuretics, alter calcium metabolism and may either interfere with establishing a diagnosis of PHPT (thiazides) or contribute to or cause the disease (lithium).

FAMILY HISTORY

It is critical to obtain and consider the family history in all patients. Table 1 summarizes familial hyperparathyroid disorders, genetic characteristics, presentation, and associated features. Patients with FHH are generally symptom free and rarely benefit from surgical intervention. Patients with MEN1 usually present with PHPT before age 30 and are likely to develop recurrent disease. Patients with MEN2A generally present with medullary carcinoma of the thyroid. Their parathyroid disease, when present, is usually mild and managed by removing only enlarged parathyroid glands during resection of their thyroid cancer. However, it is critical to rule out pheochromocytoma before surgical exploration. Explorations for PHPT in patients with MEN1 are guided by the concept that every parathyroid cell is genetically abnormal and therefore prone to recurrence. In effect, the surgeon should debulk the parathyroid disease and either leave a single remnant or transplant viable parathyroid tissue to ease management of recurrent disease. The other genetic conditions listed in Table 1 are rare; however, the autosomal dominant inheritance pattern results in 50% of male and female patients inheriting the syndrome. It is also important to obtain genetic counseling for these individuals.

REVIEW ALL AVAILABLE DATA AND EXAMINE THE PATIENT

Planning intervention for remedial parathyroid exploration is an exercise in investigation, imaging, and hypothesis generation. The initial step requires a carefully performed history and physical examination, including detailed review of previous operative notes, illustrations, pathology reports, and imaging studies. The physical examination will confirm the site of previous exploration and include a general assessment of the patient. Laryngoscopy by either indirect mirror examination or with a flexible nasopharyngoscope is essential to rule out or evaluate the extent of vocal cord dysfunction due to previous laryngeal nerve injury. This is critical because patients with complete unilateral vocal cord paralysis can have a normal voice, and subsequent injury to the contralateral recurrent laryngeal nerve would be devastating.

TABLE 1 Familial Hyperparathyroid Disorders, Genetic Characteristics, Presentation of Primary Hyperparathyroidism (PHPT), and Associated Features

Disorder	Inheritance	Responsible Gene	Chromosomal Location	PHPT	Associated Tumors
MEN1	AD	*MEN1*	11q13	High penetrance (approximately 90%); multiglandular	Pituitary, EPT
MEN2A	AD	*RET*	10q21	Low penetrance (approximately 20%); multiglandular/adenoma	MTC, pheochromocytoma
HPT-JT	AD	*HRPT2*	1q21-q32	Cystic parathyroid tumors; 15% risk of carcinoma	ossifying fibroma, renal lesions
FIHPT	AD	*HRPT2*	1q21-q32	Adenoma/multiglandular	
	AD	*MEN1*	11q13	Adenoma/multiglandular	
	AD			Adenoma/multiglandular	
ADMH	AD	*CDC73*	1q13.2-21	Multiglandular/adenoma

IS REMEDIAL INTERVENTION APPROPIATE?

Patients present with a wide range of symptoms and signs, including those who are symptom free, with minimal elevations of serum PTH and calcium levels or those with life-threatening hypercalcemic crisis. In addition, the anticipated difficulty of remedial exploration for what is likely a single missed parathyroid adenoma varies widely from patients who present for a first or six time reexploration for parathyroid remnants or parathyroid carcinoma. Critical judgment is required to balance the probability of success and morbidity with the probable benefit and lifespan. Once the decision has been made for surgical intervention, imaging is always indicated and critical for operative planning.

PREOPERATIVE LOCALIZATION

Several localization studies are available; however, their quality is highly dependent on the equipment used and the commitment and skills of the imaging team. In general, normal parathyroid glands cannot be visualized on imaging studies. Furthermore, all imaging is more sensitive in patients with single versus multigland disease. Ultrasound examination of the neck is often the first study obtained because it is readily available, avoids ionizing radiation and is relatively inexpensive. It is highly dependent on the skills of the imager. It can provide exquisite detail and demonstrate a hypoechoic nodule in the neck in both eutopic and ectopic locations (Fig. 2). Because ultrasonography cannot penetrate the sternum or clavicles and is compromised in patients with multinodular goiters, Hashimoto's thyroiditis, obesity, or retroesophageal parathyroid glands, its limitations must be recognized.

Technetium-99m sestamibi scanning using single photon emission computed tomography is also a first-line imaging study. Unlike ultrasonography, enhanced sestamibi uptake is due to the increased mitochondrial content seen in adenomatous or hyperplastic parathyroid glands. The scans can detect ectopic parathyroid glands in the neck and mediastinum (Fig. 3). The quality of the scans is extraordinarily variable depending on the institution where they are performed.

Four-dimensional CT scans (4D CT) have emerged as a sensitive and at times invaluable study. The fourth dimension is time and is obtained by multiple runs with intravenous (IV) contrast (Fig. 4). This

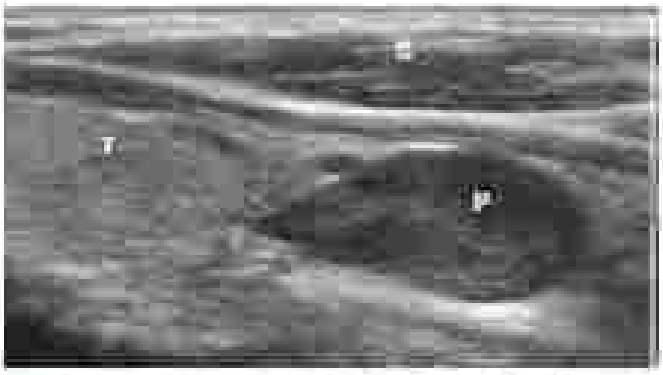

FIG. 2 Ultrasound demonstration of a left lower parathyroid adenoma as a hypoechoic ovoid mass (*P*) lateral to the thyroid lobe (T) and posterior to the overlying strap muscles (S).

FIG. 3 Technetium-99m sestamibi scan demonstrating a mediastinal parathyroid adenoma in a patient who had undergone previous coronary artery bypass grafting. In this case, the left internal mammary artery graft to the left anterior descending coronary artery draped over the parathyroid adenoma. Physiologic sestamibi uptake is seen in the salivary glands.

study is often positive when ultrasonography and sestamibi fail but exposes the patient to moderate amounts of ionizing radiation and IV contrast. In several institutions 4-D CT scanning has emerged as a first-line imaging study. Although MRI scans have been reported to be useful, they are inferior compared to 4D CT scans and rarely used except in pregnant patients who cannot be exposed to ionizing radiation.

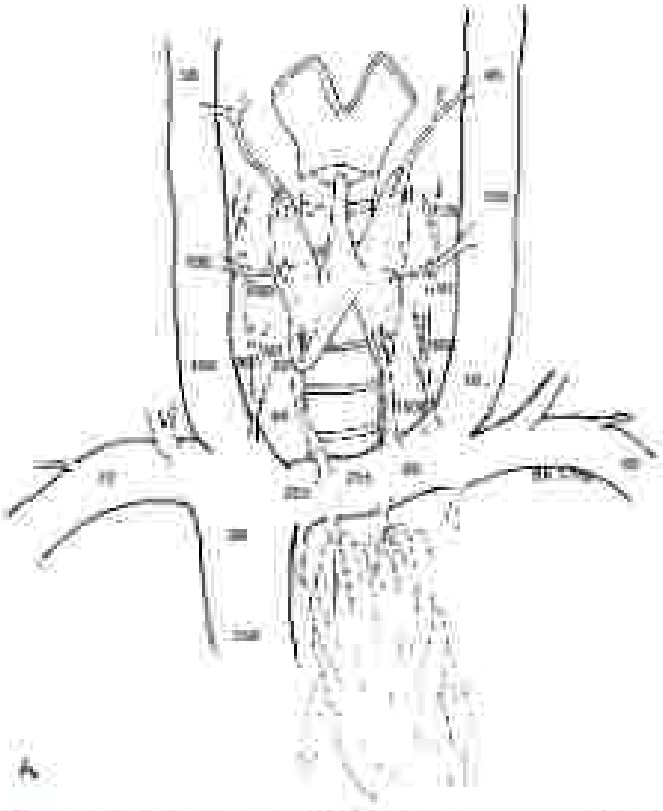
FIG. 4 Four-dimensional CT scan demonstrating a persistent parathyroid adenoma (arrow) in the left carotid sheath directly posterior to the common carotid artery (C).

If the results of the above noninvasive imaging studies are negative, discordant, or noncontributing, invasive imaging should be considered. Invasive imaging procedures are never indicated to de novo (unexplored) patients due to their risks and expense. The easiest is ultrasound-guided aspiration of a putative enlarged parathyroid gland. This is a relatively simple outpatient procedure. It is essential to aspirate the ultrasound-identified lesion and measure PTH levels because cytology alone may fail to discriminate a parathyroid gland from a thyroid nodule. This procedure must be organized with the clinical pathologists who analyze PTH to be certain that the collection conditions are optimized.

Parathyroid localization with arteriography and venous localization is the most sensitive and expensive of the localization studies. It should only be performed by experienced angiographers, and multiple venous samples are required from the neck and mediastinum. Access is usually obtained via the femoral vessels. The utility of this study is enhanced by on-site PTH analyses because data obtained in near real time informs the radiologists whether they have a subtle but not diagnostic PTH gradient, thereby directing them to obtain superselective samples from small blood vessels as shown in Fig. 5A. The corresponding operative photograph demonstrated a carotid sheath parathyroid adenoma (Fig. 5B). In addition, demonstration of an inappropriately positive gradient allows termination of the study. In the rare patient in whom imaging fails to identify a candidate lesion, it is better to delay surgery if possible until imaging is positive.

FORMULATE A WORKING HYPOTHESIS

Based on the cumulative information, the surgeon should formulate a literally working hypothesis. (1) Is it likely that the patient has single-site recurrence? (2) Are both recurrent nerves functional? (3) Is the



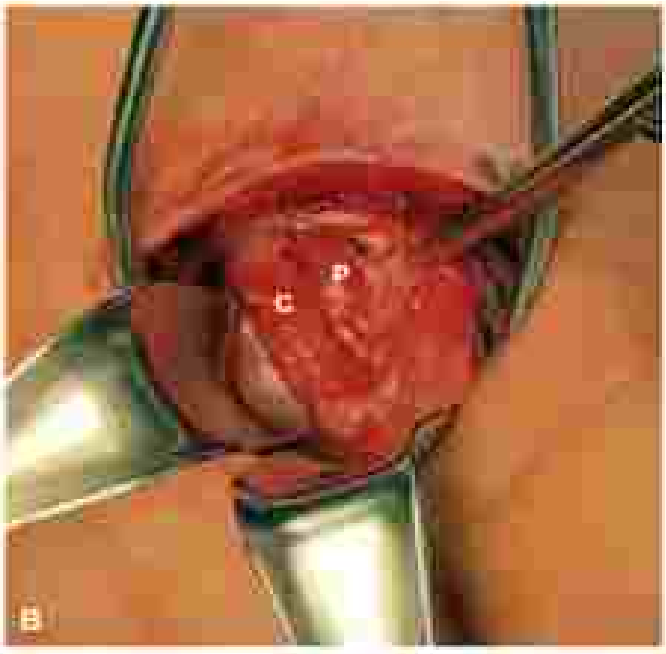


FIG. 5 (A) Selective venous sampling with on-site PTH measurement in a patient with multiple failed parathyroid explorations. The two samples obtained in the left inferior posterior neck (1,649 pg/mL and 1,276 pg/mL) are 12 times greater than the other samples, demonstrating near lateralization. (B) Operative image from the patient demonstrating an ectopic parathyroid adenoma (P) medial and posterior to the common carotid artery (C).

TABLE 2 Differential Diagnosis of Persistent or Recurrent Primary Hyperparathyroidism

Missed adenoma	40%
Inadequate resection for parathyroid hyperplasia	20%
Recurrent disease in a subtotal resection site	18%
Parathromatosis	12%
Parathyroid carcinoma	5%

FIG. 6 Video-assisted anterolateral operative finding in a patient with metastatic parathyroid carcinoma implanted on the parietal pleura next to the lung. Innumerable metastatic implants precluded curative resection.

imaging reasonably convincing? (4) Does the site of recurrence likely represent the only residual parathyroid tissue? (5) If all the imaging is noncontributing, should the surgeon proceed with exploration?

DIFFERENTIAL DIAGNOSIS OF PERSISTENT OR RECURRENT PHPT

The differential diagnosis of persistent or recurrent PHPT and their relative frequencies are listed in Table 2. Most are due to inadequate initial surgery where the surgeon was unable to identify a single parathyroid adenoma. However, it is not uncommon for a surgeon to fail to appreciate subtle asymmetric parathyroid hyperplasia and perform an inadequate resection.

In patients who have recurrent disease after undergoing a successful subtotal resection, the most likely site of recurrence is at the subtotal site because the residual abnormal parathyroid tissue has grown to the point that it causes recurrent disease. Other rare causes of recurrent disease are parathromatosis where an abnormal parathyroid gland had been ruptured during resection and multiple recurrent nodules of benign implanted parathyroid tissue have grown in soft tissues. Finally, parathyroid carcinoma recurrence usually presents at the site of previous resection. However, distant sites of metastasis can also occur as shown in Fig. 6.

LOCATIONS OF PATHOLOGIC PARATHYROID GLANDS IN THE REOPERATIVE NECK AND MEDIASTINUM

Surgeons who undertake parathyroid surgery must have a clear understanding of the anatomy and embryology of the parathyroid glands. The anatomic locations of persistent or recurrent PHPT are demonstrated in Fig. 7. The vast majority are in the neck and can be resected by cervical exploration. Most mediastinal sites can also be

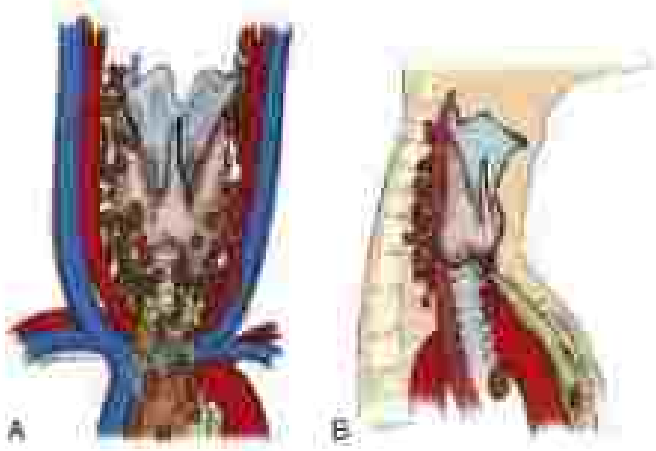

FIG. 7 Sites of persistent or recurrent parathyroid glands in the neck and mediastinum seen on anteroposterior (A) and lateral (B) views. The vast majority are located in the neck, and the retroesophageal space is a frequent site of disease. (From Udelsman R, Donovan PI. Essentials of parathyroid surgery: imaging and localization. In: Cameron JL, ed. Current Surgical Therapy. 10th ed. Philadelphia: Elsevier Saunders; 2011:722–726.)

approached by a cervical approach. However, a rare ectopic mediastinal parathyroid, such as those in the aortopulmonary window may require a partial sternotomy, a complete sternotomy, a Chamberlain procedure, or a transthoracic endoscopic approach. Other ectopic sites include retroesophageal, intrathymic, intrathyroidal, carotid sheath, retromandibular, and intravascular locations.

SURGICAL EXPLORATION

Once the surgeon has verified the diagnosis and the team has agreed to proceed to exploration, a preoperative working hypothesis should be generated, and, in the best of circumstances, a single enlarged parathyroid gland has been localized. A fundamental concept in remedial cases is to do as little exploration as required, but as much as necessary to achieve a durable cure. Ideally a unilateral cervical approach will be successful; however, bilateral exploration may be necessary, and supplementary techniques and adjuncts are essential.

OPERATIVE AJUNCTS

Intraoperative PTH Assay

Intraoperative PTH analysis requires a rapid PTH assay in proximity to the operating room and is a critical adjunct for initial and especially reoperative parathyroid surgery. The assay will demonstrate a physiologic clearance curve of elevated circulating PTH once all hypersecreting parathyroid tissue has been removed. By confirming cure with a high degree of confidence, the surgeon can terminate the operation and obviate unnecessary exploration, thereby protecting critical structures. The assay can also be used to analyze excised tissue by an ex vivo aspiration and prove whether it is of parathyroid origin, thereby rendering intraoperative frozen section analysis obsolete. Finally, in rare cases, the assay can analyze intraoperative bilateral internal jugular vein samples obtained in the inferior neck, which may demonstrate an ipsilateral gradient suggesting a pathologic hypersecreting parathyroid gland upstream.

Other Adjuncts

A variety of other adjuncts have been proposed and abandoned by most experienced parathyroid surgeons. These include the following: (1) Intraoperative ultrasonography because it adds little incremental information compared to a well performed preoperative study. (2) Intraoperative neural monitoring of recurrent nerve function,

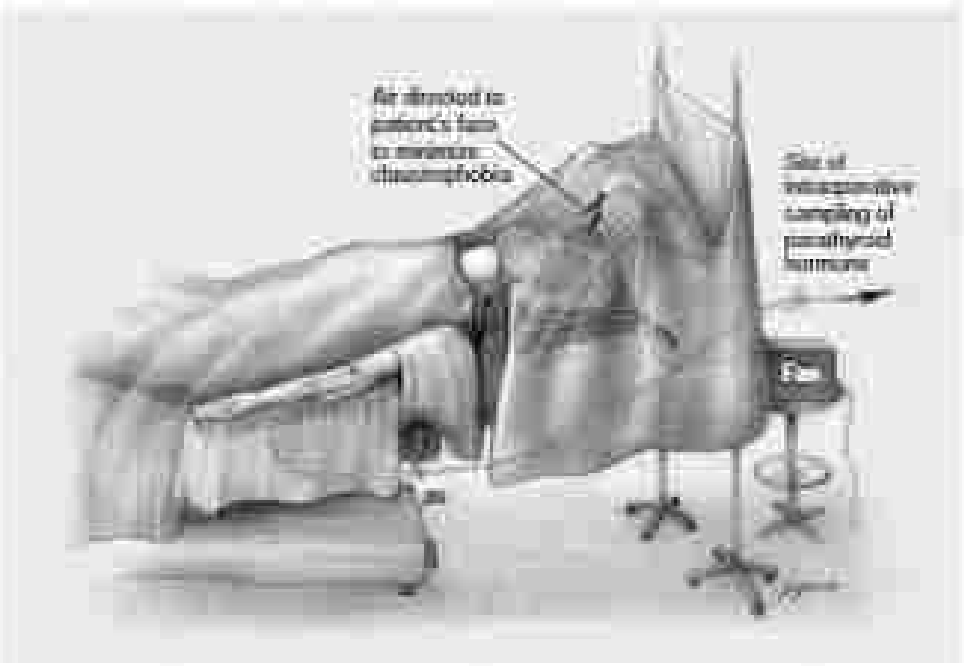

FIG. 8 Operative setup for an awake minimally invasive parathyroidectomy including peripheral intravenous sampling of parathyroid hormone. [illegible] (Adapted from [illegible] Surgery [illegible] Wilkins, 2012.)

because well performed prospective studies, mainly in thyroid surgery, failed to demonstrate improved outcomes with regard to postoperative recurrent nerve function. (3) Use of an intraoperative gamma probe after IV administration of technetium labeled sestamibi because it yields little incremental information compared to a well performed preoperative study. In addition, it does not replace the utility of intraoperative PTH analysis.

OPERATIVE APPROACHES

Many operative approaches are available, ranging from an awake minimally invasive neck parathyroidectomy to bilateral cervical exploration under general anesthesia with or without mediastinal exploration. The selection of approach is highly dependent on the location of the index lesion(s) and the experience of the surgeon. In general, the least invasive approach is preferred guided by preoperative imaging.

Minimally Invasive Approach

A minimally invasive neck parathyroidectomy is appropriate in patients with persistent or recurrent PHPT who appear to have single site disease demonstrated on preoperative imaging studies. This procedure can be performed with the patient under local or superficial cervical block anesthesia in combination with monitored anesthesia with supplemental IV sedation as shown in Fig. 8. An advantage of operating on an awake patient is the opportunity to serially examine the patient's voice during exploration to confirm functional integrity of the recurrent laryngeal nerves. The intraoperative rapid PTH assay is required to optimize this procedure. The approach can be extended to include bilateral exploration and, if necessary, converted to general anesthesia.

Lateral Approach

The lateral approach can be accomplished during a minimally invasive parathyroidectomy because a superficial cervical block results in excellent analgesia. The lateral approach, demonstrated in Fig. 9, is particularly attractive for intraesophageal or other posterior parathyroid glands because it allows for early exposure into the carotid sheath and avoids adhesions associated with the more common anterior approach. It expedites early recurrent laryngeal nerve identification and can also be performed with the patient under general anesthesia.

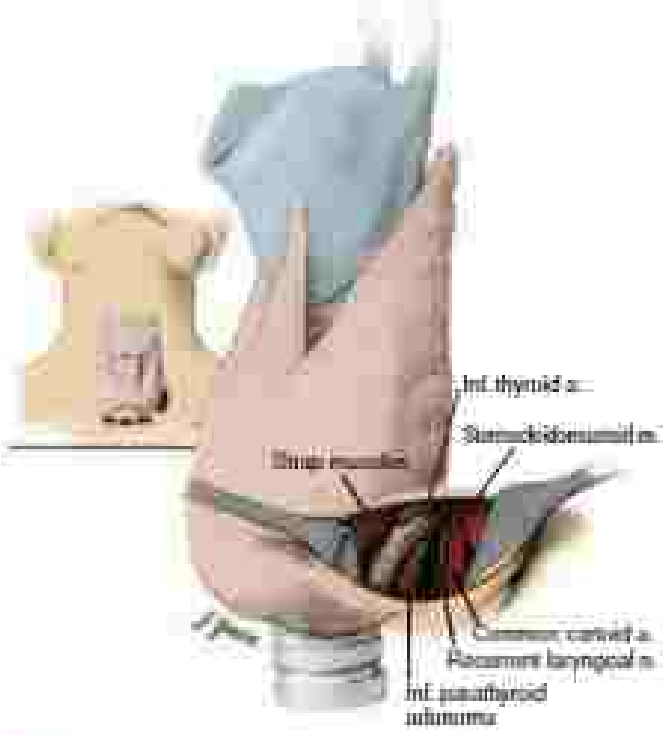

FIG. 9 Lateral approach for cervical exploration in primary hyperparathyroidism. The plane between the strap and sternocleidomastoid muscles is opened using the previous Kocher incision. This facilitates posterior access and avoidance of scar tissue. (Adapted from [illegible] Surgery of primary hyperparathyroidism. In: [illegible] 2012.)

Difficult Exploration

Remedial parathyroid surgery requires flexibility. Imaging is often inaccurate or misleading because it is common to encounter lymph nodes or thyroid nodules that appear consistent with enlarged parathyroid glands on one or more imaging studies. At times, remedial

FIG. 18 Parathyroid autografting technique to the brachioradialis muscle. (From Udelsman R. Secondary hyperparathyroidism. Operative techniques in General Surgery. 1999;1:68.)

exploration becomes an exercise in exploration of autopsy and exhaustion. The most important concept is to avoid creating a lifelong complication by resecting the only residual parathyroid tissue because it is far better to live with mild chronic PHPT than to render a patient aparathyroid. Accordingly, the surgeon must know how to perform a subtotal resection of parathyroid tissue, leaving a well-vascularized remnant of viable parathyroid tissue weighing 20 to 40 mg. In some cases, heterotopic autotransplantation of parathyroid tissue, preferably in the nondominant brachioradialis muscle, will be required (Fig. 18).

An array of other techniques is occasionally required for difficult cases. These include bilateral internal jugular vein sampling for a unilateral PTH gradient, thymic lobectomy based on the presumed location of a missing parathyroid gland, carotid sheath exploration, cervical thymectomy, and extensive retroesophageal explorations. In rare cases, ipsilateral ligation of the inferior thyroid artery can result in infarction of the culprit occult parathyroid adenoma. However, this is only done when the ipsilateral thyroid lobe has been excised.

Mediastinal Exploration

The vast majority of mediastinal parathyroid gland excisions can be performed by a well-trained parathyroid surgeon via a transcervical approach. There are typically performed for intrathymic and intrathoracic retroesophageal parathyroid adenomas. A rare patient will require a transthoracic approach and a variety of options including video-assisted thoracoscopic, transsternal, or anterior mediastinotomy (Chamberlain procedure) are usually performed by a thoracic surgeon. A blind median sternotomy in the absence of a positive imaging study is not recommended.

COMPLICATIONS OF SURGERY

Complications associated with redo parathyroid surgery are rare but higher than those associated with de novo cases. These include recurrent or superior laryngeal nerve injury, pneumothorax, bleeding, infection, internal jugular vein injury and esophageal injury. The overall complication rates in the best series range from 1% to 3%. Neurological complications such as urinary bladder distention, deep venous thrombosis, and cardiac complications are also uncommon.

The risks of permanent hypoparathyroidism should always be considered during remedial cervical exploration. Patients who have undergone previous explorations, especially when one or more parathyroid glands were excised, are at higher risk. Furthermore, any patient who has had a previous cervical exploration may have had the blood supply to one or more parathyroid glands compromised. Accordingly, it is possible that, by removing a single abnormal gland in the redo setting, the surgeon is excising the only residual functional parathyroid tissue. This can have devastating long-term consequences because patients who are aparathyroid are difficult to manage. Therefore during remedial exploration the surgeon should use an intraoperative PTH assay because the clearance of PTH can help the surgeon determine whether there appears to be sufficient residual postresection parathyroid function. It may be necessary to autotransplant parathyroid tissue to a heterotopic site, preferably the nondominant brachioradialis muscle. It is also important to recognize that, if parathyroid autotransplantation is anticipated, the parathyroid tissue must be maintained viable and harvested as long as possible because warm ischemia time should be minimized, and excised parathyroid tissue should be held in a saline solution in a container immersed in an ice slurry. Parathyroid autotransplantation is demonstrated in Fig. 18.

NONOPERATIVE APPROACHES

Nonoperative techniques have been described to ablate hypersecreting parathyroid tissue. They require the ability to localize an abnormal parathyroid gland in the neck or mediastinum and employ image-directed ethanol injection or angiolysis with catheter-based injection of hypervascular contrast agents. Both techniques are inferior to surgical resection and are associated with recurrent laryngeal nerve injury, as well as high recurrence rates.

Medical treatment for patients with persistent or recurrent PHPT is routinely used before surgical intervention and in some cases in lieu of surgical treatment. The most important aspect of medical management is to treat severe hypercalcemia with hydration to improve renal, cardiac, and cognitive function. A variety of medications can then be used including bisphosphonates and the calcimimetic agent cinacalcet.

POSTOPERATIVE MANAGEMENT

Postoperative management of redo parathyroidectomy patients is similar to, but more intense than, de novo cases because the risks are higher. Recurrent nerve injury and postoperative bleeding resulting in acute airway compromise are of paramount concern. In addition, postoperative hypocalcemia is exacerbated because these patients often have a reduced mass of normal parathyroid tissue and are also likely to have hungry bone syndrome. Serial measurement of postoperative serum calcium levels will confirm cure and enable early oral calcium treatment and selective use of the active vitamin D analog, calcitriol (Rocaltrol). At times, IV calcium replenishment with a solution of calcium gluconate can be life-saving.

RESULTS

The cure and complication rates associated with remedial surgery for PHPT can approach those obtained for de novo cases when performed by experienced teams. Cure rates above 95% and complication rates between 1% and 3% have been reported in large series. High success rates are also associated with reductions of hospital-based and outpatient expenses.

CONCLUSION

Remedial surgery for PHPT is challenging and rewarding because dramatic improvements occur for the vast majority of patients. However, disastrous consequences, including bilateral recurrent laryngeal nerve injuries and lifelong refractory hypocalcemia, can be devastating. Surgeons who are interested in performing these procedures are urged to obtain the requisite skills and judgment by training with experienced endocrine surgeons.

Surgical Management of Secondary and Tertiary Hyperparathyroidism

Zeya T. Sahli, MD, and Martha A. Zeiger, MD, FACS

Hyperparathyroidism (HPT) is a product of autonomous secretion of parathyroid hormone (PTH) from one or more parathyroid glands. Secondary HPT develops after chronic parathyroid gland stimulation from hypocalcemia, hyperphosphatemia, or vitamin D deficiency and, results in increased PTH synthesis and parathyroid cell proliferation among all four glands. This occurs most commonly "secondary" to chronic kidney disease (CKD), with up to 90% of patients with renal failure developing the disease by the time hemodialysis is required. Secondary HPT can also be caused by vitamin D deficiency or gastrointestinal malabsorption due to chronic pancreatitis, small bowel disease, or malabsorption-dependent bariatric surgery. When left untreated, changes such as decreased extracellular calcium sensing, vitamin D, and klotho and fibroblast growth factor 1 receptors may cause further derangement in calcium metabolism, leading to tertiary HPT. Up to 30% of renal transplant recipients with secondary HPT are at risk for development of tertiary HPT. Unlike secondary HPT that is associated with hypocalcemia, patients with tertiary HPT exhibit normal to elevated calcium levels and hypophosphatemia.

The prevalence of secondary or tertiary HPT is difficult to determine because of the variability in diagnostic criteria. A consistent indicator of their prevalence is the rate of parathyroidectomy (PTX). Data from the Healthcare Cost and Utilization Project's Nationwide Inpatient Sample database showed 52,971 PTX admissions for secondary HPT performed in the United States between 2002 and 2011, a rate of 1.4 PTX per 1000 patients.

Physicians should have a high level of suspicion for the diagnosis of HPT when evaluating patients with renal failure (Box 1). Symptoms can include bone pain due to renal osteodystrophy, hyperphosphatemia, and hypercalcemia. More severe symptoms due to HPT occur at PTH levels greater than 1000 pg/mL. Calciphylaxis or calcific uremic arteriolopathy, a disease in which calcium accumulates in small vessels of fat and skin, can be found in patients with renal failure involving subcutaneous vascular calcification and calcium necrosis (Fig. 1). This sign is indicative of severe HPT and its often fatal sequelae, and PTX should be offered because it can enhance wound healing.

Medical Management

Secondary HPT can initially be managed medically, whereas tertiary HPT is treated surgically. Primarily, calcium and calcitriol supplementation can be used to slow the progression of secondary HPT until the patient can undergo renal transplantation. Other treatment options include calcimimetics, phosphate binders, and vitamin D analogues. Approved by the Food and Drug Administration in March 2004, Cinacalcet is a calcimimetic that functions by allosteric activation of the calcium sensing surface receptor expressed by parathyroid gland chief cells to reduce PTH production. It is commonly used among patients with end stage renal disease who are not transplant candidates because its use before renal transplantation has been associated with rebound hypercalcemia and hypophosphatemia if discontinued at the time of transplantation. Moreover, its long-term effect on patients or allograft survival has not been studied.

Investigations into Cinacalcet's effect on disease progression and PTX rates have been ongoing. The randomized trial Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) found that CKD patients treated with Cinacalcet were less likely to develop secondary HPT (relative hazard ratio, 0.31; 95% confidence interval [CI], 0.26–0.37). Another randomized, double-blind, placebo-controlled clinical trial study reported a significant reduction in the risk of needing PTX (HR, 0.07; 95% CI, 0.03–0.22), fracture (HR, 0.46; 95% CI, 0.27–0.97), and cardiovascular hospitalization (HR, 0.63; 95% CI, 0.43–0.86) among the Cinacalcet group compared with placebo. The PTX rate has decreased from 2.9 per 1000 patients in 2003 to 2.3 per 1000 patients in 2011, likely due to increased medical management. However, the rate increased to 5.4 per 1000 patients in 2006 and has remained relatively stable despite the increased clinical use of Cinacalcet. This may be due to higher treatment doses used in clinical trials than those used in clinical practice, thus the overestimation of its benefits.

Parathyroidectomy

Despite the initial medical management of secondary HPT, PTX is required in approximately 30% of patients after 5 to 10 years of dialysis and up to 40% after 20 years (see Box 2). The goals of parathyroid surgery include the immediate reduction in PTH levels, long-term symptomatic relief, and end-stage organ improvement. Due to the paucity of randomized clinical trial data, indications for and timing of PTX vary

Surgical Management of Secondary and Tertiary Hyperparathyroidism

Zeyad T. Sahli, MD, and Martha A. Zeiger, MD, FACS

Hyperparathyroidism (HPT) is a product of autonomous secretion of parathyroid hormone (PTH) from one or more parathyroid glands. Secondary HPT develops after chronic parathyroid gland stimulation from hypocalcemia, hyperphosphatemia, or vitamin D deficiency and, results in increased PTH synthesis and parathyroid cell proliferation among all four glands. This occurs most commonly "secondary" to chronic kidney disease (CKD), with up to 40% of patients with renal failure developing the disease by the time hemodialysis is required. Secondary HPT can also be caused by vitamin D deficiency or gastrointestinal malabsorption due to chronic pancreatitis, small bowel illness, or malabsorption dependent bariatric surgery. When left untreated, changes such as decreased extracellular calcium sensing, vitamin D, and klotho and fibroblast growth factor 1 receptors may cause further derangement in calcium metabolism, leading to tertiary HPT. Up to 30% of renal transplant recipients with secondary HPT are at risk for development of tertiary HPT. Unlike secondary HPT that is associated with hypocalcemia, patients with tertiary HPT exhibit normal to elevated calcium levels and hypophosphatemia.

The prevalence of secondary or tertiary HPT is difficult to determine because of the variability in diagnostic criteria. A consistent indicator of their prevalence is the rate of parathyroidectomy (PTX). Data from the Healthcare Cost and Utilization Project's Nationwide Inpatient Sample database showed 52,971 PTX admissions for secondary HPT performed in the United States between 2002 and 2011, a rate of 1.4 PTX per 1000 patients.

Physicians should have a high level of suspicion for the diagnosis of HPT when evaluating patients with renal failure (Box 1). Symptoms can include bone pain due to renal osteodystrophy, hyperphosphatemia, and hypercalcemia. More severe symptoms due to HPT occur at PTH levels greater than 1000 pg/mL. Calciphylaxis or calcific uremic arteriolopathy, a disease in which calcium accumulates in small vessels of fat and skin, can be found in patients with renal failure involving subcutaneous vascular calcification and calcium necrosis (Fig. 1). This sign is indicative of severe HPT and its often fatal sequelae, and PTX should be offered because it can enhance wound healing.

Medical Management

Secondary HPT can initially be managed medically, whereas tertiary HPT is treated surgically. Primarily, calcium and calcitriol supplementation can be used to slow the progression of secondary HPT until the patient can undergo renal transplantation. Other treatment options include calcimimetics, phosphate binders, and vitamin D analogues. Approved by the Food and Drug Administration in March 2004, Cinacalcet is a calcimimetic that functions by allosteric activation of the calcium sensing surface receptor expressed by parathyroid gland chief cells to reduce PTH production. It is commonly used among patients with end stage renal disease who are not transplant candidates because its use before renal transplantation has been associated with rebound hypercalcemia and hypophosphatemia if discontinued at the time of transplantation. Moreover, its long-term effect on patients or allograft survival has not been studied.

Investigation into Cinacalcet's effect on disease progression and PTX rates have been ongoing. The randomized trial Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) found that CKD patients treated with Cinacalcet were less likely to develop secondary HPT (relative hazard ratio, 0.31; 95% confidence interval [CI], 0.26–0.37). Another randomized, double-blind, placebo-controlled clinical trial study reported a significant reduction in the risk of needing PTX (HR, 0.07; 95% CI, 0.03–0.15), fracture (RR, 0.46; 95% CI, 0.27–0.78), and cardiovascular hospitalization (RR, 0.63; 95% CI, 0.43–0.86) among the Cinacalcet group compared with placebo. The PTX rate has decreased from 7.8 per 1000 patients in 2003 to 3.3 per 1000 patients in 2011, likely due to increased medical management. However, the rate increased to 5.4 per 1000 patients in 2006 and has remained relatively stable despite the increased clinical use of Cinacalcet. This may be due to higher treatment doses used in clinical trials than those used in clinical practice, thus the overestimation of its benefits.

Parathyroidectomy

Despite the initial medical management of secondary HPT, PTX is required in approximately 20% of patients after 5 to 10 years of dialysis and up to 40% after 20 years (Box 2). The goals of parathyroid surgery include the immediate reduction in PTH levels, long-term symptomatic relief, and end-stage organ improvement. Due to the paucity of randomized clinical trial data, indications for and timing of PTX vary

greatly among experts. Because there is no consensus on the required percentage reduction of PTH to account for cure, the presence or absence of symptoms among HPT patients should be considered.

INDICATIONS FOR SURGERY

Symptomatic Patients

All patients with symptomatic HPT should be considered a surgical candidate. There is no clear consensus regarding PTH cutoff levels as clear indications for surgery. The National Kidney Foundation recommends PTX in patients with a PTH greater than 800 pg/mL associated with hypercalcemia or hyperphosphatemia refractory to medical therapy as an indication for surgery. Among children, the authors recommend PTX for a PTH level greater than 1000 pg/mL or doubling associated bone disease. However, the Kidney Disease: Improving Global Outcomes Group recommends a PTH target threshold for treatment nine times above the upper limit of normal for the PTH assay (e.g., 585 pg/mL).

Symptom-Free Patients and Patients Waiting for Transplantation

Among symptom-free patients, consensus among experts regarding indications for PTX is also lacking. HHD patients with a PTH greater than 1000 pg/mL that is refractory to medical therapies should undergo PTX. However, PTX patient selection must be individualized on the basis of age, comorbidities, and risk-benefit evaluations. Younger patients (<65 years) with little comorbidity are more likely to tolerate surgery and benefit over the long term. Moreover, observational studies have documented the benefits of PTX, including a reduction of 10% to 37% in mortality, 33% to 41% in cardiovascular risk, 32% in fracture risk, as well as improvements in erythropoietin resistant anemia, nutritional status, and humoral and cellular immunity. All transplant candidates, with or without symptoms, with a PTH greater than 800 pg/mL and despite optimal medical therapy should be referred for subtotal PTX.

Renal Transplant Recipients

Despite the potentially high incidence of tertiary HPT, PTX is only performed in less than 10% of renal transplant recipients who harbor this disorder at 1 year after surgery but should be considered the standard of care and recommended to all.

BOX 1 Symptoms of Hyperparathyroidism

- Fatigue/mood status changes
- Renal calculi
- Proximal muscle pain
- Bone pain due to osteitis fibrosa cystica, mainly affecting weight-bearing joints including hips, knees, ankles, and lower back
- Joint pain, joint inflammation due to periarticular calcium deposits
- Bone fracture, nontraumatic fractures or nonhealing of fractures
- Pruritus
- Calciphylaxis, resulting in expanding, painful, cutaneous, purpuric lesions that cause tissue calcifications and ischemic necrosis that lead to dry gangrene if untreated

PREOPERATIVE MANAGEMENT

Preoperative evaluation includes patient risk assessment and counseling. Risk assessment of HHD patients is important for the selection of appropriate surgical candidates because patients who have HHD may have chronic comorbidities that prevent safe surgery. These comorbidities include coronary artery disease, heart failure, myocardial infarction, hypertension, stroke, anemia, uremic coagulopathy, pulmonary disease, and general debility. Moreover, patients with calciphylaxis may develop unique complications, including peripheral vascular disease and wound sepsis, potentially requiring vascular/interventional procedures or wound debridement, respectively. Although renal transplant patients are commonly healthier, their immune system is medically suppressed, which may increase the risk of postoperative complications. Coordination with the patient's nephrologist or dialysis center should be done when scheduling surgery to have the patient undergo dialysis 1 day before surgery and to avoid unnecessary delay caused by conditions such as hyperkalemia.

Preoperative localization studies should be performed to localize ectopic glands among patients with secondary or tertiary HPT. Either 99mTc Sestamibi scans or four-dimensional computed tomography

FIG. 1 Calciphylaxis showing cutaneous purpuric lesions and ischemic necrosis on the nares (*A*) and medial leg (*B*) of a patient with secondary hyperparathyroidism. (From Ali SI, Appel RG, Chen J: Secondary and tertiary hyperparathyroidism: state of the art surgical management. Surg Clin North Am. 2009;89:1277–1293.)

BOX 1 Adult Parathyroidectomy Indications for Secondary vs Tertiary HPT

Secondary HPT

- Calciphylaxis
- Patient preference
- Medical observation not possible
- Symptoms due to hyperparathyroidism
- Failure of maximal medical management with:
  - Hypercalcemia
  - Hypercalciuria
  - PTH >800 pg/mL
  - Hyperphosphatemia (with calcium × phosphorus >70)

Tertiary HPT

- Severe hypercalcemia (serum calcium >12.5 mg/dL)
- Persistent hypercalcemia (serum calcium >10.2 mg/dL >3 months after surgery)
- Osteoporosis
- Symptomatic hyperparathyroidism

scans should be used. The importance of preoperative imaging among patients with secondary/tertiary HPT is highlighted by that 32% of recurrent or persistent cases are due to supernumerary glands. In cases of reoperation, including previous thyroidectomy, parathyroidectomy, carotid endarterectomy, or cervical spine surgery, vocal cord visualization by laryngoscopy should be performed to exclude prior recurrent laryngeal nerve injury. Preoperative ultrasound examination may identify abnormal parathyroid glands or abnormalities in the thyroid gland that may require further evaluation or simultaneous surgical management.

EXTENT OF SURGERY

The extent of parathyroid surgery ranges from targeted PTX to subtotal or near-total PTX, or total PTX with or without heterotopic autotransplantation. A total PTX with a heterotopic autotransplantation removes all cervical parathyroid glands, including supernumerary, that can be identified and autotransplants a small portion of a gland to a new, nonpulsatile site such as the neck, chest, or forearm. Subtotal parathyroidectomy is the resection of three (or more, if supernumerary glands are present) glands and subtotal resection of a fourth gland, with preservation of a viable, histologically confirmed remnant approximately the size of a normal gland.

Published literature regarding the recommended extent of surgery in both secondary and tertiary HPT is inconsistent. For this reason, the decision regarding extent of surgery is largely dependent on surgeon preference in addition to several other factors, including whether the surgery is primary or reoperative and whether the patient has an existing or planned renal transplant. In contradistinction to total PTX and autotransplantation, a parathyroid gland remnant left during subtotal PTX mitigates against postoperative permanent hypocalcemia because of the maintenance of its original blood supply congruent with that of an autograft. However, the risk of recurrent HPT has been shown to be greater among patients undergoing subtotal rather than total PTX with autotransplantation. Moreover, total PTX without autotransplantation has been reported to prevent recurrence more effectively than with autotransplantation. Patients presenting with calciphylaxis are associated with more than 50% mortality within the first year, and thus it is recommended that they undergo total parathyroidectomy without autotransplantation.

Targeted PTX is not commonly performed among patients with secondary or tertiary HPT but can be considered in patients with recurrent HPT or in post-renal transplant patients with single or double adenomas, reported in up to 29% among patients who have undergone renal transplantation. However, this may be associated with an increased risk of recurrence. Patients with a relative contraindication for future neck surgery because of prior history of repeated neck surgery, known recurrent laryngeal nerve injury, or significant medical comorbidities, should undergo a total PTX with autotransplantation to facilitate access to the gland in case of recurrent HPT. Currently, debate exists regarding the need for a prophylactic thymectomy. Thymectomy should be performed, however, during the search for a missing inferior parathyroid gland or supernumerary glands.

SURGICAL TECHNIQUE

The patient should be placed in a supine position with the neck hyperextended. Potential sites of autotransplantation should be exposed and prepped. General anesthesia is required for most patients undergoing PTX with bilateral neck exploration. However, local anesthesia has been also been described in patients deemed to be at too high a risk for general anesthesia. A standard Kocher incision measuring 3 to 5 cm should be made through skin and platysma. Superior and inferior flaps should be created in usual fashion to thyroid cartilage superiorly and sternal notch inferiorly. Strap muscles are divided longitudinally in the midline and retracted (Fig. 1). Throughout the procedure the recurrent laryngeal nerves should be noted and carefully preserved. First, all four parathyroid glands should be exposed after a thorough bilateral neck exploration. Biopsy, capsular rupture, or fragmentation of the glands should be avoided to prevent parathyromatosis.

Identification of fewer than four parathyroid glands should prompt a search for the missing gland. The surgeon should have an intimate familiarity with parathyroid embryology and be aware of the following ectopic locations: the tracheoesophageal groove, retroesophageal, ectopic/mid-parathyroid, carotid sheath, intrathyroidal, mediastinal, and thymus (Fig. 2). Parathyroid tissue should be confirmed on frozen section.

Intraoperative PTH Monitoring

Unlike in the case of primary HPT, an established intraoperative PTH monitoring protocol, such as the Miami criteria, to confirm treatment has not been established to confirm cure of patients with secondary or tertiary HPT. The reason for this is due to the change in PTH half-life from 2.2 minutes in patients with normal renal function to 4.8 minutes in ESRD patients as a result of the decreased renal clearance. Despite this, recommendations regarding PTH level decline during surgery compared with baseline value are commonly used. These include a recommended range of decline of 50% to 80% at anywhere between 10 and 20 minutes after PTX as a reliable predictor of postoperative cure.

Creating A Parathyroid Remnant

During subtotal PTX, the parathyroid remnant should be created first before resection of other glands to monitor its viability throughout the operation. The parathyroid remnant should be approximately 50 to 100 mg and, preferably, an inferior parathyroid gland remnant. Choosing an inferior gland leaves the remnant in a safe position, away from the recurrent laryngeal nerve should the patient require reoperation and resection. Marking the remnant with a titanium clip or nonabsorbable suture facilitates its localization in the event of a reoperation.

Creating an Autograft

Autotransplantation entails mincing a portion of the excised gland into a total of 10 to 15 pieces approximately 1 to 2 mm that are then inserted into one or several pockets subcutaneously or intramuscularly in the neck, chest, or forearm. Before autotransplantation, a frozen section should confirm parathyroid tissue. There is no consensus

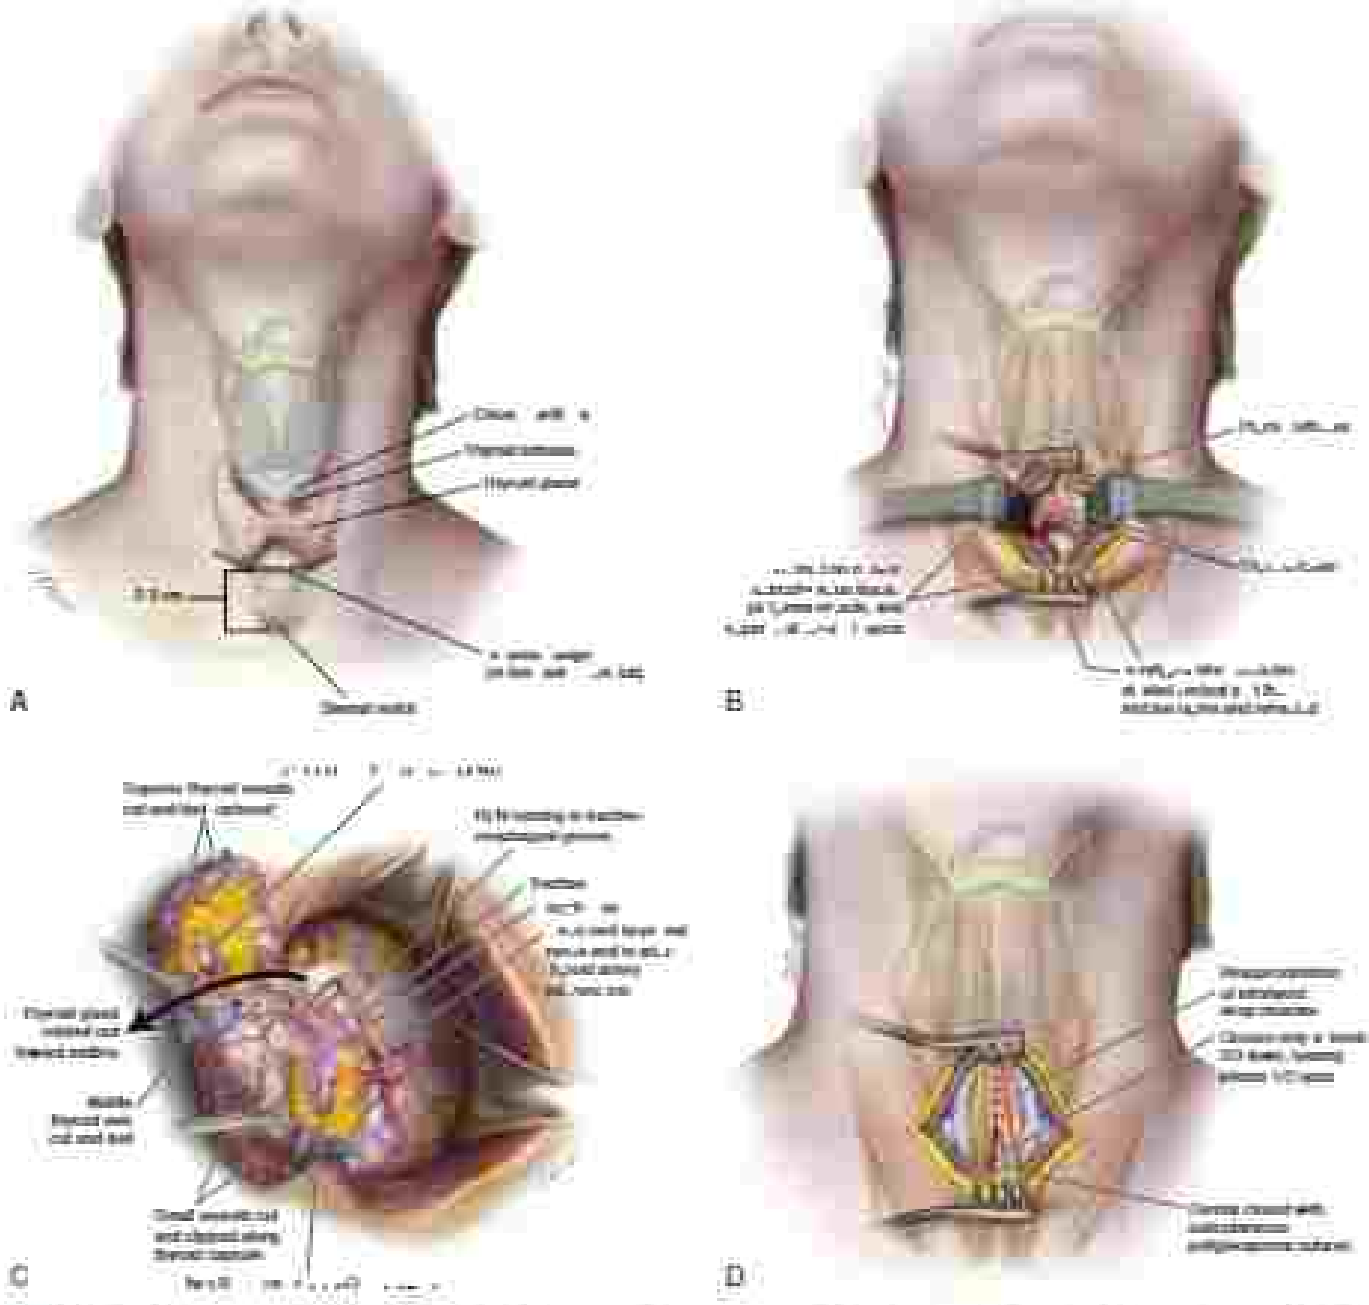

FIG. 2 Parathyroidectomy steps highlighted. (A) A 2- to 3-cm incision will allow access to a majority of parathyroid glands. (B) Middle raphe of the infrahyoid strap musculature has been identified and retracted to reveal the thyroid isthmus. (C) Parathyroid glands are identified with careful dissection; the recurrent laryngeal nerve may be confirmed if necessary. Conservative ligation of the superior vascular pedicle may be required for adequate visualization. (D) Wound closure includes shallow subcutaneous and platysmal suture approximation to prevent the overlying soft tissue from adhering to the trachea and resulting in poor cosmesis. (From Kuhnigk E, Hauss FR. Atlas of oral and maxillofacial surgery. Philadelphia: Elsevier; 2014.)

regarding the optimal site for grafting. Implantation and resection of subcutaneous parathyroid autografts is simpler to perform than intramuscular procedures. Regardless of implantation sites, parathyroid fragments often infiltrate surrounding tissues, which may make resection of all foci challenging. Furthermore, one must always be circumspect about an additional cervical gland complicating the picture of recurrent HPT.

We recommend implanting the autograft in the nondominant forearm brachioradialis muscle or subcutaneously because of its relatively easy access under local anesthesia for reexplorations. Furthermore, determination of autograft function can be performed by comparing PTH levels of blood samples drawn from the antecubital vein of the implanted arm versus the contralateral arm. Patients with a forearm autograft may require several reoperations to completely remove autografts from the forearm because of regrowth causing recurrent HPT. For this reason, during reexploration procedures, it may be appropriate to excise all viable autograft tissue.

The sternocleidomastoid muscle is another convenient location for autotransplantation as it is within the operative field. A third possible location for autotransplantation is in the middle to lower third

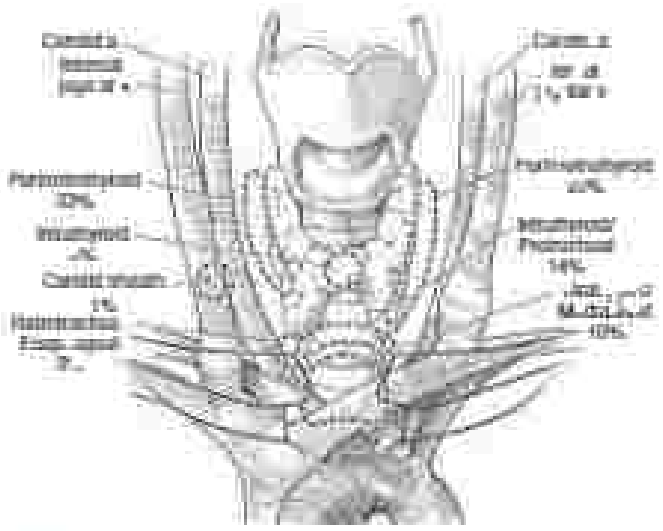

FIG. 3 Locations and frequencies of parathyroid glands removed at reoperation. (From Akerström G, Grimelius L, Heath H. Review: parathyroid surgery. Operative Techniques. 2010;21:72–81.)

of the proximal area subcutaneously. The autograft can be easily located and excised under local anesthesia in the event of a recurrence. Autografts are rarely placed intramuscularly in the chest due to technical difficulties.

Cryopreservation

When possible, we recommend cryopreservation of parathyroid tissue in patients undergoing subtotal or total PTX that are at high risk of hypoparathyroidism. The preserved tissue can be used for delayed autotransplantation in case of parathyroid remnant ischemic necrosis or autograft failure. However, cryopreservation of parathyroid tissue is available in less than 20% of centers. Variable success rates have been reported ranging from 17% to 83%.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Among ESRD patients, parathyroid surgery has a similar operative complication rate despite an increased risk for uremia-related bleeding diathesis among ESRD patients. However, patients with ESRD are up to five times more likely to be readmitted when compared with surgery for patients with primary HPT. The shared risks include bleeding and hematoma, wound infection, superior laryngeal nerve or recurrent laryngeal nerve injury, or hypoparathyroidism. Moreover, 5% to 20% of patients experience persistent disease, which is defined as hypercalcemia or PTH level above the recommended target range according to CKD stage after PTX. Compared with patients with primary HPT, patients with ESRD are more likely to develop postoperative transient hypocalcemia or hungry bone syndrome—the hyperdynamic, osteoblastic uptake of calcium into bones. Severe postoperative hypocalcemia may occur in up to 97% of ESRD patients and, for this reason, protocols must be in place to administer perioperative calcitriol, intravenous calcium gluconate during the immediate postoperative period, dialysis or readmission, along with oral calcium, magnesium, and calcitriol when discharged home. Patients with hypocalcemia should also be considered for continuous cardiac monitoring due to potential QT prolongation.

Patients typically do not require pain medications stronger than acetaminophen. Patients may resume dialysis after surgery in the hospital, however, the minimum amount of heparin should be used during the first few dialysis sessions to minimize the risk of neck hematoma.

After hospital discharge, patients should be followed up with a baseline laboratory profile of serum and ionized calcium, magnesium, and serum PTH at 1 to 8 weeks after surgery, and vitamin D levels at 3 and 6 months. Long-term follow-up, with serum calcium measurements, at least annually, is important because the time for ESRD patients to achieve new homeostasis can vary significantly, and, for this reason, laboratory results should be interpreted with caution and be monitored for potential persistent or recurrent HPT.

SUMMARY

Surgical management of secondary and tertiary hyperparathyroidism is a complex surgical issue due to the lack of specific guideline consensus. Despite a 1.1% increase in the incidence of ESRD in 2016, the prevalence of secondary/tertiary HPT increased approximately 3.5%, likely because of a decline in mortality rate among these patients according to the United States Renal Data System. These statistics highlight the importance of knowing how to effectively manage these patients. Ongoing research and discussion regarding the surgical management of secondary and tertiary HPT is needed. A well-developed prospective multiinstitutional randomized controlled clinical trial comparing the three procedures (subtotal versus total with autotransplantation versus total without autotransplantation) is needed.

Subtotal parathyroidectomy is the preferred surgical approach. However, all three procedures are safe and effective at treating HPT and its associated metabolic disturbances. Future advances in our understanding regarding the ideal surgical management of these patients will aid in the creation of consensus guidelines.

Metabolic Changes Following Bariatric Surgery

Ali Tavakkoli, MD, FACS, FRCS, and Robert M. Cooney, MD, FRCS, FCCM

METABOLIC CONSEQUENCES OF OBESITY

The accumulation of excess body fat results in obesity, which is commonly defined as a body mass index (BMI) greater than 30. The BMI uses the ratio of weight to height (kg/m^2) to estimate adiposity. Although BMI is easy to calculate, it has several limitations. For example, athletic individuals may have an elevated BMI due to increased muscle mass (vs excess fat). Although obesity can be defined as percentage body fat greater than 32% in women and 25% in men, these calculations are difficult. More importantly, neither BMI nor percent body fat provide information regarding the distribution of excess body fat, which is critical because the metabolic consequences of obesity are determined by both the amount and distribution of body fat. Abdominal or visceral obesity leads to a chronic inflammatory state caused in part by the release of free fatty acids and cytokines from adipose tissue. Visceral obesity is associated with increased risk of insulin resistance, hyperlipidemia, hypertension, cardiovascular disease (CVD), and stroke. This pattern is also referred to as *android* obesity and is more commonly seen in men. The gynoid pattern of obesity is characterized by an excess accumulation of subcutaneous fat in the gluteal and hip thigh areas, is more commonly seen in women, and is less frequently associated with adverse metabolic effects. The importance of central obesity is highlighted in populations who, despite relatively low BMIs, have high levels of abdominal adiposity (visceral obesity). Such groups (e.g., Asians) are prone to adverse effect of obesity at a lower BMI. A simple measurement of waist circumference or waist to hip ratio can address central adiposity but does not accurately address height and fat content. A waist circumference of more than 35 inches in women or 40 inches in men indicates higher risk of metabolic syndrome and obesity related comorbidities, and a waist to hip ratio above 0.85 for females or 0.90 for males can be used to classify obesity.

Although the obesity epidemic in the United State is well documented, affecting 40% of women, 35% of men, and 17% of children and adolescents, the problem is an international one, with many Western countries reporting similar rates. Some of the highest rates of obesity in adults are observed in some of the South Pacific Islands such as Samoa. The global epidemic of obesity is multifactorial and has genetic, environmental, and epigenetic roots. Although recent exposure of humans to an environment with excess cheap food leads to an imbalance between caloric intake and energy expenditure results in increased risk of obesity, this risk is modulated by genetic risk factors, lifestyle, culture, and economic factors.

Although adipose tissue was originally thought to be a relatively quiescent accumulation of stored calories, more recent studies indicate adipose tissue to be metabolically and hormonally active. In severe obesity, excess lipid accumulates in these metabolically active adipocytes, as well as hepatocytes and muscle cells. Excess accumulation of nutrients and fat within these cells leads to increased secretion of adipocyte derived peptides (e.g., leptin, adiponectin, resistin) and cytokines (e.g., tumor necrosis factor α, interleukin 6) collectively referred to as adipokines. The paracrine and endocrine actions of these adipokines contribute to a state of chronic low grade inflammation, which in turn interferes with many physiologic cellular processes (such as insulin signaling) and leads to the metabolic derangements seen in obesity (such as insulin resistance and diabetes).

The obesity induced inflammatory state adversely affects most organ systems in the body and contributes to a shortened life expectancy. Each 5 unit increase in BMI is associated with a 30% increase in all cause mortality, with BMIs greater than 40 associated with a reduced life expectancy of 8 to 10 years. Obese individuals have a poor quality of life with increased risk of many life threatening conditions, including cancers, heart disease, type 2 diabetes, hypertension, stroke, hyperlipidemia, and sleep apnea. The prevalence of these comorbidities often increases with the severity of obesity (Table 1). This is most evident when looking at type 2 diabetes. At age 18, women with a BMI of 30 to 35 have a 51.6% lifetime risk of developing diabetes, which is increased to 71.4% for those with a BMI greater than 35.

Although modest weight loss (5%–10% excess weight) can lead to reductions in the risk of these chronic diseases, nonsurgical weight loss is often unsuccessful or short lived in 90% to 95% of patients. Thus bariatric surgery has become the standard of care in the treatment of medically complicated or morbid obesity.

METABOLIC IMPROVEMENTS AFTER WEIGHT LOSS SURGERY

Weight Loss

The term excess body weight loss (EBWL), calculated using the actual and ideal body weight, has traditionally been used by surgeons to describe degree of weight loss, although there is a general move away from this metric, with total body weight loss or BMI reduction being increasingly used. Not surprisingly, the degree of weight loss varies between procedures. The mean EBWL is 70% to 80% for biliopancreatic diversion with or without duodenal switch (BPD), 60% to 70% for Roux-en-Y gastric bypass (RYGB), 50% to 60% for sleeve gastrectomy (SG), and 40% to 45% for laparoscopic adjustable gastric banding (LAGB) at 2 years. In general, procedures with higher weight loss are also associated with increased short and long term complications. The balance between the desired weight loss and surgical risk influences the patients when choosing an operation and the surgeons when offering the procedure.

The mechanisms underlying the weight loss are multifactorial and vary by procedure. The proposed mechanisms for postsurgical weight loss are summarized in Table 2. Of critical importance are long term reductions to appetite and hunger after surgery. In contrast, nonsurgical weight loss leads to increased hunger and reduced energy expenditure, which presumably contributes to the ultimate failure of dieting to achieving long term weight reduction. Weight loss surgery prevents such physiologic responses and maintains hunger control despite limited caloric intake.

Long term, follow up studies such as the Swedish Obesity Study demonstrate significant long term weight loss in surgical patients compared with control subjects, with up to 20 years of follow up. The durability of postsurgical weight loss is a concern for patients and clinicians. Definition of successful weight loss in bariatric surgery patients varies depending on the procedure but for gastric bypass is described as losing and maintaining 50% or more EBWL. Most patients regain some weight after reaching their nadir weight, with pathological weight regain (>20% of the maximal weight loss) reported in 15% to 20% of patients. This observation highlights the fact that bariatric surgery is not a replacement for long term lifestyle changes that are needed to help maintain weight loss. A commitment to changes to diet and exercise are critical for long term success. The importance of such changes and the need for regular postoperative follow up with the bariatric team should be emphasized to patients before surgery.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease is present in more than 70% of individuals with a BMI greater than 35 and represents a spectrum of

TABLE 1 Risks of Cardiovascular and Metabolic Disorders With Obesity

Life expectancy	• 30% increase in mortality rate for each 5 unit increase in BMI • In patients with BMI >40, life expectancy is reduced by 8 years
Hypertension	• 5 fold risk of hypertension in obese individuals • 85% of hypertensive patients have a BMI >25
Cardiovascular disease	• A 9% increase in cardiovascular mortality rate with each unit increase in BMI
Type 2 diabetes	• Men with BMI >35 have a 42 fold increase in risk of diabetes compared with men with BMI <23 • 74% lifetime risk of type 2 diabetes if BMI>35

BMI, body mass index.

disease characterized initially by the accumulation of liver fat (steatosis), which, if severe, causes inflammation and nonalcoholic hepatosteatitis (NASH) and later fibrosis or cirrhosis. Hepatic steatosis and NASH, markers of central adiposity, are believed to be important in the pathogenesis of obesity related metabolic disorders often referred to as metabolic syndrome (visceral adiposity, insulin resistance and hyperinsulinemia, hyperuricemia, hyperlipidemia). NASH is now a leading cause of cirrhosis in the United States and one of the main indications for liver transplantation. Therefore resolution of NASH related hepatic injury is an important endpoint in bariatric and metabolic surgery. Studies have shown that weight loss operations lead to a near universal improvement in the severity of hepatic steatosis, inflammation, and fibrosis. Imaging studies using magnetic resonance imaging have shown that liver volume is reduced within 1 month after surgery and liver steatosis is resolved in about 80% of patients by 6 months. Overall RYGB leads to greater improvement in liver disease compared with restrictive only procedures (SG and LAGB) because of better weight loss.

Lipid Profiles

Dyslipidemia is seen in up to 50% of patients undergoing bariatric surgery, with over 80% experiencing an improvement or resolution of this comorbidity within 2 years of surgery. Surgery leads to significant reductions in triglyceride with a more modest decrease in total cholesterol. High density lipoprotein (HDL) levels are also significantly increased. There is variation in the remission rate of dyslipidemia between the common bariatric procedures, and better results are achieved by the more malabsorptive operations. Comparing SG and RYGB, gastric bypass leads to a reduction in cholesterol, low density lipoprotein (LDL) and an increase in HDL, whereas the SG only increased HDL without altering LDL levels. Both operations lead to a significant decrease in triglycerides. The 5-year remission rates for dyslipidemia are about 40% after SG and 60% after RYGB.

Hypertension

Hypertension is common in obesity and rises in prevalence with increasing weight. The odds ratio for hypertension is 1.7 for overweight compared with normal-weight individuals, 2.6 for BMI 30 to 34.9, 3.7 for BMI 35 to 39.9, and 4.8 for BMI of 40 or more. In the normal weight population (BMI <25), hypertension is present in 15% to 20% of population, rising to 30% to 40% in those with BMI greater than 30. Elevated blood pressure is seen in up to 50% of patients undergoing bariatric surgery, with 60% to 70% documenting an improvement or remission after weight loss surgery. Improvements in blood pressure are also linked to weight loss, and the remission rates vary between the bariatric procedures.

A European study of patients undergoing RYGB or intensive medical therapy showed the rate of hypertension remission was 89% for the surgical group versus 23% for the control group. In randomized studies comparing RYGB to SG, hypertension remission rates at 5 years were reported at 50% to 70% for RYGB and 30% to 40% for SG. Remission rates are generally lower for LAGB (around 20%) and higher for BPD (40%–80%).

TABLE 2 Proposed Mechanisms for Weight Loss After Bariatric Procedures

Physical restriction of food intake	Unlikely. Although a common belief especially in case of LAGB, there is little data to support this. Food transit through the stomach is only minimally altered after LAGB and the upper pouch compartment is empty of food within 1–2 minutes after ingestion. BPD has a large gastric reservoir and yet leads to the best weight loss results.
Malabsorption	Unlikely. Although a degree of this occurs after BPD, little malabsorption is seen after LAGB, SG or RYGB.
Decreased hunger signals and reduced food intake	This is true for all bariatric procedures, and secondary to neuro hormonal changes seen after surgery.
Increased energy expenditure and diet induced thermogenesis	Although this has been documented in rodents, there is little data to support this in humans.
Changes in food preference	Changes in food preference have been documented and are related to pain in alterations in reward and taste, as well as concerns about physiologic implications of ingestion of certain foods that may lead to dysphagia or dumping syndrome.
Changes in gut microbiota	Animal studies demonstrate a role for intestinal microbacteria in obesity and diabetes. Definitive human data are presently lacking, but this is an area of significant scientific interest.

BPD, biliopancreatic diversion + duodenal switch; LAGB, laparoscopic adjustable gastric banding; RYGB, Roux-en-Y gastric bypass; SG, sleeve gastrectomy.

Cardiovascular Risk and Mortality

CVD remains the leading cause of death in the United States. Several risk scores have been developed to calculate an individual's risk of having a cardiovascular (CV) event and used to help guide strategies for primary prevention. Of these risk scores, the Framingham Risk Score (FRS) is widely used. This risk score is calculated based on age, sex, smoking status, as well as cholesterol, HDL, and systolic blood pressure. These parameters are all improved after bariatric surgery, and it is therefore not surprising that weight loss procedures have

TABLE 3 Weight Changes and Metabolic Improvements After Bariatric Procedures

	TBWL (%)	Hypertriglyceridemia Remission	Hypertension Remission	Type 2 Diabetes Remission
RYGB	30%–35%	60%–65%	60%–70%	75%–80%
SG	30%–25%	50%–60%	30%–60%	50%–70%
LAGB	10%–15%	40%–70%	20%–30%	30%–60%

LA, L laparoscopic adjustable gastric banding; RYGB, Roux-en-Y gastric bypass; SG, sleeve gastrectomy; TBWL, total body weight loss.

been shown to reduce CHD and the 10-year risk of a cardiac event by 40%. Serum and laboratory risk predictors, such as C-reactive protein, have also been shown to decline after surgery by about 60%.

Several large cohort studies have shown that the reductions in risk factors also translate to reductions in overall mortality rate. In a large cohort study from Utah, at a mean follow up of 7.1 years, the overall mortality rate was reduced by 40%. Specifically, the cause-specific mortality rate decreased by 56% for coronary artery disease, by 92% for diabetes, and by 60% for cancer. Similar improvements in mortality rates have also been reported in the Swedish Obesity Study, which showed at 10 years a 23.7% unadjusted (30.2% adjusted) reduction in overall mortality.

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a common endocrine disorder of unknown cause characterized by menstrual abnormalities with hyperandrogenism and is a common cause of infertility, especially in severe obesity. Up to 50% of those with PCOS are overweight or obese, and phenotypic severity of PCOS is reported to correlate with severity of insulin resistance and to worsen with increased weight. In a meta-analysis of available data, incidence of PCOS before surgery was 45.6%, which significantly decreased to 6.8 % at 12-month follow up. Surgery has been reported to normalize menstruation in majority of cases, with improvements in infertile PCOS patients seeking pregnancy.

Reproductive Function and Pregnancy after Bariatric Surgery

Reproductive function and pregnancy are important topics to consider because 80% of individuals having bariatric surgery are women, and many of them are of reproductive age. Obesity is commonly associated with infertility, which is multifactorial in nature. Increased adipose tissue results in overproduction of the hormones leptin, estrogen, and testosterone. Impaired leptin signaling and increased levels of estrogen interfere with the hypothalamic, pituitary ovarian axis, resulting in dysfunctional uterine bleeding, anovulatory cycles, and reduced fertility. Insulin resistance is commonly observed with visceral adiposity, resulting in increased ovarian production of testosterone and decreased production of sex hormone binding globulin by the liver. In aggregate, these changes result in an increase in free androgen index, libido, and PCOS. Obesity also impacts body image and sexual health, which can also adversely impact reproductive function.

Women who are planning to have bariatric surgery are advised to avoid pregnancy and use reliable forms of birth control for 1 to 2 years after surgery. The rapid weight loss that occurs after bariatric surgery poses risks for both mother and baby. Many young women undergoing bariatric surgery have been unable to get pregnant for years despite being active sexually and do not routinely use contraception. However, rapid changes in hormonal function and fertility after bariatric surgery mandate education regarding the need for contraception to prevent pregnancy in the early postoperative period. Although oral contraceptives are normally very effective, after RYGB and other malabsorptive surgeries, oral contraceptives may be less effective due to impaired absorption. Other types of birth control, including transdermal and vaginal systems and barrier methods, should be considered. Once weight loss has stabilized, women interested in becoming pregnant should consider antepartum consultations with a dietitian, bariatric specialist, and obstetrician. Obesity is also associated with multiple complications related to pregnancy including gestational diabetes, hypertension, preeclampsia, congenital malformations, and stillbirth.

Several studies have examined the effects of bariatric surgery on outcomes of pregnancy with matched control subjects. Collectively they suggest that risk of gestational diabetes and large for gestational age infants during pregnancy are decreased after bariatric surgery. Although preterm birth, stillbirth, and congenital malformations were not impacted, the risk of small for gestational age babies appears to be increased after bariatric surgery. Several recent studies suggest that surgical weight loss before pregnancy has the potential to reduce the risk of obesity and metabolic risk factors by epigenetic mechanisms involving DNA methylation. These data raise potentially important questions regarding the benefits of bariatric surgery in future offspring. However, additional data are needed to further understand the long-term risk and benefits of maternal bariatric surgery on future offspring.

Type 2 Diabetes

Of all metabolic changes after bariatric surgery, none have been as impressive as the improvements in glucose homeostasis. Type 2 diabetes has reached epidemic proportions in the United States, and, despite significant investments in preventive measures, the rate is set to continue to climb. The diabetes epidemic is worldwide, significantly impacting countries such as China and Southeast Asia, including India, where about half of the world population of diabetic patients live. The number of patients with diabetes is expected to climb to more than 600 million worldwide by 2040. New pharmacological therapies (glucagon-like peptide 1 [GLP-1] analogues and dipeptidyl peptidase IV inhibitors) have been disappointing, and many diabetics fail to reach the therapeutic goals set by the American Diabetic Association and other endocrine societies (HbA_{1c} <7%). These trends and the remarkably rapid improvement in diabetes seen after bariatric interventions have pushed surgery to the forefront of diabetes treatment and created the field of Metabolic Surgery, defined for this purpose as "manipulation of the gastrointestinal tract with the goal of treating diabetes."

The observation that alterations in gastrointestinal anatomy can lead to diabetes resolution was first noted in the 1960s, and improvements in glycemic control after weight loss operations have been well documented since the early reports in 1995. Several large studies and meta-analyses have confirmed that all bariatric procedures lead to significant improvements in glucose control and diabetes remission, although success rates vary among the different operations, with RYGB and BPD offering the best chance of disease remission (Table 3). Although improvements in glycemic control are expected after any form of weight loss (surgical or diet induced), studies have confirmed weight independent effects on diabetes after RYGB and BPD.

There have now been at least 11 randomized studies confirming that bariatric surgery leads to better diabetes control than intensive

medial therapy. In the study comparing LAGB to medical therapy, surgery led to a diabetes remission (defined by fasting glucose <126 mg/dL and HbA_{1c} <6.5% in the absence of pharmacologic therapy) rate of 73% versus 13% for the medical arm at 2 years. The improved outcomes in surgical arm were linked to improved weight loss. Mingrone et al compared medical therapy to RYGB or BPD and showed that, at 5 years, diabetes remission (defined by fasting glucose <100 mg/dL and HbA_{1c} <6.5% in the absence of pharmacologic therapy) was seen in 0% in the medical arm compared with 37% in RYGB and 63% for BPD. The 5-year results of the Surgical Therapy and Medications Potentially Eradicate Diabetes Efficiently Trial, which compared medical therapy to RYGB or SG, and reported the remission rate (defined as HbA_{1c} <6% with or without medications) was 5% in the medical group versus 20% in the RYGB and 23% in the SG arms. In a large cohort study of more than 800 patients who had RYGB, with a 98% long term follow up rate, the 12 year diabetes remission rate was 51%.

These data have prompted many of the diabetes societies to alter their treatment guidelines for management of type 2 diabetes and recommend surgery in patients with poorly controlled diabetes and BMI less than 35 (see below section on surgery in low BMI patients). Although the antidiabetic effects of LAGB are directly linked to weight loss, the studies point to a weight independent effect for RYGB and BPD. This topic has received significant scientific attention over the last several years with many proposed mechanisms (Table 4). Although many hormones have been investigated to help elucidate the mechanisms of weight independent effect of RYGB on glucose homeostasis, there has been limited progress. GLP-1, an incretin hormone that leads to enhanced insulin secretion and satiety, has been shown to increase after many bariatric procedures. It is, however, likely that this is not the only contributing factor, and it appears that isolation of the proximal bowel from nutrient exposure also plays a critical role by altering nutrient sensing. Alterations in signaling represent another potential mechanism contributing to the metabolic benefit of surgery.

Cases of post RYGB hyperinsulinemic hypoglycemia have been reported, the cause of which remains unclear. Although initially the symptoms were thought to be related to pancreatic β cell hyperemia (nesidioblastosis), this theory is now questioned, with alternative hypotheses proposed and under study, including those related to changes in intestinal hormone secretion and rate of intestinal glucose absorption. These symptoms can often be managed with careful dietary modifications.

METABOLIC SURGERY AND FUTURE DIRECTIONS

The slow progress in finding effective new medical therapy for type 2 diabetes, the increasing prevalence of the disease, and increasing data confirming effectiveness of bariatric surgery to diabetes remission have been the impetus behind recommendations to lower the BMI threshold for surgical intervention in diabetic patients to 30. There is also an intense interest in understanding the scientific mechanisms underlying the antidiabetic effects of these procedures to help develop less invasive alternatives that can replicate their metabolic benefits. Alternative surgical procedures have been tested, and there has been significant investment in developing endoluminal devices for treatment of diabetes, heralding with it the emerging field of "interventional diabetology."

Surgery in Diabetic Patients with Low BMI

The 1991 NIH Consensus statement recommends bariatric surgery in patients with BMI greater than 35 and type 2 diabetes. Although most patients with type 2 diabetes are overweight or obese, around 20% have BMI below 35 and fail to qualify for surgical intervention based on their BMI. They struggle with their chronic disease, which is often poorly controlled by medications alone. Considering the impressive results of bariatric surgery, there is great interest in lowering the BMI threshold for diabetic patients who desire surgical intervention. It has been suggested to lower the surgical threshold BMI to 30, with a reduction to 27 for those of Asian ethnic origin where adverse metabolic effects are seen at a lower BMI.

A meta analysis of all randomized surgical studies looked at the outcomes of surgery in low BMI patients and showed that surgery can be effective in this group. The Diabetes Surgery Summit II in 2015 gathered the leading international diabetes organizations and surgical societies together and recommended that patients with BMI greater than 30 and diabetes that is poorly controlled with medications should also be considered for surgery. There is no consensus, however, about the best surgical procedure for these patients. In a randomized study from Taiwan involving diabetic patients with BMI of 25 to 34, RYGB was shown to be more effective than SG in achieving diabetes remission (95% vs 47%). The mean postoperative BMI was 22.8 for RYGB and 24.4 for SG, confirming that the patients do not experience excessive weight loss and their postoperative weight remains within normal range. The Diabetes Surgery Summit II's recommendations, which was endorsed by more than 40 international societies, was that patients with BMI greater than 30 and poorly controlled diabetes on

TABLE 4 Proposed Mechanisms for Antidiabetic Effects of RYGB and Other Similar Procedures

Restriction and acute decrease in food intake after surgery	Unlikely. Food intake is reduced after many GI surgeries where patients are kept off by mouth. Most these surgeries however lead to a state of insulin resistance rather than sensitivity.
Malabsorption	Unlikely. No evidence that RYGB leads to enough nutrient malabsorption to account for the rapid improvement in diabetes.
Changes in post-prandial incretin response	Post-prandial GLP-1 levels are increased after these surgeries leading to enhanced insulin release. This is likely due to earlier delivery of food to the distal small bowel where GLP-1 is primarily secreted.
Isolation of proximal bowel from nutrient flow	Evidence points to a role for proximal bowel in sensing nutrient availability and quality. Isolation of this region of the intestine from nutrient exposure can lead to alterations in nutrient absorption and glucose homeostasis. This idea is behind some of the metabolic devices in development.
Intestinal gluconeogenesis	Rodent studies have suggested that ability of proximal bowel to generate glucose and release it to the portal circulation leads to changes in hepatic insulin sensitivity and glucose homeostasis. Human studies are lacking.
Changes in circulating bile acids	Human and animal studies have shown increased circulating bile acid levels in patients after RYGB, and linked this to improved glucose homeostasis.

GI, Gastrointestinal; GLP-1, glucagon-like peptide-1; RYGB, Roux-en-Y gastric bypass.

medication should also be considered for surgery. However, despite this recommendation, surgery is rarely used in this patient group, and bariatric surgical procedures are not covered in low BMI patients by most insurance providers in the United States.

Adolescent Bariatric and Metabolic Surgery

Childhood obesity has more than doubled in children and quadrupled in adolescents in the past 30 years. Studies have also shown that childhood obesity is strongly linked to adult obesity and that obese youth are more likely to have risk factors for cardiovascular disease, such as high cholesterol or hypertension. In a population-based sample of 5- to 17-year-olds, 70% of obese youth had at least one risk factor for cardiovascular disease. Current estimates predict a decrease in life expectancy in obese adolescents of 5 to 20 years depending on additional risk factors such as race and sex. Although studies are limited, current data suggest bariatric surgery is as safe in adolescents as it is in adults, having similar success in both weight reduction and resolution of metabolic derangement. Because of the paucity of long-term outcome data, the role of bariatric surgery in the pediatric patient remains controversial. When pediatricians were polled, even for adolescents with life-threatening comorbidities, half of the respondents would not refer their patients who are under 18 years of age for bariatric surgery.

In a study of 541 adolescent (12–19 years) patients undergoing bariatric surgery, mean age was 17 years, with a BMI of around 50. The most common procedure was LSG, followed by RYGB and LAGB, with mean BMI changes of −28%, −31%, and −18%, respectively, at 1 year. For RYGB and SG, BMI changes of −29% and −25% were maintained at 3 years. In a prospective study of 242 adolescent patients in the United States (Teen Label) similar weight loss rates were reported at 3 years, along with improvements to cardiometabolic health and weight-related quality of life.

Alternative Surgical Procedures

The surgical rearrangement of gastrointestinal anatomy is thought to be critical to the metabolic success of most bariatric procedures. This includes (1) isolation of duodenum and proximal bowel from nutrient exposure and (2) earlier exposure of distal bowel and ileum to undigested food (Table 1). Some surgical groups have worked on developing alternative novel procedures that achieve one or both of these goals and could have therapeutic value to diabetic patients with low BMI. Of these procedures, duodenal-jejunal bypass and ileal interposition with or without sleeve gastrectomy have received the most attention and been tested in human subjects with good early results. These procedures are, however, complex, and it is not clear whether they offer any advantages in terms of effectiveness, durability, or safety over the more standard procedures such as RYGB.

Endoluminal Devices

With the recognition that gastrointestinal manipulation can lead to improvements in glycemic control, several endoluminal devices are in development with the goal of replicating the metabolic success of bariatric procedures without the need for an invasive procedure. There are many such devices in various stages of development, and a few have received regulatory approval. This reduction will herald an era when diabetes management will not be only handled by endocrinologists, but also by surgeons who will help manage the obese diabetics by means of surgery, as well as advanced interventional endoscopists who will deploy the endoluminal devices to manage the patients with poorly controlled diabetes who do not qualify for surgery or wish to avoid it.

Cardiovascular Disease Risk Reduction After Bariatric Surgery

Essa M. Aleassa, MD, Ali Aminian, MD, and Philip R. Schauer, MD

Cardiovascular disease (CVD) is a summative term that relates to diseases of the heart and blood vessels. Examples of these diseases include coronary artery disease, heart failure, stroke, hypertension, and cardiomyopathy. The Centers for Disease Control and Prevention data, through the National Health and Nutrition Examination Survey 2013 to 2016, estimated that 48% of adults older than 20 years were affected by CVD. The prevalence of CVD excluding hypertension is 9%. The prevalence is elevated with increasing age. Although the mortality rate owing to the different CVD entities vary, collectively they are responsible for more deaths than cancer and trauma. Coronary heart disease is the most common (43.2%) cause of CVD related death followed by stroke (16.9%), hypertension (9.8%), and heart failure (9.8%).

The health care and economic burden of CVD on the community are major. The Healthcare Cost and Utilization Project tallied more than 8 million admissions in 2014 and 88 million outpatient visits, and 4.7 million emergency department encounters in 2015 related to a primary diagnosis of CVD. CVD is among the leading conditions filed for disability in the United States. The American Heart Association projected that by the year 2035, CVD will affect 45% of the United States population in some form, with total medical cost cost to be around $1.1 trillion.

Risk factors leading to CVD are well established, among which is obesity. It is considered an independent risk factor, especially when the obesity is most pronounced in the trunk, otherwise known as central obesity. This chapter will shed light on the relationship between central obesity and CVD. Furthermore, it will discuss the effect of bariatric and metabolic surgery on CVD risk factors and actual reduction of cardiovascular events such as myocardial infarction, stroke, and death.

medication should also be considered for surgery. However, despite this recommendation, surgery is rarely used in this patient group, and bariatric surgical procedures are not covered in low BMI patients by most insurance providers in the United States.

Adolescent Bariatric and Metabolic Surgery

Childhood obesity has more than doubled in children and quadrupled in adolescents in the past 30 years. Studies have also shown that childhood obesity is strongly linked to adult obesity and that obese youth are more likely to have risk factors for cardiovascular disease, such as high cholesterol or hypertension. In a population-based sample of 5- to 17-year-olds, 70% of obese youth had at least one risk factor for cardiovascular disease. Current estimates predict a decrease in life expectancy in obese adolescents of 5 to 20 years depending on additional risk factors such as race and sex. Although studies are limited, current data suggest bariatric surgery is as safe in adolescents as it is in adults, having similar success in both weight reduction and resolution of metabolic derangement. Risk factors leading to CVD are well established, among which is obesity. It is considered an independent risk factor, especially when the obesity is most pronounced in the trunk, otherwise known as central obesity. This chapter will shed light on the relationship between central obesity and CVD. Furthermore, it will discuss the effect of bariatric and metabolic surgery on CVD risk factors and actual reduction of cardiovascular events such as myocardial infarction, stroke, and death.

BOX 1 Cardiovascular Disease Risk Factors, Including Major Independent Factors Accounted for in the Framingham Risk Score*

Traditional Nonmodifiable

- Age (men >45 years; women >55 years)†
- Family history of premature CHD (CHD in male first-degree relative age <55 years; CHD in female first-degree relative age <65 years)
- Sex
- Race

Traditional Modifiable

- Smoking‡
- High blood pressure (blood pressure >140/90 mm Hg or on antihypertensive medication)‡
- High cholesterol (low HDL cholesterol [<40 mg/dL])‡
- Diabetes
- Prediabetes

Emerging Nontraditional Cardiovascular Disease Risk Factors (Associated With Visceral Obesity)

- Insulin resistance/hyperinsulinemia
- Dyslipidemia with elevated triglycerides, low HDL cholesterol, and increased apolipoprotein B serum concentrations
- Procoagulation and abnormal fibrinolysis with increased serum fibrinogen concentrations and increased production of plasminogen activator inhibitor
- Inflammation with increased serum levels of C-reactive protein, tumor necrosis factor, interleukin-6
- Endothelial dysfunction
- Premature atherosclerosis
- Microalbuminuria

*The current version of the Framingham Risk Score (FRS) was published in 2008. The score is used to estimate the 10-year cardiovascular risk of an individual based on data obtained from the Framingham Heart Study. The score is sex specific. Individuals with low risk have 10% or less CHD risk at 10 years, those with intermediate risk have 10% to 20% CHD risk, and those with high risk have >20% CHD risk. In the current version of the FRS, diabetes was removed from the score, if a person has type 2 diabetes, he or she is classified as having a CHD risk equivalent.

†Black race is a risk factor for CVD, but it is not included in the FRS.

‡Smoking, high blood pressure, and low HDL cholesterol are modifiable risk factors that are included in the FRS.

CHD, Coronary heart disease; CVD, cardiovascular disease; FRS, Framingham Risk Score; HDL, high-density lipoprotein.

TABLE 1 International Diabetes Federation Criteria for Metabolic Syndrome

International Diabetes Federation defines metabolic syndrome as the presence of central obesity* (defined as waist circumference by ethnicity plus two of the following four factors)	
Raised triglycerides	>150 mg/dL (1.7 mmol/L) or specific treatment for this lipid abnormality
Reduced HDL cholesterol	<40 mg/dL (1.03 mmol/L) in men <50 mg/dL (1.29 mmol/L) in women or specific treatment for this lipid abnormality
Raised BP	Systolic BP >130 or diastolic BP >85 mm Hg
Raised fasting plasma glucose	>100 mg/dL (5.6 mmol/L) or previously diagnosed type 2 diabetes If >5.6 mmol/L or 100 mg/dL, oral glucose tolerance test is strongly recommended but is not necessary to define presence of the syndrome

*If body mass index is >30 kg/m², central obesity can be assumed and waist circumference does not need to be measured.

BP, Blood pressure; HDL, high-density lipoprotein cholesterol.

BOX 2 Diagnostic Criteria for Metabolic Syndrome as Defined by the National Cholesterol Education Program Adult Treatment Panel III

Three or more of the following five cardiovascular risk factors:

1. Central obesity (waist circumference >102 cm in men; >88 cm in women)
2. Hypertriglyceridemia: triglycerides >1.7 mmol/L (>150 mg/dL)
3. Low high-density lipoprotein: <1.03 mmol/L (<40 mg/dL) in men; <1.29 mmol/L (<50 mg/dL) in women
4. Systemic hypertension: blood pressure >130/85 mm Hg or medication
5. Elevated fasting plasma glucose: glucose >5.5 mmol/L (>100 mg/dL)

CARDIOVASCULAR DISEASE RISK FACTORS

Overview

CVD risk factors have been extensively studied and can be divided into traditional and nontraditional risk factors. Furthermore, the traditional risk factors can be subclassified into modifiable and nonmodifiable (Box 1). Population-based studies have revealed that most CVD is due to lifestyle-related risk factors such as dietary risks, low level of physical activity, and tobacco smoking. Other risk factors are high systolic blood pressure, triglyceride cholesterol levels, fasting plasma glucose (FPG) levels, and body mass index (BMI). In 2012, Fryar and colleagues had estimated that approximately 47% of the United States population already had one of three risk factors for CVD, that is high blood pressure, tobacco smoking, and high cholesterol levels.

Traditional nonmodifiable risk factors for CVD are increasing age, sex, race, and family history of premature coronary heart disease. Men are at higher risk of CVD. Patient sex also dictates the age cut-off as to when the risk for CVD increases (>45 years for men and >55 years for women). Patients of black race are at a higher risk for CVD than their white race counterparts. Having a family history of CVD in a first-degree family member increases the risk for CVD. This appears to be more pronounced in certain ethnicities.

Metabolic Syndrome

Metabolic syndrome, previously known as syndrome X, is a cluster of conditions that lead to CVD and type 2 diabetes. The International Diabetes Federation (IDF) revised the term to metabolic syndrome. Metabolic syndrome is diagnosed by the presence of central obesity and two or more metabolic risk factors. These risk factors are high systolic blood pressure, triglyceride cholesterol levels and FPG, and low high-density lipoprotein (HDL) cholesterol (Table 1). National Cholesterol Education Project Adult Treatment Panel uses similar clinical criteria to define metabolic syndrome (Box 2). The prevalence of metabolic syndrome in the United States is estimated to be 34.2%. The prevalence increases with age affecting >43% of patients aged 65 years or older. It has been shown that metabolic syndrome substantially increases risk for CVD (relative risk [RR], 1.78; 95% confidence interval [CI], 1.58 to 2.00). Furthermore, all-cause mortality was higher in patients with CVD in the presence of metabolic syndrome (RR, 1.58; 95% CI, 1.38 to 1.78).

Diabetes Mellitus

Diabetes mellitus is an endocrine disorder in which blood glucose level is dysregulated. It is further subclassified by the pathogenesis of the dysregulation. More than 98% of diabetes mellitus is of type 2. In type 2 diabetes, insulin is produced by the pancreas but is inadequate to maintain normal glucose levels due to insulin resistance in body tissue. Type 2 diabetes is a major risk factor for CVD. The prevalence of type 2 diabetes has been increasing with an upward annual trend by 30.5%. Of note, approximately 80% of youth with type 2 diabetes have obesity. The prevalence of type 2 diabetes has been up trending among adults as well, regardless of the sex and ethnicity. Diabetes is associated with microvascular and macrovascular complications that can eventually lead to CVD. Furthermore, a longitudinal study conducted by the National Health Interview Surveys enrolled patients with and without diabetes between 2000 and 2009 and followed them through 2011. It concluded that patients with diabetes had a higher overall and CVD-related mortality as compared to patients without diabetes.

Obesity

Central obesity is determined by the measurement of the waist circumference. The waist circumference is sex and ethnic group–specific. However, based on the IDF definition, patients with a BMI of 30 kg/m^2 or greater are assumed to have central obesity and do not require waist circumference measurement. Obesity has been recently declared as a chronic disease, not merely a risk factor. The prevalence of obesity has been increasing over the past decades. Its prevalence in 2016 was 18.5% and 39.6% of the youth and adult population in the United States, respectively. Obesity is classified by the severity of the BMI calculated as kilograms per square meter. Normal BMI is less than 25 kg/m^2, whereas overweight and obesity are diagnosed with BMIs of 25 to 29.9 kg/m^2 and 30 kg/m^2 or greater, respectively.

BOX 3 Cardiovascular Conditions Associated With Obesity

- Early and accelerated atherosclerosis
- Hypertension
- Myocardial infarction or acute coronary syndrome
- Structural heart changes and congestive heart failure
- Atrial fibrillation
- Sudden cardiac death
- Stroke

Obesity is associated with many other comorbidities (Box 3). Its presence specifically increases the lifetime risk for CVD, type 2 diabetes, hypertension, sleep apnea, and venous thromboembolism. Overall obesity has been linked to increased all cause mortality (hazard ratio [HR], 1.18; 95% CI, 1.12 to 1.25). This might be explained by the increased risk for other comorbidities that accompany weight gain. When the different ranges of weight were compared side by side in young adults, the higher the weight class the higher the HR was for mortality. Moreover, patients with overweight, obesity, and extreme obesity had HR of 1.07 (95% CI, 0.94 to 1.2x), 1.41 (95% CI, 1.16 to 1.73), and 2.46 (95% CI, 1.91 to 3.16), respectively.

Effect of Weight Loss on Cardiovascular Disease Risk

Lifestyle-Induced Weight Loss

Obesity has been established as an independent risk factor for CVD. Furthermore, weight loss has been linked to improvement of the CVD risk factors individually; that is decrease in BMI, systolic blood pressure, triglyceride levels, and fasting blood glucose. Weight loss strategies are numerous. Weight loss of any degree is encouraged as every pound lost may potentially decrease the risk for CVD. This notion stems from lifestyle intervention studies such as the Look AHEAD (Action for Health in Diabetes) trial. The Look AHEAD trial is the largest trial of its kind. It aimed to assess the benefit of lifestyle induced weight loss on CVD risk factors. The study enrolled 3165 patients with type 2 diabetes and overweight and obesity. The participants were randomly assigned to either intensive lifestyle intervention or to diabetes support and education. The patients were followed up for 4 years. The initial results of the study published in 2013 showed that patients who lost at least 5% to 10% of their excess body weight had an improved CVD risk factors profile. This was reflected in decrease in BMI, systolic blood pressure, diastolic blood pressure, and triglycerides. An increase in HDL cholesterol was also noted (Table 2). However, an improved CVD risk profile does not necessarily equate with absolute risk reduction. The 10 year Look AHEAD follow up study in 2014 showed that weight loss by lifestyle intervention compared with the control group (6% vs 5.5%) did not reduce the rate of cardiovascular events in patients with obesity and type 2 diabetes.

Drug-Induced Weight Loss

Medical weight loss using drugs has been on the rise. Their use has been limited due to cardiovascular and central nervous system adverse effects. However, a few drugs have been recently investigated

TABLE 2 Mean Changes in Weight and Cardiovascular Disease Risk Factors in Intensive Lifestyle Intervention and Diabetes Support and Education Groups, and the Difference Between Groups Averaged Over 4 Years as Reported in 2010 by the Look AHEAD Group

Measure	Diabetes Support and Education	Intensive Lifestyle Intervention	Between-Group Mean Difference	P value
Weight, % initial weight	−0.68	−6.15	−5.7	<.001

for cardiovascular safety such as lorcaserin, orlistat, and liraglutide. These medications have been Food and Drug Administration approved for patients with CVD. Use of orlistat has been associated with improvement of systolic and diastolic blood pressure and lipid profile. This is believed to be secondary to weight loss. Liraglutide was found to decrease cardiovascular events in a population with type 2 diabetes. The study concluded that the reduction in cardiovascular events was not exclusive for patients with obesity, therefore weight loss alone may not necessarily be the only driver of CVD risk reduction with this agent. Although lorcaserin has been established to be safe in patients with CVD, it is unknown if it has a positive effect on CVD.

Metabolic and Bariatric Surgery: Overview of Common Procedures (Fig. 1)

Metabolic and bariatric surgery, unlike lifestyle intervention and weight loss medications, have been shown to decrease weight substantially. Ample evidence exists on the benefit of metabolic and bariatric surgery in improving the cardiovascular risk profile and metabolic diseases. This benefit has also been translated to improved quality of life and overall survival, although randomized controlled cardiovascular outcome trials have yet to be conducted. Bariatric and metabolic surgery are believed to improve cardiovascular risk profile through weight loss and perhaps other mechanisms such as reduced inflammation. The operative safety

TABLE 3 Weight Loss and Resolution Rates of Obesity-Associated Comorbidities after Weight Loss Surgery According to Procedure Performed as Summarized by a 2004 Systematic Review of 22,094 Patients

	Gastric Banding	Gastric Bypass	BPD or DS	Total
Excess weight loss	47%	62%	70%	61%
Resolution of type 2 diabetes	48%	84%	99%	77%
Resolution of hyperlipidemia	38%	67%	91%	79%
Resolution of hypertension	47%	68%	83%	62%
Resolution of sleep apnea	95%	80%	97%	86%

of metabolic and bariatric procedures has been established. Moreover, most procedures can be performed laparoscopically. These procedures differ in their effect magnitude and durability of weight loss and the degree of metabolic disease resolution (Table 3). They also have different risk profiles that needs to be included in the informed consent (Table 4).

Effect of Bariatric Surgery on Cardiovascular Disease Risk Factors

Improving glucose and lipid metabolism and systemic inflammation are among the principal biochemical mechanisms by which bariatric surgery reduces CVD risk. The surgically induced weight loss and associated blood pressure improvement also contribute independently to decreasing CVD risk.

Glycemic Control

Insulin resistance and type 2 diabetes mellitus are remarkably improved after bariatric surgery. In 1995, a landmark article by Pories and colleagues described the durable effect of bariatric surgery in controlling type 2 diabetes mellitus. Since then, many reports have emerged confirming the therapeutic effect of the various bariatric procedures in patients with prediabetes (with impaired fasting glucose) and type 2 diabetes.

In fact, bariatric surgery has been shown to improve insulin sensitivity and play a role in prevention by halting the development of diabetes in patients with prediabetes. Currently, the mechanisms for such postoperative improvement in glucose metabolism as a function of time remain an active area of research. Clinically, however, improved glycemic control occurs within days after surgery, even when the amount of weight loss is insufficient to explain the observed improvement. In one series, Schauer and colleagues reported immediate postoperative independence from oral hypoglycemic agents on discharge from hospital after Roux-en-Y gastric bypass (RYGB) in 30% of patients who were on such medication preoperatively. What is more remarkable than the ability of bariatric surgery to completely reverse established diabetes is the ability to put the condition into remission for prolonged periods of time. In a study published by Pories and colleagues, 83% of 146 patients with diabetes experienced remission on a mean follow-up of 9.6 years after RYGB.

The best evidence for the durability of remission over time comes from a large scale controlled observational study, the Swedish Obese Subjects (SOS) project. This study showed reversal of diabetes in 72.3% of the surgical group as compared with just 16.8% of the control group at 2 years of follow-up (odds ratio [OR], 48.5; 95% CI, 21.9 to 78.2; $P < .001$). The durability of this remission was related to maintenance of weight loss. At 15 years, as weight regain was observed, diabetes remission rates remained impressive but were decreased to 30% in the surgical group and 6.3% in the controls (OR, 6.3; 95% CI, 2.1 to 18.9; $P < .0012$).

Meta-analyses of smaller scale studies also demonstrate the durability of diabetes remission after bariatric surgery. A 2009 meta-analysis by Buchwald and colleagues reviewed the results of 621 studies and observed an overall 78.1% resolution of clinical manifestations of diabetes after surgery, noting that the proportion of patients with diabetes resolution or improvement was similar before or after 2 years of follow-up. Diabetes resolution was reported to be the greatest for patients undergoing biliopancreatic diversion (BPD) with duodenal switch (95.1%), followed by RYGB (80.7%), and adjustable gastric banding (AGB) (54.7%). A limitation of this study rests in the use of clinical reports of diabetes remission rather than hard biochemical markers of glucose control.

The American Society for Metabolic and Bariatric Surgery (ASMBS) recently published a position statement that systematically reviewed medium- and long-term durability of weight loss and diabetic outcomes after bariatric surgery. The position statement concluded that more than 50% of patients with RYGB had sustained remission on 15 year follow-up.

Strong evidence for the superiority of bariatric surgery to conventional medical therapy in achieving improved glycemic control in diabetic patients is accumulating. We now have evidence from many well-designed randomized controlled trials (RCTs) that address this question using hard biochemical markers of glucose metabolism, such as FPG and hemoglobin A_{1c} (HbA_{1c}) as endpoints. In 2008, Dixon and colleagues found that remission of diabetes was significantly higher in patients who underwent laparoscopic adjustable gastric banding (LAGB) than in those who received standard treatment (73% vs 13%) when comparing a surgical group of 30 patients with diabetes to a matched control group of 30 patients over 2 years based on achieving an HbA_{1c} less than 6.2%, an FPG less than 7 mmol/L, and no antidiabetic medications. In 2012, Schauer and colleagues released the first report from the Surgical Therapy and Medications Potentially Eradicate Diabetes Efficiently randomized clinical trial. This study randomly assigned 150 patients with type 2 diabetes mellitus (mean age, 49 years; 48% women; mean preoperative HbA_{1c} 9.2%), with equal duration of diabetes before surgery, between intensive medical therapy alone versus medical therapy plus RYGB, or sleeve gastrectomy (SG), placing 50 patients in each of the three groups. After 1 year, weight loss was greatest in the RYGB group, and an HbA_{1c} less than 6% (primary endpoint) was achieved in 42% of patients after RYGB, in 37% after SG, and in only 12% after medical therapy. Two year follow-up results, published in 2017, showed weight loss of −23%, −19%, and −5% for RYGB, SG, and medical therapy, respectively. With that, HbA_{1c} less than 6% was achieved in 22.4%, 16.9%, and 0 patients after RYGB, SG, and medical therapy, respectively. Also in 2012, Mingrone and colleagues published results of their study on bariatric surgery versus conventional medical therapy for type 2 diabetes mellitus. Their primary endpoint was diabetes remission at 2 years as measured by an FPG less than 5.6 mmol/L and an HbA_{1c} less than 6.5% in the absence of diabetic drug therapy. Patients (mean age 45.4 years; 47% women; mean preoperative HbA_{1c} 8.65%) were randomly assigned between RYGB, BPD, and medical therapy. Better glycemic control was observed in the surgical groups after 2 years, and although diabetes remission rates were 95% and 75% after BPD and RYGB, respectively, no remission was seen in the medical therapy group. An important post hoc analysis also showed that, unlike previously seen with the LAGB in the Dixon and colleagues trial, initial BMI and postoperative weight loss were not predictive of the improvement in hyperglycemia seen after surgery. Furthermore, the 5 year follow-up of Mingrone and colleagues' RCT showed 43%

TABLE 4 Bariatric Procedure-Related Postoperative Complications

Procedure	Complications	
	Early Postoperative Period (< 30-day)	Late
LRYGB	Anastomotic leak with peritonitis Abdominal abscess Pulmonary embolism Bleeding Pulmonary complications Acute distal gastric dilatation Roux limb obstruction Wound infection	Stomal stenosis Marginal ulcer Dumping syndrome Intestinal obstruction Internal hernia Incisional hernia Cholecystitis Vitamin and mineral deficiencies Weight regain Hypoglycemia
LBPD ± DS	Same as LRYGB	Same as LRYGB with the following being more common in the BPD procedure than in RYGB if aggressive prophylactic measures are not followed postoperatively: Anemia Protein calorie malnutrition Vitamin B_{12} deficiency Hypocalcemia Osteoporosis Fat soluble vitamin deficiency Night blindness
LSG	Staple line leak Abscess Hemorrhage Sleeve stricture Wound infection	Intractable nausea ± vomiting Reflux symptoms Gastric dilation Weight loss failure Weight regain
LAGB	Hemorrhage Wound infection Food intolerance Reflux Nausea ± vomiting Slippage Wound infection	Reflux symptoms Erosive esophagitis Esophageal dilation Pouch enlargement Band slippage Gastric prolapse Vomiting Tubing-related problems Leakage of the reservoir Band erosion Weight loss failure Lower average weight loss

BPD, biliopancreatic diversion; LAGB, laparoscopic adjustable gastric banding; LBPD ± __, laparoscopic biliopancreatic diversion with or without duodenal switch; LRYGB, laparoscopic Roux-en-Y gastric bypass; LSG, laparoscopic sleeve gastrectomy; RYGB, Roux-en-Y gastric bypass.

and 17% of the BPD and RYGB patients, respectively, achieved diabetes remission compared with none of the medical therapy patients. Another prominent long-term RCT was reported by Schauer and colleagues in 2018, that compared intensive medical and lifestyle intervention with and without the addition of RYGB in achieving durable weight loss and improvement of type 2 diabetes. At 5-year follow-up, 95% and 88% of the RYGB and medical therapy patients achieved an HbA_{1c} level of less than 7.0%.

Although bariatric surgery for patients with poorly controlled type 2 diabetes mellitus and BMI 35 kg/m^2 or greater is commonly considered an acceptable therapy, such treatment remains controversial for patients with class I obesity, or BMI between 30 and 35 kg/m^2. In 2011, the IDF released a position statement recognizing the role of bariatric surgery as a treatment option alternative for patients with class I obesity whose diabetes cannot be adequately controlled by optimal medical regimens, especially in the presence of other major CVD risk factors. The American Diabetes Association recommendations with regard to bariatric and metabolic surgery have been evolving over the years to favor surgical management of type 2 diabetes in patients with obesity. Their recently released standard of care guidelines (2019) indicate that surgery for class I obesity and diabetes should be considered in patients who fail to achieve weight loss and resolution of comorbidities with nonsurgical management. In 2018, the ASMBS also reviewed the currently available clinical evidence and released a position statement highlighting the emerging role of bariatric surgery in class I obesity and type 2 diabetes mellitus. The ASMBS summarizes that AGB, SG, and RYGB have all been shown to be safe in randomized trials and are effective in patients with BMI of 30 to 35 kg/m^2 in the short and medium term. It also states that patients with class I obesity who are unable to achieve substantial and durable weight and comorbidity control with nonsurgical therapeutic methods should be considered eligible for surgery.

Lipid Metabolism

As visceral adiposity diminishes and insulin resistance improves after bariatric surgery, so does the metabolic syndrome with its associated components, including dyslipidemia, thereby decreasing CVD risk. In 2008, Ikeda and colleagues performed a population-based retrospective study and showed the prevalence of metabolic syndrome to decrease from 87% to 29% of 100 patients who were surgically treated, whereas the risk reduction was only 10% in the nonsurgical group over a mean follow-up period of 3.8 years. Postoperative improvements in serum lipid profiles have now been documented in numerous reports, and include reductions in total cholesterol, low-density lipoprotein (LDL) cholesterol and triglycerides, and increases in HDL cholesterol. These changes are seen in the majority of patients and are more frequent after procedures with a malabsorptive component. One study by Nguyen and colleagues in 2006, for example, found that 82% of patients on lipid-lowering therapy were off such drugs 1 year after RYGB. A much larger retrospective study performed in 900 patients showed that plasma concentrations of triglycerides, HDL cholesterol, and LDL cholesterol all significantly improved over a similar 1-year time frame after RYGB. Heneghan and colleagues, a smaller study, demonstrated improvement in apolipoprotein B levels as early as 3 months postoperatively. After BPD, long-term 5- to 10-year improvements in dyslipidemia is particularly impressive with resolution rates of 91% to 100% having been reported.

Inflammatory State

Many investigators have now described the favorable modulation of a number of obesity-associated inflammatory markers after bariatric surgery. Adipose tissue is no longer viewed as inert energy storage tissue; it is now appreciated as an endocrine organ, which produces a spectrum of adipokines that have important inflammatory and immune functions. Obesity, particularly the central or abdominal type, is seen as a state of chronic systemic inflammation contributing to various aspects of CVD risk, including accelerated atherosclerosis and endothelial dysfunction. Surgically induced weight loss and the resultant improvement in visceral adiposity, insulin resistance, dyslipidemia, and reduction in inflammatory molecules all contribute to improving the inflammatory state. High-sensitivity C-reactive protein (CRP) levels, for example, show consistent decreases after bariatric procedures by up to 80%. In one study in which over 450 patients were followed for about 1 year, CRP levels were above the 3 mg/dL cut-off level in only 10% of patients postoperatively compared with 50% before RYGB.

Although interleukin (IL)-6 levels have been shown to decrease by up to 41% after bariatric surgery, Brethauer and colleagues observed no such decrease in IL-6 or IL-10 after RYGB in a prospective study of inflammatory markers. Leptin, plasminogen activator inhibitor 1, and CRP levels decreased significantly; however, at 3 and 6 months of follow-up. Fibrinogen and IL-1Ra levels also decreased, and adiponectin significantly increased at 6 months in our study. Adiponectin is an important adipose tissue–derived cytokine, which is decreased in obesity and increased with weight loss surgery anywhere from 30% to 140% in some reports. The function of adiponectin is not fully understood at this time, but it correlates positively with improved insulin sensitivity. It can also cause vasodilation by stimulating nitric oxide in endothelial cells and contribute to decreased atherogenesis and CVD risk.

Effect of Bariatric Surgery on Cardiovascular Disease and Mortality

It is now recognized through multiple observational studies that surgically induced weight loss is associated with a reduction in overall mortality (Table 2). The strength of available evidence varies and is limited by study design, surgical procedure, and patient selection. In 2004, the McGill Bariatric Cohort Study was among the first to report that a 67% excess weight loss at 5 years was associated with an HR reduction for mortality of 89% in a retrospective case-control analysis comparing over 1000 patients surgically treated to over 7000 controls with normal BMI. A retrospective study from the University of Utah also showed a survival advantage to their surgical group after RYGB with a mean follow-up of 7.3 years: the adjusted long-term mortality in the surgical cohort of 7925 patients decreased by 60% compared with the same size matched control group (HR, 0.4; $P < .001$). Coronary artery disease–related mortality decreased by 56% in the surgical cohort in this retrospective case-control matched study. Survival benefits were even demonstrated by others in higher-risk Medicare patients with 2-year follow-up data; specifically, a survival advantage was seen as early as 6 months postoperatively in the younger than 65 years age group and as early as 11 months in the older than 65 years age group.

Despite the evidence from observational studies for improved CVD risk profile and survival in general after bariatric surgery, what remains to be established is whether this risk reduction translates into decreased incidence of CVD and related mortality. The best evidence to address this question at present comes from the SOS project. The SOS study is a nonrandomized, matched, prospective observational study in which more than 4000 patients were enrolled and followed over time in Sweden. Reports on the primary endpoint (overall mortality) of the SOS project were published in 2007 (Fig. 2). A 23.7% overall unadjusted (20.7% adjusted) mortality decrease was observed in patients with bariatric surgery at 10 years compared with a well-matched nonsurgical control population. This improvement in overall mortality after bariatric surgery, along with the repeated observations of the beneficial effect of such surgery on diabetes, dyslipidemia, and hypertension, suggests that bariatric surgery directly influences CVD. In fact, the most recent report from the SOS project described the impact of obesity surgery on the predefined endpoints of myocardial infarction and stroke, reported as fatal and total (fatal and nonfatal) cardiovascular event incidence rates (Fig. 3). The study groups included 2010 patients with bariatric surgery (BMI: >34 kg/m^2 in men; BMI >38 kg/m^2 in women) receiving gastric bypass (15.2%), gastric banding (16.2%), or vertical banded gastroplasty (68.1%), and 2037 contemporaneously matched controls with obesity receiving usual medical care. Over a median follow-up of 14.7 years (range 0 to 20 years), bariatric surgery was associated with a reduction in the number of cardiovascular deaths and first time cardiovascular events (fatal or nonfatal), after controlling for the cardiometabolic risk profile at baseline. Compared with controls, the adjusted HR of bariatric surgery for fatal cardiovascular events was 0.47 (95% CI, 0.24 to 0.83; $P < .001$); for fatal cardiovascular events, the adjusted HR of 0.47 (95% CI, 0.29 to 0.76; $P = .02$). It is noteworthy that weight loss was only approximately 16% at 15 years in the treatment group, whereas over time the control group showed weight changes around a maximum of 7%. Interestingly, secondary subgroup analyses of the SOS data failed to demonstrate an association between initial BMI and postoperative health benefits of bariatric surgery. Even the magnitude of surgery-induced weight loss did not predict cardiovascular events in this cohort. This puts into question the current clinical practice of using BMI as a main indication and eligibility criteria for bariatric surgery, when cardiovascular benefits are realized independent of differences and changes in body weight. Further post hoc analysis of the SOS data revealed that, unlike baseline BMI or the magnitude of postoperative weight loss, a high baseline insulin level was in fact a predictor of cardiovascular events in the study. This suggests that weight-independent mechanisms rather than the magnitude of weight loss alone may explain part of the cardiometabolic benefits of surgery. Moreover, Carlsson and colleagues have shown in a recent meta-analysis published in 2017, that patients postbariatric surgery were at a lower risk of dying from CVD compared with patients who did not have bariatric surgery (HR, 0.42; 95% CI, 0.25 to 0.72; $P < .001$).

Very recently, Aminian and colleagues, in a cohort study of 13,722 patients with obesity and diabetes (including 2287 patients who underwent metabolic surgery and 11,435 matched controls), showed that metabolic surgery compared with usual care was associated with a significantly lower risk of major cardiovascular events, including coronary events, cerebrovascular events, heart failure, atrial fibrillation, nephropathy, and all-cause mortality (HR, 0.61; 95% CI, 0.55 to 0.68; $P < .001$).

B

FIG. 2 (A) Overall mortality reported in the Swedish Obese Study comparing persons who underwent surgical intervention versus controls. (B) Univariate mortality. The hazard ratio for subjects who underwent bariatric surgery as compared with control subjects was 0.76 (95% confidence interval, 0.59 to 0.99; P = .04) with 129 deaths in the control group and 101 deaths in the surgery group.

To gain further insight into the role of bariatric surgery in reducing CVD risk and improve cardiac structure and function, Yeat and colleagues performed and published a systematic review of over 19,500 patients with bariatric surgery in 33 clinical studies. Although diagnostic criteria, cardiovascular risk factor reporting, and cardiac imaging parameters varied across published reports evaluated by the review, useful results were summarized: baseline preoperative prevalence of hypertension, diabetes, and hyperlipidemia were 44%, 19%, and 44%, respectively. On mean follow up of 38 months (3 to 156 month range), an average of 34% excess weight loss was reported, and this was associated with a postoperative resolution/improvement of hypertension, diabetes, and hyperlipidemia in 63%, 73%, and 62% of patients, respectively. What is most remarkable about the review is that echocardiographic data from 715 patients were summarized and evidence for significant improvements in left ventricular function, with regression in hypertrophy after surgery and improved diastolic function, was observed. This adds to current evidence that bariatric surgery enhances future

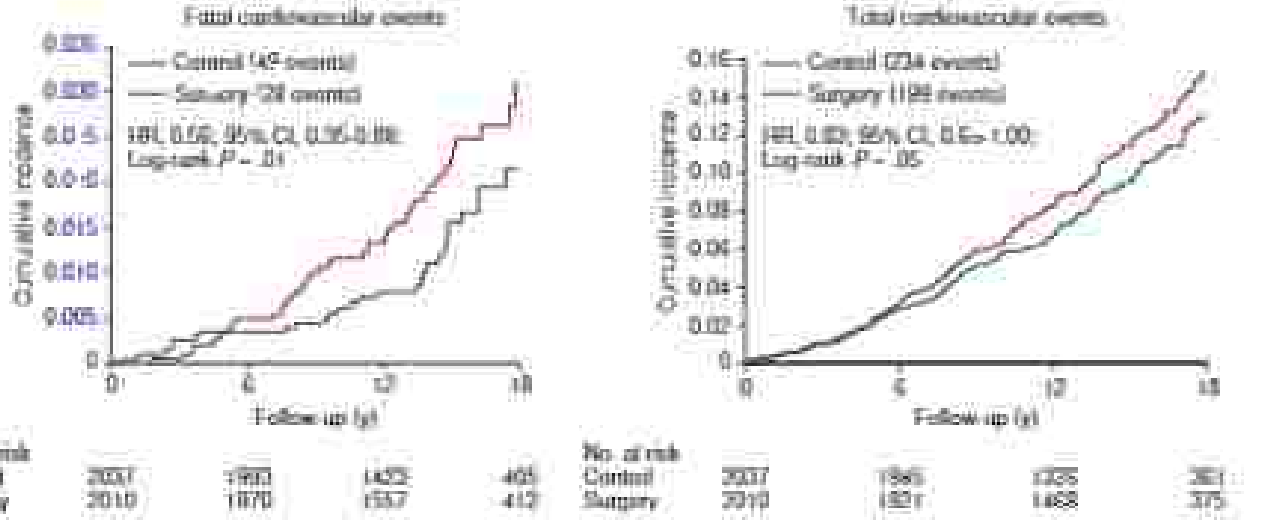

FIG. 2 Review of the key results from the Swedish Obese Subjects (SOS) trial—a prospective controlled intervention study of bariatric surgery. Cumulative incidence of fatal and total cardiovascular events (myocardial infarction + stroke) in the control and surgery groups of the SOS study (*left*). Fatal cardiovascular events (myocardial infarction + stroke) in control subjects and patients undergoing surgery during follow-up for up to 18 years. *Right*, Total cardiovascular events, that is fatal or nonfatal events, in control and surgery patients for up to 18 years. Calculations are based on data available on July 1, 2011. (*From* Sjöström L, Peltonen M, Jacobson P, et al. Bariatric surgery and long-term cardiovascular events. *JAMA*. 2012;307[1]:56-65.)

cardiovascular health and may in fact be doing so by having direct physiologic and organ effects on the heart.

A recent nationwide study by Ahmed and colleagues assessed the effect of having a history of bariatric surgery on the length of stay and mortality in patients admitted with a primary diagnosis of heart failure exacerbation. The study showed that patients with a history of bariatric surgery had a significantly lower mortality rate and length of hospital stay compared with patients with no history of bariatric surgery (0.96% vs 1.86%; OR, 0.52; 95% CI, 0.35 to 0.77; $P = .001$). Moreover, these favorable outcomes persisted when matching patients by propensity score (0.86% vs 1.86%; OR, 0.52; 95% CI, 0.35 to 0.77; $P = .001$).

CONCLUSIONS

The pandemics of obesity, diabetes, and CVD have multifactorial impact on individuals and societies. The surgeon's current role in addressing this pandemic cannot be underrated as research into improving therapeutic interventions, understanding mechanisms of bariatric procedures, and developing preventive strategies continue. Beyond weight loss, bariatric surgery is proving to have remarkable metabolic and cardiovascular effects in the short and long term and its safety profile continues to improve. Recently, national and international societies have started to advocate a role for bariatric surgery even in patients with class I obesity with poorly controlled type 2 diabetes mellitus, especially in the presence of other CVD risk factors. Results of large-scale systematic reviews and important long-term prospective studies, like the SOS study, all point to the important role of bariatric surgery in improving cardiovascular risk profile and decreasing the overall incidence of cardiovascular events in patients with severe obesity over long follow-up. However, many clinicians and investigators alike argue that clear and convincing evidence of cardiovascular risk reduction after bariatric surgery remains elusive until such time that a well-conducted RCT provides definitive supporting evidence. Regardless of the reality of conducting such a definitive trial, surgeons and scientists will continue to find innovative ways to study and serve patients with severe obesity and CVD.

NONMELANOMA SKIN CANCERS

Paul N. Manson, MD, and Michael P. Grant, M[illegible] CS

[illegible]

RISK FACTORS AND PRECURSER LESIONS

Risk factors for BCC and SCC include a number of carcinogens. The most agreed on is sunlight. Cumulative exposure to sun, especially [illegible] tropical sun without protection, in fair skinned individuals who burn rather than tan, is the most generally discussed and accepted risk. Although there is a clear relationship between sun exposure and the incidence of nonmelanoma skin cancers, clinicians debate the exact relationship, and most agree that the relationship to the development of SCC is linked more closely than is BCC. Patients who have had sun lamp treatment for psoriasis are especially prone to skin SCC. Some individuals believe that microtrauma to the skin contributes to the etiology of skin BCC. We know that tumors are more common on sun-exposed surfaces such as the face, scalp, and neck; we also know that radiation exposure, such as that commonly delivered at one time for acne in teenagers, also predisposes to the development of cases of skin cancer and thyroid cancer.

Certain lesions are assumed to be precancerous. Actinic keratoses (AKs) are red, crusty lesions that erupt and sometimes develop cutaneous horn proliferation or thick layers of scaly skin. They have an incidence of in situ and invasive squamous cell skin cancer development of at least 1.0%. Treatment of these lesions with destructive treatments such as liquid nitrogen, curettage, or excision seems reasonable in appropriate patients. Others believe that topical chemotherapy such as 5-fluorouracil can eliminate superficial lesions.

Because sun exposure has been implicated in the predisposition to these lesions, there has been considerable attention to programs aimed toward preventing excess exposure, especially sunburns. Two guides to this prevention are "Safe Sun Guidelines" and "Skin protection from Ultra Violet Light exposure." The exact effectiveness of this prophylaxis is not known but under study.

We also know that genetics may contribute to the development of these lesions. There are hereditary conditions such as basal cell nevus syndrome that predispose to the development of hundreds of multiple cutaneous basal cell skin cancers. Northern Europeans, such as those of Irish and English heritage, also seem more prone to the development of skin cancer. Mutations in oncogenes (RAS and p53) have been implicated with the sonic hedgehog signaling pathway for BCC. The *PTCH* (patched) gene on chromosome 9Q has been suggested in the genesis of these lesions as well.

Recent literature has emphasized higher risk lesions in the BCC and SCC groups that predisposed to incomplete resection, and therefore lesion persistence, recurrence, and metastasis. These are described later in this chapter so that they may be treated with more gentle evaluation with greater attention to complete clearance.

Finally, we know that immune suppression, such as that used for organ transplantation, leads to a greatly increased frequency of cutaneous skin cancer after a period of 10 to 15 years. It is not unusual for these individuals to finally suffer lethal aggressive skin cancers as a result of this immunosuppression. Those who are immunosuppressed

also tend to experience more aggressive lesions, which are less differentiated, have a higher recurrence rate, and a lower cure rate.

Ultraviolet light exposure, such as that used in psoriasis treatment, frequent sunburns (which impair local skin immunity), and certain medications can predispose to skin cancers. Although occurrence at a young age has been implicated by some to have an adverse effect on prognosis, there is not general agreement that this is a significant risk factor for a poorer outcome.

CLINICAL EVALUATION OF BCC AND SCC

The physical examination and evaluation of BCC (Fig. 3) and SCC (Fig. 4) first includes an analysis of tumor location and size. The tumor should be characterized by its apparent appearance as a probable skin cancer type. The evaluation should evaluate the borders of the tumor and the entire local and regional area and examine local lymph nodes. A generalized skin examination and a complete history and physical would indicate whether the lesion is primary, recurrent, or has less common features. The general health of the patient dictates treatment considerations. Certain locations have been known to predispose to recurrence (such as fusion planes, which are areas where the primitive parts of the face come together in the fetus) or head and neck BCC, the areas of the nasal labial fold, and the groove between the nose and the cheeks. Certain areas such as the ear, mucosal surfaces, genitalia, and lip tend to produce SCC that possesses a greater capacity for metastasis. The mask area of the face has been known to have deeper skin cancers that are more likely incompletely resected and therefore have a higher risk for recurrence or persistence. These lesions, which are greater than 1 cm in diameter or more than ... mm in thickness, present more risk of persistence and recurrence than do smaller lesions. In general, all lesions that have higher risk should have surgical complete margin determination.

Although curettage and desiccation were formally appropriate for small, ... to 10 mm or less, low risk lesions, a higher recurrence rate must be accepted; the practice is becoming distinctly less common in academic medical centers as an acceptable treatment. We know that tumors that have occurred in areas of prior radiation treatment, those that occur in areas of prior scar (i.e. "arsenic ulcer"), persistent ulcers such as pressure sores, and BCC or skin SCC that has perineural involvement all have a lower cure rate, lower overall survival, and higher recurrence rates. Lesions where large nerve perineural involvement is confirmed should have magnetic resonance imaging evaluation with gadolinium to rule out perineural spread. We have rarely had patients with facial poorly differentiated squamous cell carcinomas who present with sensory symptoms (numbness) and on magnetic resonance imaging have perineural spread proximally along the cranial nerves up to the skull base. In these lesions, and for those with higher risk of infiltrative spread, the peripheral and deep margins may be increased to accommodate these unfavorable histologic characteristics. With regard to skin SCC, moderate and poorly differentiated lesions have a higher recurrence rate and a greater potential for infiltrative local spread and local or regional lymphatic and or systemic metastasis.

Originally, skin SCC was divided into several grades, however, most pathologists believe that two general groups of behavior can be identified for squamous cell cancers: (1) well differentiated and (2) a group consisting of moderately differentiated, poorly differentiated, and undifferentiated lesions. Although the prognosis within the latter groups becomes dramatically worse in the poor and undifferentiated categories (which, like melanomas, are capable of to transit metastasis) the tendency is to treat these as high risk lesions with wider and deeper resection margins, perhaps sentinel lymph node biopsies if the lesion is greater than " cm area or 2 mm deep, and histologic confirmation of negative peripheral and deep margins before defect closure or "ap reconstruction is accomplished.

...ost as SCC has higher risk types characterized by less differentiated lesions, BCC has been characterized into various histologic subtypes, some of which carry a higher risk of more infiltrative spread, and in particular spread frequently exists beyond the apparent clinical margins. Skin BCC can be divided into two broad groups based on their activity and tendency for subtle infiltrative spread. It is very unusual for BCC to exhibit lymph node or systemic metastasis, and these lesions are frequently neglected, previously radiated, and/or multiply recurrent lesions. Nonaggressive subtypes (A) of BCC are (1) keratotic, (2) infundibulocystic, (3) nodular type, and (4) superficial. These are the less aggressive types of BCC, and primary lesions in this group may generally be managed with 5 mm resection margins.

The subtypes (B) possessing more risk include those with more aggressive growth patterns and include (1) micronodular, (2) infiltrative, (3) sclerosing, (4) morpheaform, (5) desmoplastic, and (6) basosquamous. These tumors in group B.6 include areas that have the histologic appearance of both BCC and SCC in some parts of the lesion, and this process likely represents a "collision" type lesion that should be treated according to the differentiation of the squamous cell type component.

Some basal cells are pigmented (Fig. 5) and are easily confused with melanoma by appearance. The difference is established pathologically only.

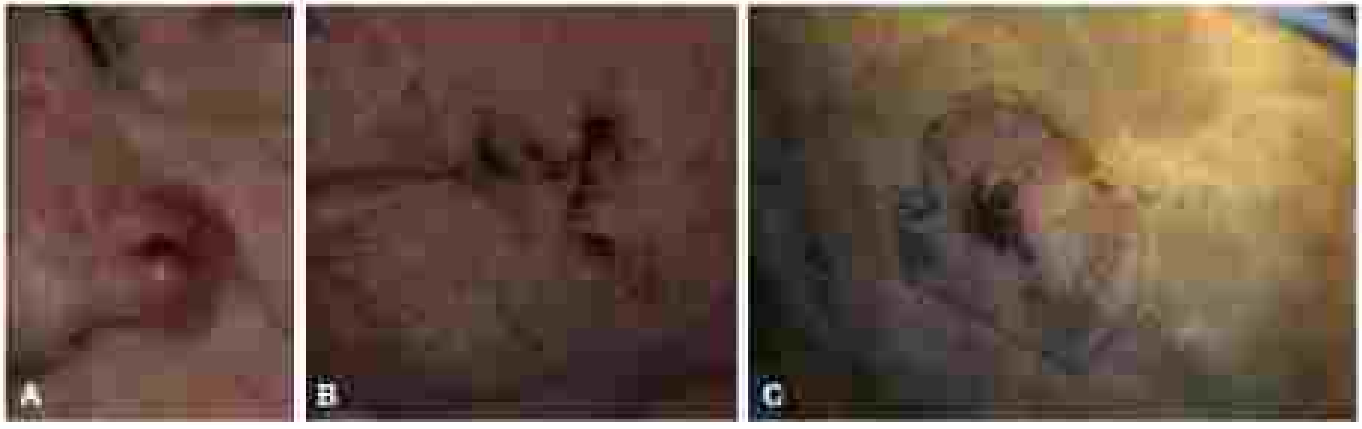

FIG. 3 (A) Nodular basal cell carcinoma presents as a surface of pink, firm, translucent, gravelly well-circumscribed tissue in the skin. It may be accompanied by telangiectasia and some redness of surrounding skin. The tumor shown is in the nasal alar. (B) Morphoeiform basal cell skin cancer has a flat, red, crusty appearance with poorly defined borders. (C) Intermediate basal cell skin cancer has diffuse, irregular, infiltrative characteristics and is red with areas of crusting and ulceration. Thickening and vascularity are variably present.

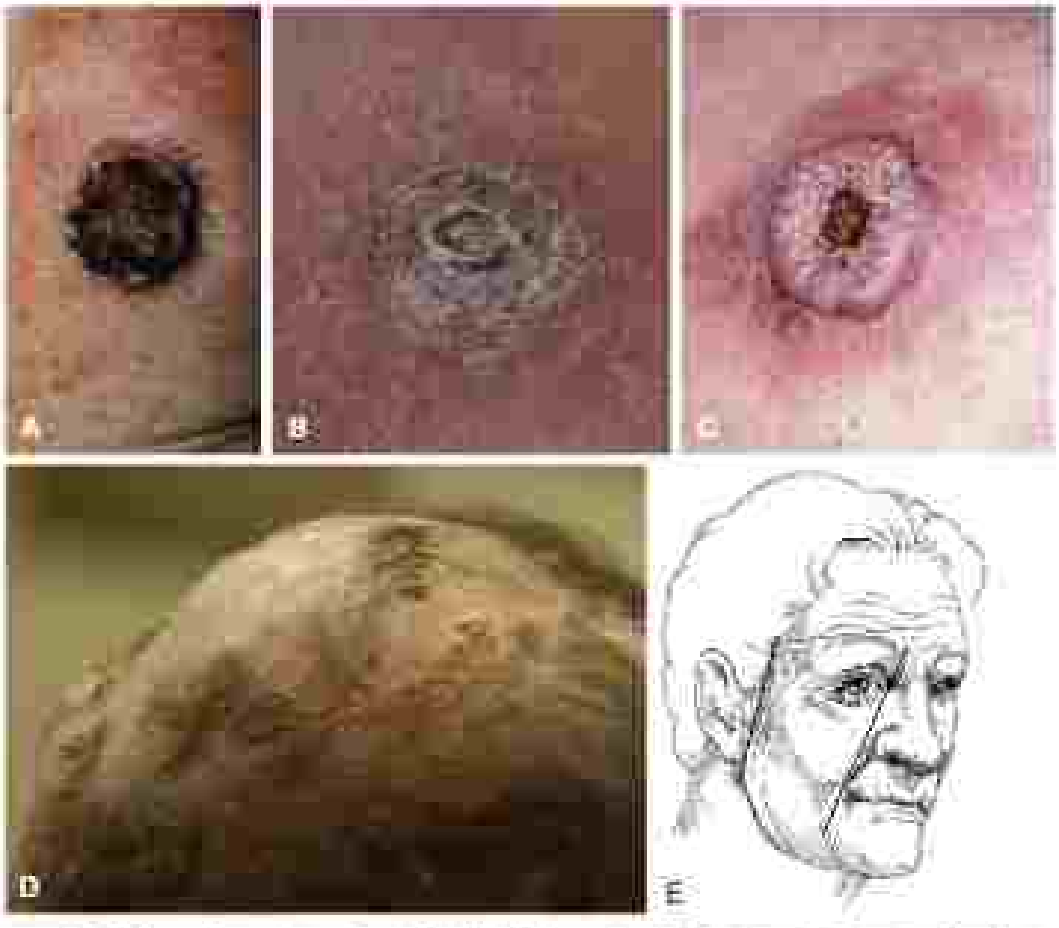

FIG. 4 (A–C) Squamous cell skin cancer, keratoacanthoma variant, has a nodular appearance with rolled, translucent margins and some surrounding erythema. It grows rapidly, often from week to week, and frequently is ulcerated in the center. (D) Squamous cell skin cancer may have a flat, red, scaly appearance with considered cutaneous horn formation. The overlying thin is bleeding. Loss of thickening of the skin in the area of cancer is seen. Well differentiated tumor are often flat and diffusely infiltrative. (E) The "mask" area of the face represents where total tumor ablation occurs. In these areas basal cells may invade more deeply, following the planes of fascia.

BCCs or SCCs that develop in an area of chronic ulceration or chronic scarring (so-called Marjolin's ulcers) such as burn scars and pressure sores have a worse prognosis, perhaps related partly to the difficulty of making the diagnosis and therefore to late detection and the larger size of these lesions.

The rapidity of growth according to the history provided by the patient is important because some lesions will double in size quite rapidly, such as the keratoacanthoma (Fig. 4A–C) variant of SCC. These lesions should be completely excised because the more rapidly growing lesions should be removed for diagnosis as soon as feasible as

FIG. 1. (A) Pigmented basal cell skin cancer resembles melanoma in appearance, with the difference being distinct histologically only. They frequently demonstrate redness, bleeding, and brown-black pigmentation. (B) Author technique for marking margins of resection: (1) lesion border is traced, (2) surgical margin is added to the lesion border, and (3) further margin or orientation of the resection is considered to accomplish a direct closure without "dog ears," and perhaps oriented parallel to the relaxed lines of skin tension.

most of these lesions are malignant, and it is impossible to differentiate the benign keratoacanthoma lesions clinically.

Nerve symptoms are especially concerning such as numbness, pain, burning, paresthesias, and, in the case of motor nerves, paralysis, or muscular symptoms such as weakness or double vision. These symptoms immediately place treatment of the tumor in a high-risk category.

Subtypes of squamous cell, such as the adenoid cystic type or adenosquamous carcinoma, and those producing squamous cell variants are tumors whose characteristics increase the risk of incomplete resection, recurrence, and metastasis. Desmoplastic cutaneous SCC similarly has a high risk of recurrence resulting from incomplete resection because of deeper extensions along fascial planes with failure to achieve clear margins. Although some have suggested that invasion of a tumor into the fat or invasion deep enough to penetrate lymphatics constitutes (as is known with melanoma) more potential for recurrence and metastasis resulting from invasion of blood and lymph vessels, confirmation of this opinion is as yet incomplete. These characteristics certainly should be noted by the treating physician, and more extensive treatment/evaluation locally, regionally, and systemically should be contemplated.

SCC IN SITU

SCC in situ represents full thickness atypia of the upper skin layer (epidermis) but the lesions are still noninvasive and may be treated by simple complete excision. Because dermal invasion is not seen in these lesions, metastasis is not possible, so complete excision is all that is necessary. Although some believe that topical chemotherapy agents such as fluorouracil can be used for SCC in situ, excision is the treatment of choice and especially with margin pathology for tissue demonstrating any evidence of recurrence, persistence, or previous failure of treatment. Superficial therapies for actinic keratosis or very superficial basal cells or in situ SCC include 5-fluorouracil, or Imiquimod. It is difficult to predict the cure rate of these treatments because they are not predicated on complete biopsies and follow-up is generally incomplete and lacking biopsy proof of eradication.

Clinical Appearance and Patient Examination

The clinical appearance of lesions such as SCC and BCC is characteristic. They include color change, nodularity and ulceration (Figs. 3, 4, and 5). Scaling and telangiectasia are frequent. Generally, the skin is reddened and thickened. Hairing or keratosis may be present, and both types of lesions frequently demonstrate surrounding premalignant lesions, such as keratosis. Frequently squamous cells arise in areas of actinic keratoses, which are known to be precursor lesions.

Once the diagnosis is suspected, a complete regional examination of the skin and lymph nodes should be completed. A complete, careful skin examination is always recommended because of the frequency of additional lesions. Attention should particularly be directed to sun-exposed skin sites. Patients with SCC and BCC are at increased risk for developing melanoma as well as additional nonmelanoma skin cancers.

To determine the best treatment for a particular skin cancer, it is often necessary to obtain a full-thickness lesion biopsy. This information is usually able to establish lesion type, differentiation, and histologic type. Although these biopsies are commonly used, they may not reveal the full extent of tumor penetration and may miss areas that provide more accurate classification of the tumor. Biopsies that include the deep reticular dermis are more accurate in identifying deeper processes and in characterizing the lesion. Infiltrative histology or deeper penetration will be missed by more superficial biopsies, in particular. higher risk lesions may be incompletely diagnosed by these biopsies. , or instance, a shave biopsy of an SCC will frequently be read as SCC in situ and not confirm the invasive component of the lesion. We know that SCCs with poorly or undifferentiated histologic characteristics and those greater than 2 cm in area or more than 2 mm thick (tumor can invade lymph vessels in the dermis) are at more risk for infiltrative spread and lymph node involvement. Some practitioners, based on the histologic confirmation of aggressive characteristics, will do a sentinel lymph node examination for these lesions. Although clinically enlarged nodes can have a needle aspiration biopsy, a negative result by needle aspiration does not eliminate the need for an excisional biopsy of an enlarged lymph node if the initial needle biopsy is benign.

The most recent two decades have resulted in improved treatment of both BCC and SCC. This is related primarily to accurate pathologic characterization of the tumor and to tailoring the treatment to the aggressiveness of the lesion. Although either surgery or radiation can be used for early lesions, surgery is generally preferred because of its confirmation of diagnosis and complete margin evaluation, and (usually) one step definitive, efficient treatment. In some cases, age, cosmesis, or functional considerations of the part affected may cause the patient to choose radiation in certain cases. In general, treatment by surgery should include a complete excision of the lesion with an additional margin where margin size relates to the differentiation or subtype and thus the behavior of the tumor. The margins and accuracy of pathologic confirmation of complete resection become much more important in more serious lesions.

Although in the past, curettage or desiccation was used for many skin cancers, today this treatment is becoming less common because of the desire to achieve a complete histologic examination. Most skin lesions should be excised with confirmation of the diagnosis and the excision margins, especially for more aggressive cancers. These

cancers of higher risk need complete excision, confirmed with standard pathologic peripheral and deep margin evaluation (either Mohs micrographic or standard pathology in which frozen section and permanent sections confirm negative deep and peripheral margins).

When curettage and/or electrodessication is used, if the subcutaneous tissue is reached, surgical excision should be performed. The effectiveness of treatment for superficial lesions by curettage depends on the clinicians' perception of reaching appropriate normal dermis tissue. Fat, being less dense than dermis, is not able to be used to detect entry the characteristics of normal skin tissue. In addition, if some of the tumor curettaged is sent for biopsy identification of a higher risk lesion should prompt a secondary surgical excision. Curettage does not provide pathologic confirmation of negative margins nor a more thorough complete evaluation of the tissue.

Complete Excision and Peripheral Margin Evaluation

Low risk tumors, BCCs (less than 2 cm) with well differentiated and nonaggressive characteristics, can generally have a greater than 95% to 99% cure rate with 4- to 5-mm clinical margins. The perception of a negative margin depends on identification of the edge of clinically normal skin without erythema, telangiectasia, or any characteristics of the tumor. A nodular lesion with a surrounding rim of erythema must be treated beyond the erythema, which could represent invasion of skin by cancer. With regard to SCC, margins of 5 to 6 mm are considered more appropriate. Recurrent lesions generally deserve more margin, such as 1 cm. Lesions that are capable of in transit metastasis, such as poorly differentiated and multidifferentiated skin SCC, need an additional margin of tissue, perhaps 1 to 2.5 cm to account for the possibility of in transit and intralymphatic spread beyond clinically evident boundaries. These lesions behave like melanoma in that they are capable of intralymphatic spread, which can appear adjacent to the lesion or to regional lymphatics or lymph node drainage areas.

MARKING FOR RESECTIONS

Careful tracing of the exact clinical edges of the tumor with marking ink under good illumination is required. The proper peripheral margin for cure is then added to the exact lesion border of the tumor, with a second line of marking ink indicating the true resection margin. Excision of large lesions, or those representing scars in tension planes, may require 10 mm margins, with clear deep and peripheral margins confirmed.

Reconstruction of the Defect

In most cases, elliptical excision with the long axis oriented parallel to the relaxed lines of skin tension, and layered primary closure, with careful side to side approximation, is appropriate. In some areas, secondary intention healing can be used. The scar from such healing may be more depressed, shiny, and obvious than that occurring from primary layered wound closure. Skin grafting, either partial or full thickness, is a simple method of closure of larger defects where side to side approximation cannot be obtained. In the face, cosmetic considerations of appearance may lead to closure of defects with local flaps, and more extensive lesions need distant flap reconstruction with secondary procedures for cosmetic improvement. In all cases, we believe that absolute confirmation of negative surgical margins is always necessary before any complex closure, such as a flap, is accomplished.

Confirmation of negative Margins

Techniques for rapid or intraoperative evaluation of margins include intraoperative frozen section assessment and Mohs surgery. In the Mohs technique, an immediate determination of the full length of each margin is performed. Either of these techniques may have the immediate margin evaluation supplemented by a further determination of permanent margins in cases where more confirmation is desired. Finally, in higher risk lesions, and especially in those where a more complex reconstruction is required, good confirmation of margins can be obtained by intraoperative (and then should be confirmed by permanent) analysis techniques before reconstruction is undertaken. The wound may be left open or dressed with an allograft while awaiting the final pathologic opinion. Another technique that has been suggested, in which the size of the lesion would produce a large open defect to manage wound, is that of resection of a small strip of tissue at each of the four peripheral margins anticipated for the lesion, with immediate closure of the thin strip defect edge to the remaining central specimen, leaving the major portion of the lesion intact as the four peripheral strip margins biopsies are evaluated. The margins can then be altered appropriately and the remainder of the lesion resected at the definitive resection and reconstruction.

A complete assessment of the deep and all peripheral margins, being careful to label these so that they are clearly able to be analyzed by the pathologist in proper sequence and in proper orientation, is desired for most lesions. We have learned to resect each margin separately and place it separately labeled in a separate bottle for clarity, which eliminates the confusion generated by having the specimens serially examined and labeled by three to four separate individuals, which is the usual pathologic sequence of specimen processing. For all high risk lesions, a complete determination of all peripheral and deep margins is necessary; this should be completed before any reconstruction is accomplished. If the margins are equivocal in such lesions, a repeat assessment is performed awaiting the results before any reconstruction is initiated. An allograft can be placed over the defect until the permanent complete margin evaluation is available. We prefer at least consideration of sentinel node evaluation in poorly differentiated or undifferentiated high risk SCC, although the benefit of this technique in the minority in less differentiated SCC has yet to be proven.

Enlarged Regional Nodes

Positive needle or excisional biopsies of an enlarged regional lymph node or positive sentinel node biopsies predict the need for removal of regional lymph nodes. This sentinel node biopsy technique, in high risk lesions, has minimized the use of elective regional node dissection, limiting morbidity to those with proven lymph node spread. A negative needle lymph node biopsy is suggestive but not absolutely confirmatory of a lymph node's benign status because it does not involve complete histological evaluation.

Radiation as Primary or Adjunctive Treatment

Radiation therapy in cases of primary straightforward nonmelanoma skin cancer of the head or squamous type can produce good cure rates and excellent cosmetic results. Multiple treatments are required over a period of weeks, and there is no confirmation of negative margins nor is there complete examination of the histology of the lesion to absolutely confirm its histologic characteristics. Of course, as in surgery, proper techniques must be applied. Radiation therapy is often offered to older patients or to areas where the cosmetic sensitivity of the area makes reconstruction difficult. Some physicians prefer it for thin, widespread lesions such as Bowen's disease and for patients who have widespread lesions who refuse surgery. We have found many elderly patients with lesions of the lower extremities do not do well either in terms of care or symptoms following radiation treatment.

Radiation is not generally used alone for lymph node treatment or for treatment of high risk lesions that frequently occur in the absence of initial surgical clearance, but may be added as adjunctive treatment (e.g., to poorly differentiated squamous cell lesions with the possibility of in transit spread). Sometimes, radiation with or without concurrent chemotherapy will be used following lymph node dissection in high risk cases. Radiation therapy has also been used as adjunctive treatment to patients to whom the margins are histologically but not clinically positive and for perineural involvement or where the danger of intralymphatic spread into adjacent skin is high. Patients who have extensive local penetration of tumor are also candidates for postoperative radiation, for instance, in extracapsular spread of tumor beyond lymph nodes.

Patients with disease remaining following radiation and chemotherapy may be candidates for Vismodegib, a hedgehog pathway inhibitor, when further surgery and radiation are contraindicated.

Long-Term Follow-Up of BCC and SCC

All patients with BCC and SCC, especially those with high risk lesions, should have a complete skin examination periodically, with special attention to the area where recurrence, either locally or regionally, is likely. Although most recurrences of lesions develop within a 2 year period, rarely a tumor will recur after 5 to 10 years. One third to one half of patients having BCC or SCC will develop a separate lesion within the next 5 to 10 years. Although most recurrences of lesions develop within a 2 year period, a tumor can recur in the next 5 to 10 year period. Follow up schedules should be tailored to the particular severity and extent of disease of the patient, and to the risk of recurrence and to the severity of the original lesion.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans is a fibrotic skin lesion that is uncommon. It is a tumor rising in the dermis with a low incidence. The most frequent age range of affected individuals is between 20 and 50 years. Most lesions are located on the trunk or proximal extremities, with the head and neck area affected less commonly (Fig. 6). Some patients provide a causal history of trauma; however, the relationship has not been proven. The lesion is slow growing as a rule, and for practical purposes does not metastasize; however, it has a strong tendency for local fascial extension along tissue planes to small, thin fingers that defy clinical perception. Conservative surgical excisions have (because of this) yielded up to a 60% recurrence rate, generating the recommendation that 3- to 4 cm clinical margins in Mohs surgery be used.

Dermatofibrosarcoma protuberans presents clinically as a painless, firm, red to brown or purple plaque. It can demonstrate soft areas or protrusions. This indolent presentation is often enough to prevent early diagnosis because of its benign nature. The diagnosis can prove difficult, and differentiating it from other fibrotic skin processes can require special stains. Negative biopsies in one area should not be reassuring but should prompt more biopsies and/or complete excision of a suspicious lesion. Immunostaining with CD-34 factor, XIIIA metalloproteinases, vimentin, and stromelysin-3 are helpful in making the diagnosis. The lesion is frequently misdiagnosed, both clinically and pathologically, and frequently underrecognized unless Mohs techniques are used.

Treatment

Treatment for dermatofibrosarcoma protuberans is surgical excision with wide margins. Up to 3 to 4 cm have been recommended. Currently, Mohs micrographic surgery is the surgical method of choice, which has reduced recurrence rates to about 2%. Regional lymph node biopsies are not indicated because the incidence of metastatic spread is so low, probably 1%. Although adjuvant radiation has been recommended following standard surgical treatment, it is highly recommended to achieve widely negative margins surgically, and Mohs surgery is strongly recommended. The value of supplemental radiation in patients who have widely negative Mohs surgical margins has yet to be established.

Cutaneous T Cell Lymphoma

Lymphomas may present as cutaneous lesions and include mycosis fungoides and Sézary's syndrome, which are cancers originating from T4 helper cells. These are rarer tumors that appear a reddish patch, plaque, or lump. They sometimes come or have a "psoriatic" appearance. Itching is a prominent clinical symptom. Because of its benign appearance, diagnosis is commonly delayed because it overlaps in appearance with many other cutaneous dermatologic conditions. Some patients progress to frank systemic lymphoma over time, and 5-year survival rates of the skin lesion itself vary from 50% to 100%, and often relate to the development of another internal serious blood neoplasm.

Therapy varies from excision, chemotherapy agents to topical radiation, such as skin electron beam therapy or combined chemotherapy and radiation treatment. In some cases, surgery provides control of local symptoms and apparent cure for limited lesions.

Basal Cell nevus Syndrome

Basal cell nevus syndrome or Gorlin syndrome or nevoid BCC syndrome is an inherited disorder that presents with multiple cutaneous basal cells, jaw cysts, musculoskeletal and neurologic abnormalities, and pitting of the palmar and plantar surfaces of the skin. The disease is autosomal dominant and frequently presents with odontogenic keratocysts, calcification of the falx cerebri, multiple cutaneous basal cells, and palmar and plantar pits. The lesions behave as BCC's and are usually managed with surgical excision. It is not infrequent that palmar and plantar pits contain BCC. The pits are usually small, 3 mm or less in depth. Patients will often have hundreds of BCC's over the course of their lifetime, and many eventually succumb to the disease. Topical chemotherapy agents such as Efudex have been used in an

FIG. 6 (A) Dermatofibrosarcoma protuberans looks like lumps of fibrous scar tissue, its distinct appearance helps to resolve character. The lesion must be confirmed by biopsy. Wide margins are necessary because of the tendency to extend local invasion along tissue septae. (B) Appearance of dermatofibrosarcoma protuberans in a white patient. (C) Appearance of a dermatofibrosarcoma protuberans in an African-American patient.

attempt to eradicate early superficial nonfacial basal cells but surgical excision are the treatment of choice.

Bowen's Disease

Bowen's disease is an erythematous, plaque-like lesion that represents a low grade, slow growing intraepithelial variant of SCC. Essentially, the growth of this tumor is intraepidermal and its history and progression are similar to other intradermal carcinomas such as erythroplasia of Queyrat. It is a less common malignancy that appears as a circumscribed, red or pink patch that can weep and present a scaly appearance. Many lesions occur on the trunk or lower extremities and genitalia, but the lesion can involve the head and neck region. The progression of the lesion is limited and extends normally over years. Invasive SCC can arise in these lesions, and if so, metastasis is possible. Excision to clear the margins with an initial 5-mm margin is recommended and Mohs excisions are favored. Lesions that occur in sensitive areas may require skin coverage, or lesions that are larger may require skin grafting. In the head and neck, cosmetically sensitive flap reconstructive techniques are preferred when primary closure is not possible.

Merkle Cell Carcinoma

This rare neuroendocrine skin cancer is characterized by rapid growth and very aggressive behavior. It is a firm, intradermal, red nodule that rapidly progresses to ulceration (Fig. 7). Recently, lesions have been traced to a polyomavirus infection and the disease is definitely more frequent in patients receiving immunosuppression. The disease progresses rapidly by intravascular and lymphatic spread, therefore, initial positron emission tomography imaging should evaluate the possibility of regional and distant spread. Survival is often predicted by positive regional nodes that occur in 50%, and the disease tends to be underrotated by limited surgical resections, and thus local failure is common (up to one third of patients). Local control may be improved by larger resection margins of 2 to 5 cm that often generate the need for skin grafting. Sentinel node biopsies are routinely recommended.

Periodic follow up with local, regional, and systemic monitoring by oncology is recommended. Although most recurrences occur in the first 2 to 3 years, survival is best predicted by the presence of nodal and distant disease. The behavior of Merkle cell cancer is usually more aggressive than significant invasive melanomas, and in fact, the mortality exceeds that of melanoma. The histologic diagnosis is confirmed by performing immunohistochemical staining. Because of the frequency of local failure in treatment when surgical margins are compromised, some have recommended postoperative radiation therapy for the primary tumor, draining lymphatics, and regional lymph node basins. The added value of this treatment when surgical margins are generous, sentinel lymph node biopsy is obtained, and positron emission tomography scans are negative has not been established. Adjuvant chemotherapy for regional disease has also been recommended (positive regional node disease) in addition to surgery, but its value is not proven.

FIG. 7 Merkle cell skin cancer looks like a cancerous lump that frequently grows rapidly and initially has no distinguishing characteristics. It must be differentiated by biopsy confirmed by immunostains.

Angiosarcoma

This rare vascular tumor of the skin generally occurs as a rapidly enlarging nodule or plaque, sometimes simulating a bruise (Fig. 8). Its transit metastasis occurs quickly and initial presentation with satellite nodules is not uncommon. There is a predilection for occurrence in the head and neck area and in the elderly. In one series, the mean age was 78 years and mimicked its lower male patients. Aggressive resection is indicated with 3- to 5-cm margins, frequently requiring flap or skin graft reconstructions. Sentinel lymph biopsy is recommended. Local recurrence is frequent because of the tendency for in transit metastasis, and the prognosis is quite limited with 20% or less survival being routine. These statistics and the proven aggressive behavior of this tumor have generated the recommendation that radiation and chemotherapy accompany the planned surgery. Despite these additions, the prognosis remains largely unaffected by additions to the surgical treatment proposed.

Adnexal Tumors of the Skin

Adnexal tumors occur from skin appendages such as eccrine, apocrine, sebaceous glands, and hair follicles. Some occur from fibrous or neural tissues. Sebaceous carcinomas usually present as a slightly nodulated nodule whose diagnosis is dependent on a biopsy. The prognosis varies with the aggressiveness of the lesion and wide excision with 2 cm margins to fascia are recommended. Although some practitioners perform

FIG. 8 Angiosarcoma is a rapidly growing aggressive cancer that often initially appears as a bruise or hemangioma. It is capable of early metastasis and systemic movement. (A) Angiosarcoma of the cheek with red cutaneous thickening and ulceration. (B) Angiosarcoma presenting as a nonblanching "bruise" of purple-red skin in the scalp.

sentinel lymph node evaluations in these more aggressive lesions, the value of these interventions remains to be proven.

Nonmelanoma skin cancers vary in severity from the relatively common and benign varieties to very aggressive and frequently lethal lesions. Treatment favors surgical resection predicated on accurate diagnosis and classification, with the appropriateness of treatment based on good pathologic definition of the lesion type.

Acknowledgment

We acknowledge the contributions of the panels who created the NCCN Guidelines, which form an excellent and carefully considered basis of the recommendations for diagnosis and treatment of these lesions that are summarized in this chapter. We recommend these guidelines in the strongest terms for those seeking further information and clarification, as they serve as a yearly up-to-date summary of current recommendations for diagnosis, evaluation, and treatment.

Management of Cutaneous Melanoma

Michele M. Gage, MD, and Julia R. [illegible]ange, MD, ScM

Cutaneous melanoma is the fifth most common invasive cancer in men and the sixth most common invasive cancer in women in the United States. It is the largest cause of skin cancer mortality. Most melanomas are diagnosed early and can be expected to have a good prognosis with surgery as the only active therapy. The management of regional and distant disease has changed significantly in the last decade, with the evolution of a more restrained approach to the regional nodal basin and the development of immunotherapies and targeted therapies that improve survival for patients with regional and distant disease. This chapter reviews the recommended initial evaluation and workup of melanoma, indications for surgery, surgical technique, and postoperative follow-up.

INITIAL EVALUATION OF SUSPECTED MELANOMA WITH BIOPSY

Lesions suspicious for melanoma often (but not always) display classic features such as the ABCDEs: asymmetry, border irregularity, color variegation, large diameter, or evolution over time. Other features that may be considered concerning include a new pigmented lesion after age 30, a pigmented lesion that is out of character with the patient's mole pattern, and a lesion that becomes itchy or bleeds with minor injury. A focused history and physical examination should include review of potential risk factors, personal and family history, as well as a detailed physical evaluation of the lesion, the surrounding skin area, and all potential draining lymph node basins. Risk factors for melanoma include skin type, personal or family history of melanoma, multiple clinically atypical moles or dysplastic nevi, and inherited genetic mutations. Environmental factors, including excessive sun exposure and ultraviolet-based artificial tanning, should also be assessed. A complete skin examination should be done to assess for other primary skin cancers.

Suspicious lesions should undergo biopsy with a technique that allows full-thickness pathologic assessment preferred. Excisional biopsy with a narrow 1- to 2-mm gross margin may be considered. Punch biopsy may be considered either for very small lesions or for broader lesions where it is advantageous to establish a diagnosis before any larger excision. A punch biopsy should be taken from the darkest, most raised, or otherwise most suspicious appearing portion of the lesion. Regardless of biopsy technique, a full-thickness biopsy into the subcutaneous fat is important for accurate interpretation of tumor thickness. The orientation of a potential future surgical wide local excision should be considered when performing an excisional biopsy. For example, longitudinal or oblique incisions are preferred on the extremities, whereas head, neck, and trunk biopsies should be oriented parallel to skin lines.

Patients may sometimes present to a surgeon after a shave biopsy reveals melanoma, particularly when the initial clinical suspicion for melanoma was low. Thin shave biopsies often fail to provide accurate information on tumor thickness and should be avoided when melanoma is suspected. When a thin shave biopsy has a broadly positive base, repeat biopsy may be considered before proceeding to surgical wide local excision for more accurate tumor staging, particularly if there is visibly some tumor still present at the site.

Pathology results for a melanoma biopsy should include, at a minimum, the following information: thickness in millimeters, ulceration status, dermal mitotic rate (per millimeters squared), deep and peripheral margin status, presence or absence of microsatellites. Other features to be reported include histologic type, angiolymphatic invasion, radial or vertical growth phase, tumor-infiltrating lymphocytes, and regression.

Clinical staging evaluation is guided by the clinical stage at diagnosis. Patients with thin, early melanoma (≤1.0 mm) and clinically negative nodes should not have any systemic staging studies, unless signs or symptoms of disease spread are present. Patients with melanoma larger than 1.0 mm with clinically negative nodes and no signs or symptoms of metastatic disease can also forgo systemic staging. Patients with palpable adenopathy should have radiologic evaluation with ultrasound and needle biopsy if abnormal nodes are seen. Patients with confirmed nodal metastases or suspicious signs or symptoms of distant metastases should be evaluated with cross-sectional imaging, as well as baseline liver enzymes and lactate dehydrogenase.

sentinel lymph node evaluations in these more aggressive lesions, the value of these interventions remains to be proven.

Nonmelanoma skin cancers vary in severity from the relatively common and benign varieties to very aggressive and frequently lethal lesions. Treatment favors surgical resection predicated on accurate diagnosis and classification, with the appropriateness of treatment based on good pathologic definition of the lesion type.

Management of Cutaneous Melanoma

Michelle M. Gaps, MD, and Julia R. Lange, MD, ScM

Cutaneous melanoma is the fifth most common invasive cancer in men and the sixth most common invasive cancer in women in the United States. It is the largest cause of skin cancer mortality. Most melanomas are diagnosed early and can be expected to have a good prognosis with surgery as the only active therapy. The management of regional and distant disease has changed significantly in the last decade, with the evolution of a more restrained approach to the regional node basin and the development of immunotherapies and targeted therapies that improve survival for patients with regional and distant disease. This chapter reviews the recommended initial evaluation and workup of melanoma, indications for surgery, surgical technique, and postoperative follow-up.

INITIAL EVALUATION OF SUSPECTED MELANOMA WITH BIOPSY

Lesions suspicious for melanoma often (but not always) display classic features such as the ABCDEs: asymmetry, border irregularity, color variegation, large diameter, or evolution over time. Other features that may be considered concerning include a new pigmented lesion after age 40, a pigmented lesion that is out of character with the patient's mole pattern, and a lesion that becomes itchy or bleeds with minor injury. A focused history and physical examination should include review of potential risk factors, personal and family history, as well as a detailed physical evaluation of the lesion, the surrounding skin area, and all potential draining lymph node basins. Risk factors for melanoma include skin type, personal or family history of melanoma, multiple clinically atypical moles or dysplastic nevi, and inherited genetic mutations. Environmental factors, including excessive sun exposure and ultraviolet–based artificial tanning, should also be assessed. A complete skin examination should be done to assess for other primary skin cancers.

Suspicious lesions should undergo biopsy with a technique that allows full thickness pathologic assessment preferred. Excisional biopsy with a narrow 1- to 2-mm gross margin may be considered. Punch biopsy may be considered either for very small lesions or for broader lesions where it is advantageous to establish a diagnosis before any larger excision. A punch biopsy should be taken from the darkest, most raised, or otherwise most suspicious appearing portion of the lesion. Regardless of biopsy technique, a full thickness biopsy into the subcutaneous fat is important for accurate interpretation of tumor thickness. The orientation of a potential future surgical wide local excision should be considered when performing an excisional biopsy. For example, longitudinal or oblique incisions are preferred on the extremities, whereas head, neck, and trunk biopsies should be oriented parallel to skin lines.

Patients may sometimes present to a surgeon after a shave biopsy reveals melanoma, particularly when the initial clinical suspicion for melanoma was low. Thin shave biopsies often fail to provide accurate information on tumor thickness and should be avoided when melanoma is suspected. When a thin shave biopsy has a clinically positive base, repeat biopsy may be considered before proceeding to surgical wide local excision for more accurate tumor staging, particularly if there is visibly some tumor still present at the site.

Pathology results for a melanoma biopsy should include, at a minimum, the following information: thickness in millimeters, ulceration status, dermal mitotic rate (per millimeters squared), deep and peripheral margin status, presence or absence of microsatellites. Other features to be reported include histologic type, lymphovascular invasion, radial or vertical growth phase, tumor infiltrating lymphocytes, and regression.

Clinical staging evaluation is guided by the clinical stage at diagnosis. Patients with thin, early melanoma (≤1.0 mm) and clinically negative nodes should not have any systemic staging studies, unless signs or symptoms of disease spread are present. Patients with melanoma larger than 1.0 mm with clinically negative nodes and no signs or symptoms of metastatic disease can also forgo systemic staging. Patients with palpable adenopathy should have radiologic evaluation with ultrasound and needle biopsy of abnormal nodes are seen. Patients with confirmed nodal metastases or suspicious signs or symptoms of distant metastases should be evaluated with cross sectional imaging, as well as baseline liver enzymes and lactate dehydrogenase.

Appropriate cross-sectional imaging could include computed tomography (CT) scanning of the chest, abdomen and pelvis (include neck CT in patients with head or neck primary tumor) with contrast, or whole-body positron emission CT. Brain magnetic resonance imaging with contrast is appropriate in patients with suspicious symptoms or as a baseline study in persons with melanoma stage IIIC or above.

Tumor mutation marker analysis (BRAF is the most frequent actionable marker) is necessary when the results are needed for clinical decision making. It should not be done in patients with early stage disease. Tumor mutation markers should be assessed for patients with stage III disease who are being considered for adjuvant therapies of immunotherapy or targeted therapy or clinical trials, and certainly in patients with stage IV disease when the result may determine whether targeted therapies may be considered.

SURGICAL MANAGEMENT OF MELANOMA: RATIONALE FOR SURGERY

Wide Local Excision

The surgical treatment of primary melanoma is based primarily on the thickness of the primary lesion. The purpose of the wide local excision is to remove the lesion in its entirety in clearly negative margins in such a way that the risk of local recurrence is minimized. Recommended margin widths are the ones measured in the operating room across the skin surface from the edge of the lesion. It is expected that some contraction of the skin specimen will occur, and that pathologic margins will be less than the measured surgical margin. Guidelines for wide local excision are based on several prospective randomized surgical trials spanning the last 3 decades (Table 1).

In brief, the recommended surgical treatment of melanoma in situ (Stage 0) is a 5 to 10 mm wide local excision. For melanomas 1 mm or smaller, a grossly measured margin of 1 cm results in excellent local control. Melanomas larger than 1 to 2 mm should be managed with a 1- to 2-cm excision, whereas melanomas larger than 2 mm in thickness should undergo wide local excision with a 2 cm margin. (Table 2) There may be occasions where margins can logically be modified for anatomic limitations or functional considerations in some patients.

TABLE 1 Recommended Surgical Margins of Excision of Melanoma Based on Randomized Surgical Trials and Meta-Analysis

Melanoma Thickness (mm)	Excision Margin (cm)
In situ	0.5–1.0
0.1–1.0	1.0
1.01–2.0	1.0 or 2.0
2.01–4.0	2.0
>4.0	2.0

Sentinel Lymph Node Biopsy and Lymph Node Dissection

The management of the regional node basin continues to change. Today, sentinel node biopsy is a standard staging tool for patients with primary melanoma and clinically negative regional node basin if the risk of having positive nodes is 5% or greater and if the patient wishes to have the prognostic information. In newly diagnosed patients with clinically negative nodes, national guidelines recommend sentinel lymph node biopsy for patients with melanoma more than 1 mm in thickness. Sentinel node biopsy may also be considered in select patients with thin melanoma, especially those with melanoma between 0.8 mm to 1.0 mm, particularly if there is ulceration or an elevated mitotic rate. Sentinel node biopsy for patients with melanoma 0.7 mm or less is generally discouraged but may be considered in unusual cases, such as when combined with mitotic rate of 2/mm² or more. There are patients for whom the decision whether to offer the sentinel node biopsy is unclear, such as to patients with unknown thickness as a result of a shave biopsy that yields a thickness of 0.7 mm with a transected base.

The purpose of the sentinel node biopsy is to provide prognostic information, but it does not by itself improve a patient's prognosis. However, when micrometastatic disease is detected in clinically negative nodes, the information identifies patients who may benefit from adjuvant treatment. Knowledge of the node status may be useful

to the patient to simply better informs the patient of their prognosis and help guide the type and frequency of follow-up plans. It is sometimes appropriate to decide not to perform a sentinel node biopsy in patients who are otherwise candidates for sentinel node biopsy. A decision to forego sentinel node biopsy can be a rational choice when the patient has significant comorbidities, a limited life expectancy, or simply chooses not to have it.

The role of completion lymph node dissection (CLND) in patients with a positive sentinel node has evolved with the results of two randomized clinical trials comparing CLND to nodal surveillance for patients with positive sentinel nodes. The Multicenter Selective Lymphadenectomy Trial II (MSLT-II) trial is the larger and more definitive of the two trials. The study found no significant difference in melanoma-specific survival or distant metastasis–free survival related to whether patient had completion node dissection or surveillance ultrasound scanning of the positive node basin. The observation group was monitored closely with serial nodal ultrasound scanning. CLND provided additional prognostic information and provided superior regional control but did not improve melanoma-specific survival compared with interval surveillance with ultrasound scanning. Additionally, lymphedema was reported in 24.9% of CLND patients and only 6.3% of the observation group. Today, for most patients with positive sentinel nodes, planned surveillance with serial node basin ultrasound scanning is a reasonable alternative to CLND for patients with low-risk, microscopic disease, with surveillance now preferred for most patients. The ideal patient for node basin surveillance is a patient with low-volume nodal metastases without extranodal extension who can adhere to the schedule of high-quality surveillance ultrasound scanning. Of those entering surveillance, about 25% are expected to recur in the node basin under surveillance, either with or without distant recurrence. It remains unclear whether we can define a group of sentinel node–positive patients who would gain a larger benefit from completion node dissection. Patients of concern include those excluded from randomization in MSLT-II or with high-risk features, such as those with three or more positive sentinel nodes, extranodal extension, microsatellites at the primary, more than two involved node basins, and patients who are immunosuppressed.

Clinically Positive Nodes

When clinically positive nodes (i.e., clinically palpable positive nodes) are present either at initial presentation or as a regional recurrence, staging with cross-sectional imaging must be done to rule out distant disease. If there is no disease beyond the node basin, the patient should undergo a therapeutic lymph node dissection of the affected basin. In cases of metastases to the inguinal nodes, ipsilateral obturator node dissection should be included if there are abnormal iliac or obturator nodes on cross-sectional imaging and may be considered if there are three or more positive inguinofemoral nodes or a positive Cloquet's node.

In Transit Disease

A substantial minority of patients will develop in-transit lesions over the course of their disease, usually recognized as tumor deposits in the dermis or subcutaneous tissue between the primary site (>2 cm away from the primary lesion) and the regional node basin. Patients found to have in-transit lesions have stage III melanoma and should have cross-sectional imaging for systemic staging and have the tumor sent for mutation analysis. If the patient has limited, low-volume disease, wide local excision may suffice as initial therapy, with consideration of systemic adjuvant therapy. Wide local excision of an in-transit lesion should be done with a surgical margin of 1 cm if feasible, but at least to a pathologically negative margin. If the patient has extensive in-transit disease that cannot be reasonably excised with low morbidity, then today systemic therapy is usually first line treatment, with consideration of regional perfusion or infusion techniques much less common than in the past.

Surgery in Stage IV Melanoma

Surgery in cases of advanced melanoma may be considered for two reasons: to eradicate all gross disease and for symptom palliation. Surgery in stage IV patients with a goal of rendering the patient free of disease is most likely to provide durable benefit to patients with oligometastatic disease and a long interval from primary diagnosis to the appearance of metastatic disease. In the era of newer and more effective systemic therapies, it is time to reassess the clinical scenarios in which patients might benefit from surgery. Additional clinical trials are needed to determine the optimal sequencing of surgery and medical therapies for patients with advanced melanoma.

Palliative surgery to relieve symptoms caused by metastases is appropriate when the anticipated benefit from palliation exceeds the morbidity of the procedure. For example, resection of bowel metastases to relieve obstruction or bleeding can yield palliation superior to other interventions. Expectant palliation can also be considered for control of disease that is progressing and is likely to cause disabling symptoms, such as enlarging, bulky but resectable nodal disease that may progress to symptomatic and unresectable disease if left unmanaged.

SURGICAL MANAGEMENT OF MELANOMA: TECHNIQUE

Wide Local Excision of Primary Melanoma

Cutaneous melanomas are managed with wide local excision with gross measured margins based on the melanoma thickness. Recommended excision margins refer to the gross measured margin across the skin surface from the edge of the lesion at the surgery and do not imply a necessary pathologic margin. For melanoma in situ, the excision should be a 5- to 10-mm margin, and the excision should be done into the subcutaneous tissue, but not deeper. For invasive melanoma, the radial margins to be taken are 1 cm for melanomas 1 mm or less in thickness; 1 to 2 cm for melanomas greater than 1 to 2 mm in thickness; and 2 cm for melanomas greater than 2 mm in thickness. Excision for invasive melanoma should be down to, but not including the deep fascia. Most wide local excisions on the trunk or proximal limbs can be excised with an elliptical excision and closed primarily. In many cases, primary closure is optimized with a length-to-width ratio of 3:1 (Fig. 1). The orientation of the ellipse should be chosen on the basis of the location of the melanoma. In general, the long axis of the ellipse should be parallel to the skin lines and tension lines, while also considering cosmesis. On the extremity, it can be advantageous to orient the ellipse obliquely, following the expected direction of lymphatics.

When simple primary closure is not possible, an alternate plan for coverage of the defect can be either local soft tissue coverage or

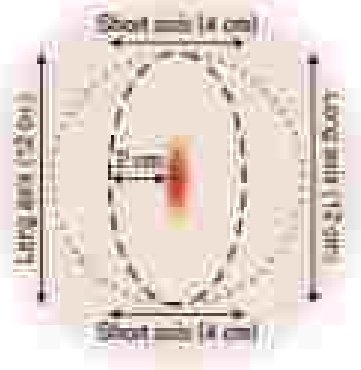

FIG. 1 Schematic of melanoma excision [illegible]

skin grafting. Soft tissue coverage with local advancement or rotation flaps preferred if possible. The overall time to healing after local advancement or rotation flap is less than with skin grafting, there is no separate donor wound to heal, and there is no need for immobilization during the initial postoperative period. The resultant surface after soft tissue advancement or rotation is likely to have a cosmetic similar to the original site. If a skin graft is necessary, greater attention to wound care is necessary, along with temporary immobilization of the area grafted. The total time to healing is greater, and there will be a resultant soft tissue defect at the site.

Wide excision for melanoma of the sole of the foot should be taken down to the plantar fascia. The defect requires coverage with skin graft or distant flap. Weight bearing must be restricted on the foot while the graft or flap heals, and healing can be difficult or delayed in patients with poor peripheral arterial flow. For melanoma of the toe, the excision margins remain the same as any other site (related to the thickness of the tumor) and therefore usually requires amputation. For a subungual melanoma, the great toe, if needed, can be amputated at the level of the proximal phalanx, with preservation of the metatarsophalangeal joint, which results in minimal change in ambulatory ability once healing is completed.

Sentinel Lymph Node Biopsy

Sentinel lymph node biopsy is a routine staging tool for melanomas with thickness 1 mm or greater (and for some thin melanomas) with clinically negative regional nodes at presentation. The sentinel node biopsy is ideally performed at the time of initial wide local excision, because its accuracy after wide excision is not well defined. The regional node basin that received lymphatic flow from a primary site is usually predictable, but in some cases there may be lymphatic flow to nodes that are outside the predicted basin. Close attention to preoperative lymphoscintigraphy is essential for accurate sentinel node identification.

Proper performance of lymphoscintigraphy and accurate communication with the nuclear medicine specialist is a critical first step in the sentinel node process. The dermis directly adjacent to the primary melanoma site is injected with technetium 99 sulfur colloid. The half-life of technetium 99 is 6 hours, and the timing of injection is optimally 1 to 18 hours before surgery. The lymphoscintigram is useful in identifying the location or locations of the sentinel node or nodes. Thoughtful attention should be given to the possibility of sentinel nodes at unexpected sites. In some cases, especially head and neck cases, preoperative localization may be aided by single photon emission CT. The surgeon should communicate directly with the nuclear medicine physician.

Once in the operating room, the location of the sentinel node should be confirmed with the gamma probe prior to final decisions regarding positioning. The gamma probe should also be used to interrogate possible lymphatic sites that did not appear on the lymphoscintigram; this will occasionally identify another basin with a sentinel node.

Some surgeons prefer the use of a second tracer, such as methylene blue, during surgery as a visual aid to sentinel node identification. Blue dye should not be used as a sole tracer without Tc sulfur colloid, because the identification rates are far lower than identification with the combination or with Tc sulfur colloid alone. Serious allergic reactions to methylene blue dye are uncommonly seen, and use of methylene blue dye is not recommended in pregnant patients. If blue dye is used, it is injected intradermally adjacent to the primary lesion a few minutes before incision at the lymph node basin site. The sentinel node procedure is found by identifying hot nodes with a gamma probe and excising the hottest nodes until the remaining nodal basin count is 10% or less of the hottest node. If blue dye is used, ideally the blue lymphatic channel coming from the injection site is visualized in the node basin and followed to the first blue node. The blue node is usually hot as well. It is common to retrieve 1 to 3 sentinel nodes per basin, but higher numbers are occasionally found. It is not necessary to place a drain at the sentinel node site.

Sentinel lymph node biopsy is associated with a low complication rate, with the most common complications being infection, seroma, and hematoma. It is expected that all patients will develop a small lymphocele at the site; it is usually small and will resolve without need for intervention. A small proportion of patients may need an office aspiration of the lymphocele if it is large or symptomatic. Lymphedema has been reported in a small proportion of patients after a groin sentinel node, especially in elderly or obese patients. When lymphedema occurs in this clinical context, it is usually mild and well tolerated and will often (but not always) resolve over several months.

Therapeutic Lymph Node Dissection

Complete lymphadenectomy for regional control of nodal disease remains important for many melanoma patients. It is necessary for patients with clinically positive nodes in the absence of distant disease and may be considered for select patients with positive sentinel nodes if they are felt to be not appropriate candidates for lymph node basin surveillance. Lymphadenectomy provides information regarding prognosis, as well as regional control of disease. The procedure should be anatomically based, excising the node basin in its entirety, while preserving key motor nerves and vasculature.

Axillary Dissection

An axillary lymph node dissection for melanoma involves complete resection of all lymph nodes at levels I, II, and III. The borders of dissection are the latissimus dorsi posteriorly, the subscapularis muscle posteriorly, the chest wall medially, and the axillary vein superiorly. The long thoracic nerve and thoracodorsal neurovascular bundle are preserved unless they are directly invaded by tumor. Level II and III nodes in some patients may be more easily accessed by drawing the arm in front of the patient's chest during the surgery, with strong retraction of the pectoral muscles. In some cases, the pectoralis minor muscle, if well developed, may be divided to obtain exposure of level III nodes to facilitate a complete resection. A closed suction drain is placed at the end of the case. Early mobilization of the arm to full range of motion and gentle physical therapy can facilitate recovery. There is approximately a 15% to 20% risk of symptomatic lymphedema. If lymphedema occurs, prompt referral to a lymphedema therapist can lessen the impact.

Inguinofemoral and Ilioobturator Dissection

The boundaries of the inguinofemoral node dissection (superficial groin dissection) are superiorly 3 to 4 cm above the inguinal ligament, medially to the pubic tubercle and the adductor longus, laterally to the anterior superior iliac spine and the lateral border of sartorius, and inferiorly to the apex of the femoral triangle. A common incision for the dissection is a modified sigmoid incision extending from medial to the anterior superior iliac spine, coursing downward and then medially below and parallel to the inguinal crease, ending near the apex of the femoral triangle. Incision design should be modified based on body habitus, preexisting incisions, need for en bloc skin resection, and location of involved nodes. Flaps are raised to expose the femoral triangle and external oblique. The spermatic cord should be undisturbed. Nodal contents are dissected down from the level of the external oblique to the inguinal ligament and from the anterior surface of the sartorius and the adductor longus. The greater saphenous vein can be identified in the medial inferior aspect of the dissection and ligated distally to assist with dissection. In patients with low volume disease and amenable anatomy, it may be reasonable to spare the greater saphenous vein. The nodes are then resected en bloc from the anterior surface of the femoral vessels taking care to secure branches of these vessels. Finally, the greater saphenous vein (if divided distally) is controlled and divided at the saphenofemoral junction. The femoral canal may be explored from beneath the inguinal ligament to excise Cloquet's node if this would be useful in determining whether to do an iliac dissection. Today, with high-quality

cross-sectional imaging, the decision of whether to do an ilioinguinal dissection is usually made before surgery, with rare need for evaluation of Cloquet's node. The sartorius muscle is often transposed medially for coverage and protection of the femoral vessels. The sartorius muscle is divided at its insertion into the anterior superior iliac spine, rotated over the femoral vessels, and sewn in place at the edge of the inguinal ligament superiorly and the fascia of the adductor longus medially. A closed suction drain is left in place.

Iliac and obturator lymph node dissection involves excision of the nodal tissue from the bifurcation of the common iliac vessels superiorly down to the distal part of the external iliac vessels, resecting nodal tissue anterior and medial to these vessels and including nodes in the obturator space medially. The iliac vessels, as well as the ureter, are to be identified and carefully preserved. A drain is not necessary in the dissected iliac/obturator space.

Inguinal dissection wounds have an infection rate of up to 15%, as well as symptomatic lymphedema rate of at least 20%. It is unclear whether lymphedema risk can be lessened with routine use a fitted compression garment at 20 to 30 mm Hg during the daytime for the first 6 months after surgery, although this is often prescribed, along with leg elevation whenever possible. Most patients after inguinofemoral or iliac/obturator dissection can expect to return to full function.

Cervical Dissection

The extent of cervical lymphadenectomy is dependent on the location of the disease and the presence or absence of direct invasion of surrounding structures. Whenever possible, a modified neck dissection is optimal, preserving the internal jugular vein, spinal accessory nerve, and sternal head of sternocleidomastoid. These structures should be excised only if there is direct tumor involvement. When there are metastases of the parotid lymph nodes, the lymph nodes in the upper neck are also at risk of harboring metastatic disease. For this reason, a neck dissection generally is performed in addition to a superficial parotidectomy.

A therapeutic neck dissection for melanoma can be associated with a 20% to 30% recurrence rate in the neck. Patients with suspected high risk of recurrence, for example, those with multiple positive nodes, extracapsular invasion, or both, may be considered for adjuvant radiation therapy.

Lymphedema

Lymphedema is a relatively common complication of axillary and inguinofemoral dissection and is often the dominant concern of patients facing these procedures. Lymphedema is an inherent risk of these procedures and can occur at any time after lymphadenectomy, even decades later. It is more frequent in patients who are elderly or obese, and those who have multiple positive nodes or postdissection radiation therapy. After surgery, all patients should take care to avoid injury or infection of the extremity at risk. It is not clear whether prophylactic limb elevation or compression garment use lowers risk in persons who do not have lymphedema. If lymphedema occurs, the patient should be evaluated promptly for precipitating factors such as soft tissue infection in the limb or disease recurrence. Patients with lymphedema without proximate cause requiring treatment (such as cellulitis or disease recurrence) should be referred to a lymphedema therapist for evaluation and management. Today, with active management, most cases can be maintained at a mild level. Attention to management of the lymphedema will be lifelong. Newer surgical techniques, such as lymph node transfer or lymphovenous bypass, are emerging as possible therapies for lymphedema, but assessment of their potential benefit requires further clinical trials.

MULTIDISCIPLINARY FOLLOW-UP

Patients with melanoma, regardless of stage, require lifelong surveillance for recurrence and possible second primary. The risk of a second primary melanoma is at least 8%, and melanoma patients are often at risk of other skin cancers, such as basal cell carcinoma and squamous cell carcinoma. All patients with melanoma require lifelong skin surveillance and evaluation of potential draining nodal basins.

Risk of recurrence of the melanoma depends on stage. Low risk patients (such as those with thin melanoma and negative nodes) may be monitored mainly by their dermatologist. Moderate- to high-risk patients should also be monitored by a surgical oncologist or a melanoma oncologist. Patients with positive nodes should have formal consultation with a medical oncologist. As newer medical therapies show survival benefit for high risk patients, adjuvant therapies with immunotherapy or targeted therapies should be strongly considered for all eligible patients. Clinical trial enrollment should be encouraged. Patients with thick melanoma with negative nodes are not currently routinely considered for systemic adjuvant therapies, but they are a high risk group that may benefit from follow-up with an oncologist.

There is no known benefit of routine cross-sectional imaging for surveillance in the absence of concerning symptoms. For patients who do not undergo lymph node dissection after a positive sentinel lymph node biopsy, node basin surveillance is critical. These patients require surveillance ultrasound scanning of the nodal basin with the positive sentinel node every 4 months for the first 2 years, and then every 6 months for years 3 to 5. Any suspicious nodes identified should be biopsied. If the biopsied node is positive, and cross-sectional imaging indicates that it is a single site of disease, the patient should proceed with surgical dissection of that basin.

FUTURE OF MELANOMA CARE

Melanoma care has evolved rapidly and will continue to change in the coming years. Care is best provided by specialists with a specific interest in melanoma. The past 2 decades have seen rapid change in management strategies for the regional node basin, and rapid development of new medical therapies for melanoma that are effective for some patients in improving survival in patients with stage III and stage IV disease. We anticipate that the development of additional treatment strategies, including neoadjuvant approaches and other multimodality plans, will continue to improve the outlook for melanoma patients.

Management of Soft Tissue Sarcoma

Alessandro Gronchi, MD, and Chandrajit P. Raut, MD, MSc

OVERVIEW

Soft tissue sarcomas (STSs) are malignant tumors that arise from mesodermal derived tissue, including fat, smooth/skeletal muscle, blood vessel, and connective tissue. Additional tumors classified as STS include malignant tumors of nerve sheath origin, derived from ectoderm. There are approximately 13,000 new cases of STS, representing 1% of all malignancies, with a slight male predominance, leading to approximately 5000 deaths per year in the United States. Although considered rare at all ages, in children, STS are the third most common solid malignancy, accounting for 15% of all pediatric cancers.

STS are a heterogeneous group of neoplasms that may be subclassified into more than 70 specific histologic conditions and may be distributed throughout the body. Approximately one-half arise in the extremities, and one-third arise in the abdomen, pelvis, and retroperitoneum. It is now recognized that the most common histologic subtype in adults is gastrointestinal stromal tumor (discussed elsewhere), followed by liposarcoma and leiomyosarcoma. In contrast, these subtypes are relatively less common in children, in whom pediatric (embryonal/alveolar) rhabdomyosarcoma and Ewing sarcoma account for more than half of all STS diagnoses.

Tumor related factors predictive of recurrence, survival, or both include size, grade (low, intermediate, or high), and histologic subtype, although the impact of these and other risk factors may vary depending on site of origin. These risk factors have recently been used to build validated nomograms for extremity and retroperitoneal sarcomas, available through a free smart phone app (www.sarcoma-score.com).

The most important treatment related factor predictive of recurrence is quality of surgical margins (negative/positive). This has been shown to be the strongest prognosticator of local failure, with a limited role, if any, in distant failure and final outcome, save for tumors located at critical sites. Pattern of failure depends on tumor grade, histology, and site of origin (which importantly influences the possibility of achieving clear surgical margins). In general, low grade tumors tend to recur locally or locoregionally, with only a low risk of distant spread. In contrast, high-grade tumors, which may also recur locally, have a much higher propensity for distant failure. Extremity STS most commonly spread to the lung when they metastasize, whereas retroperitoneal sarcomas generally recur in a locoregional pattern. Some histologic subtypes have peculiar natural histories. For example, myxoid/round cell liposarcomas tend to recur locally especially, with a lower risk to spread to distant sites even when high grade. Myxoid/round cell liposarcomas may spread to other organs (bone, abdominal cavity, paraspinal soft tissue, and bone) early in the course of the disease. Angiosarcomas are generally multifocal at presentation and very difficult to control surgically, and they can give rise to lymph node metastases and distant spread very early in the course of the disease.

Traditionally, surgical textbooks and peer reviewed literature have discussed the surgical management of STS based on site of origin. Although site of origin remains an important consideration, it has become increasingly clear that surgery must also be tailored to specific sarcoma histologic to more accurately reflect tumor biology and pattern of recurrence.

This chapter covers the management of nongastrointestinal stromal tumor STS. Surgical management is discussed both by specific histology as well as by site of origin. Although the focus of this chapter is surgery, additional treatments, such as radiation therapy or chemotherapy and imaging are considered as appropriate.

ETIOLOGY

Most sarcomas arise sporadically, without recognizable etiologic factors. Various chemical agents and herbicides have been associated with specific STS. For instance, vinyl chloride and thorium dioxide (Thorotrast) have been linked to hepatic angiosarcomas. Another well recognized risk factor is chronic lymphedema in the development of angiosarcoma, a phenomenon known as Stewart–Treves syndrome. Therapeutic and environmental exposure to radiation is associated with development of sarcomas within the treatment field at a median interval of approximately 7 to 10 years, with the most common histologic conditions being angiosarcoma and undifferentiated pleomorphic sarcoma (formerly called malignant fibrous histiocytoma or MFH, see below).

Germline genetic mutations and molecular alterations have been associated with the development of sarcomas. Li–Fraumeni syndrome, due to mutations of *p53*, is associated with both STS and osteosarcoma. Neurofibromatosis type 1 (von Recklinghausen disease), due to mutations of *NF1*, is associated with an approximately 10% risk of developing malignant peripheral nerve sheath tumors and an increased risk for developing gastrointestinal stromal tumors. Familial adenomatous polyposis, due to mutations in *APC*, is associated with desmoid tumors.

Chromosomal rearrangements may lead to gene fusions associated with sarcomas, such as the *SS18/SYT* rearrangement seen in synovial sarcoma and several others. Similarly, chromosomal amplifications may be associated with specific sarcoma histologic conditions, such as increased levels of MDM2 and CDK4 proteins in association with chromosomal 12 amplification in well differentiated and dedifferentiated liposarcoma.

GRADING

The American Joint Committee on Cancer (AJCC) has developed a staging system for sarcomas. The AJCC staging system not only incorporates the traditional variables of tumor size, nodal disease, and metastatic disease, but also tumor grade. Unlike the more common grading based on differentiation (well, moderate, or poor), STS grading is based on histology specific features, including differentiation, necrosis, and mitotic count, and is most commonly classified as low (grade I), intermediate (grade II), or high (grade III). Tumor stage incorporates both size (T1, ≤5 cm; T2, >5 cm) and depth with respect to fascia (superficial, T1a or 2a; deep, T1b or 2b). True nodal spread is rare.

However, there is considerable variability in outcome among patients within each stage. This is due in part to the fact that a critical factor, histology, is not incorporated into the AJCC staging system. Other prognostic factors, such as site of origin and patient age are also not weighted. To address this, modern nomograms (Figs. 1 and 2) based on STS histologic subtypes that consider specific prognostic factors as continuous rather than categorical variables have become available, some of which are included in the above mentioned app (www.sarcoma-score.com). They may be used immediately in the clinical setting with patients. In the long run, these may be more useful at identifying prognostically similar cohorts for future studies.

TREATMENT

Surgery remains the standard and only potentially curative therapy in the management of STS. In general, wide or radical resections are necessary to achieve negative margins. In other words, the tumor

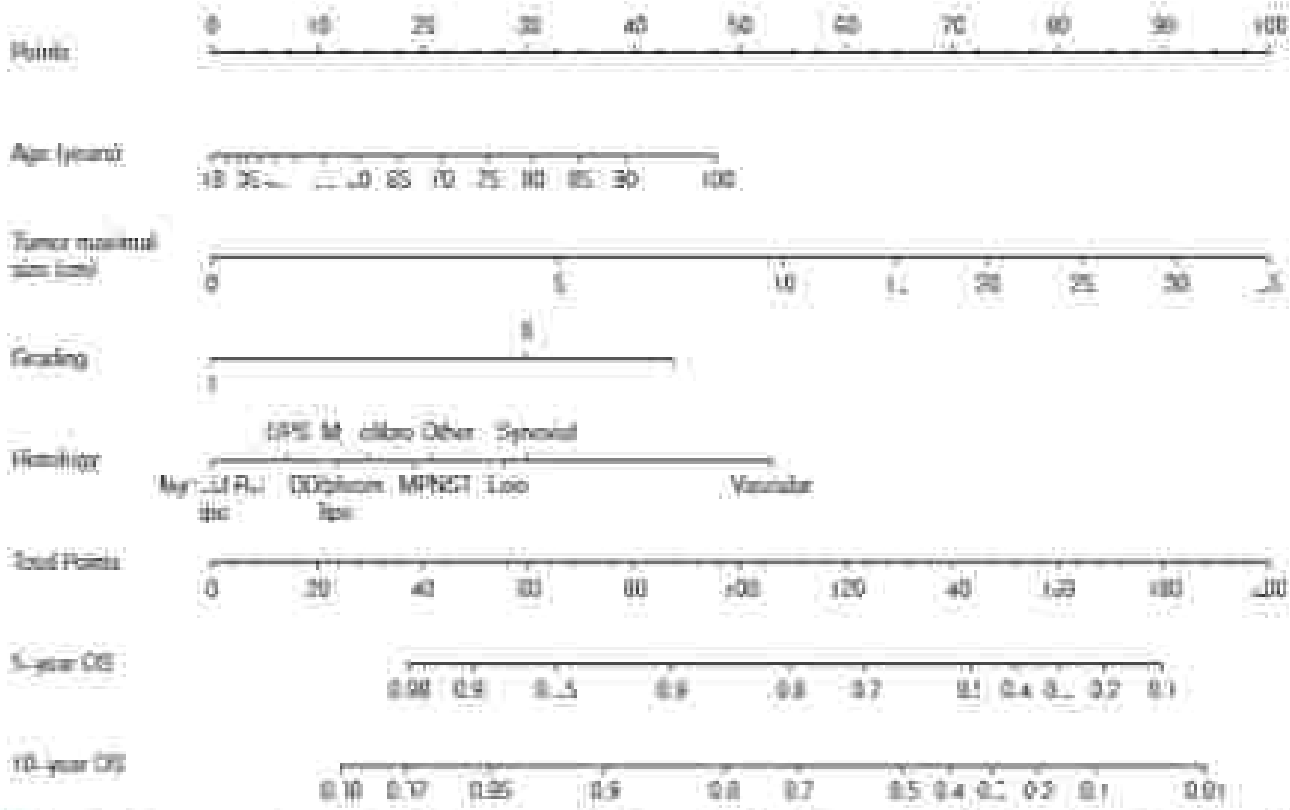

FIG. 1 Overall survival nomogram for secondary soft tissue sarcoma. must be resected en bloc with a cuff of healthy tissue all around to avoid contamination from tumor surface and removal of tumor microsatellites, which may be present in the healthy tissues surrounding the pseudocapsule. The extent of resection and adequacy of margins depends on a variety of factors, including histology and presence of an intact biologic barrier, such as muscular fascia, vascular adventitia, periosteum, or synovium.

Patients with STS should undergo evaluation at a sarcoma center because the administration of neoadjuvant or adjuvant therapy may be indicated. Generally, this involves multidisciplinary evaluation by a surgical oncologist and, depending on histology, a medical oncologist and a radiation oncologist. Reevaluation of pathology slides by a pathologist specializing in sarcomas is critical to confirm the exact histology and determine the most appropriate treatment. In fact approximately 25% of all sarcomas are initially designated with the incorrect histology, and approximately 10% are assigned the wrong histologic category in a clinically significant manner, thus impacting treatment plan. Given the complexity of many operations needed, support from other specialties, including plastic and reconstructive surgery, vascular surgery, urology, thoracic surgery, and anesthesia, is commonly required.

IMAGING

Histology and the specific imaging recommendations are discussed in further detail in the individual sections below. To better define the extent of extremity and truncal STS, including depth of invasion and relationship with neurovascular structures, an MRI of the affected site is the preferred imaging study. Further staging studies for patients with extremity STS should include chest imaging—radiography for low grade lesions and CT for intermediate- or high-grade lesions. Patients with abdominal visceral, pelvic, and retroperitoneal sarcomas should undergo CT imaging of the abdomen and pelvis and, in most cases, chest. Those with primary STS of the rectum or metastases to the liver may need further evaluation with MRIs of these sites. STS involving vascular structures, such as leiomyosarcomas arising in the wall of inferior vena cava, are usually sufficiently characterized by the standard MRI or CT imaging of the site, and CT angiography is not required. Patients with breast STS should undergo MRI imaging to define depth of extension; mammography is not routinely useful. Those with scalp STS may undergo either CT or MRI. There is no need for routine head CTs as a staging study. Although much has been written about the use of positron emission tomography (PET) in some sarcomas and many other malignancies, it is rarely indicated in routine sarcoma care. PET scans should only be ordered selectively, when attempting to resolve an ambiguous finding on other imaging or gauging treatment response under specific circumstances.

SITE-SPECIFIC TREATMENT

Extremity and Trunk Wall Soft Tissue Sarcoma

Clinical and Diagnostic Evaluation

Patients with extremity STS commonly present with a palpable mass. Initial clinical evaluation should include a thorough history and physical examination, with attention directed to size, precise location, and evidence of neurovascular compromise. No tumor markers are known for STS histology at present. After a thorough examination, MRI (or CT) of the affected site is indicated for most lesions; small, superficial lesions may be directly excised at the discretion of the surgeon. MRIs generally provide more detailed soft tissue definition but are less readily accessible, may be problematic for patients with claustrophobia, and cannot be performed in patients with retained ferromagnetic and certain types of aneurysm clips, cardiac devices, or other implants. Staging evaluation is completed by chest radiography (for low grade malignancies) or chest CT (for intermediate- or high-grade malignancies). There is no need for routine head CT (other than for shoulder soft part sarcoma) or PET scanning.

Imaging alone is rarely diagnostic of the specific sarcoma histology, with the exception of well-differentiated liposarcoma (also called atypical lipomatous tumor). Well-differentiated liposarcomas have a radiographic density similar to normal surrounding fat but tend to be well-encapsulated with thick internal septations. Such tumors may be treated with resection (complete excision with a margin of normal surrounding muscle, fat or fascia to minimize risk of local recurrence) and do not require a biopsy.

Other symptoms suspicious for sarcoma should be biopsied. We prefer to obtain core needle biopsies under radiographic guidance, although they may be performed without imaging, depending on location. Although biopsy tract recurrences are exceedingly rare, the site selected for the core needle biopsy should be planned such that it can be included in the excision used during the subsequent definitive resection or at least in the radiation field. Thus coordination between the surgeon and the interventional radiologist is required. It is important to specify "core needle biopsy" rather than fine needle aspiration because the latter rarely yields enough tissue and architecture information to distinguish between different sarcoma histologic conditions. A key advantage of core needle biopsy over an open biopsy is that the former can be directed toward a specific portion of the tumor. If a core needle biopsy fails to yield a diagnosis, an open incisional or excisional biopsy should be obtained. Although incisional biopsies have been used for diagnosis commonly, they are often performed improperly by inexperienced hands. Incisional biopsies should be performed through longitudinally oriented incisions placed such that the incision can be included in the final resection when a definitive resection is planned. If a transverse incision is used, then, when subsequent resection is required, challenges for reconstruction and risk of lymphatic disruption (depending on location) are magnified. Excisional biopsies should be confined to lesions less than 2 cm in size and superficial in location.

Surgical Treatment

Until the early 1980s, the standard of care for patients with extremity sarcomas was amputation. That changed after a seminal randomized, controlled trial conducted by Rosenberg and colleagues at the National Cancer Institute (NCI). In that trial, patients with high-grade extremity STS were randomized to undergo amputation or limb-sparing surgery with adjuvant radiation therapy. Those undergoing limb-sparing surgery headed toward a higher rate of local recurrence. Importantly, however, there was no difference in overall survival. This altered the standard treatment for extremity STS.

Currently, the goal of surgery is not only limb sparing, but also function sparing, while achieving appropriate biologic margins. Surgical resection should be carefully planned based on preoperative imaging. Resections should include not only the entire tumor (without rupture or violation of the surrounding pseudocapsule) but also an adequately wide margin (1–2 cm) of normal, noninvolved tissue. Resections performed with positive margins do result in higher risk of local recurrence and, to a lesser extent, death, especially if located at critical sites. However, a locally positive margin over a critical structure planned to adjuvant can still be accepted, provided adequate radiotherapy (generally preoperative) is performed, without compromising local control or overall survival. If the STS is close to the superficial skin, then an adequate skin paddle overlying the tumor should be resected en bloc with the tumor (Fig. 2). The surgeon should not compromise the margin by minimizing the skin resection just to avoid a skin graft or flap. Tumors extending toward but not involving the fascia should include the fascia as a margin. Superficial tumors involving the fascia should include the fascia and generally an additional margin of underlying muscle. By definition, when the investing fascia is infiltrated, the tumor is considered deep, even if it is mainly located in the superficial tissues. Similarly, deep tumors extending superficially to the fascia should include a margin of overlying subcutaneous and cutaneous tissues as a margin. It is uncommon for primary STS to violate a fascial plane, but that is not the case for recurrent STS. Deep tumors not extending into superficial tissues

FIG. 5 (A) Sagittal magnetic resonance image of a superficial myxoid, mixed pleomorphic sarcoma. (B) Planned wide skin incision around the entire mass to achieve adequate skin margin.

FIG. 6 (A) Axial magnetic resonance image of malignant solitary fibrous tumor of the thigh demonstrating deep location. (B) Due to its deep location only a minimal skin paddle around biopsy tract is needed at resection.

do not need a sizable resection of superficial tissues (Fig. 4). The tumor specimen should be oriented with marking sutures. When possible, additional margins may be sent separate from the main specimen, representing the superior, inferior, medial, lateral, superficial, and deep margins of dissection, with the true margins appropriately marked for orientation. Tumors tangentially involving bone, vessel, or nerve do not routinely require en bloc resection of these structures, as equivalent local control rates can be achieved with a carefully multidisciplinary approach of neoadjuvant radiation and surgery. Tumors abutting bone may include the periosteum as a margin if the bone is not directly invaded (Fig. 5). If bone is invaded or encased, composite resection and reconstruction may be necessary. If necessary, vascular resection and reconstruction should be considered for involved vessels (Fig. 6). If a critical nerve is encased, reconstruction with an interposition nerve graft should be considered (Fig. 7). Such reconstructions may be compromised if radiation is administered after surgery, and therefore preoperative radiation may be warranted. The specimen should be reviewed with the pathologist for optimal orientation.

Furthermore, it is critical to take into account the specific histology as described below. For instance resection for myxofibrosarcoma requires wider margins than resection for atypical lipomatous tumor

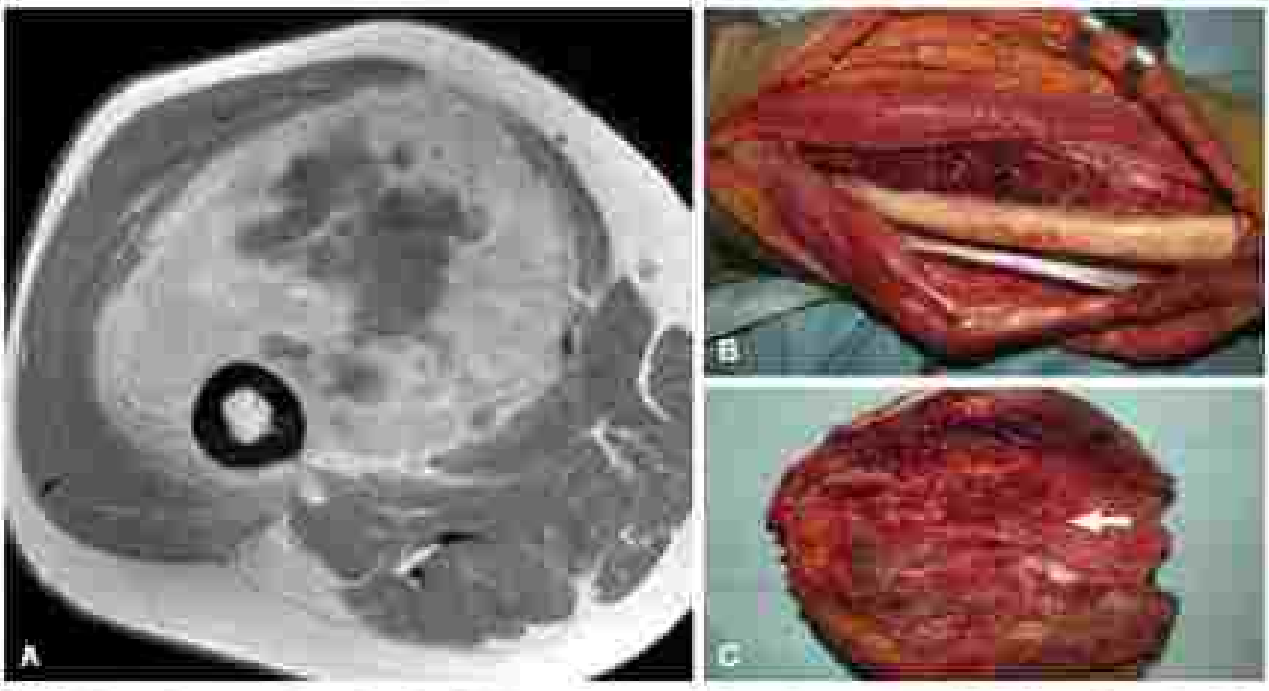

FIG. 5 (A) Axial magnetic resonance image of an unclassified pleomorphic sarcoma of the anterior compartment of the thigh partially causing the femoral shaft. The patient received preoperative conventional chemotherapy (3 courses of adriamycin + ifosfamide) and radiotherapy (for a total dose of 50 Gy). (B) Intraoperative image demonstrates periosteum stripped off en bloc with the tumor. (C) Surgical specimen, illustrating the deep margin over the bone (arrow).

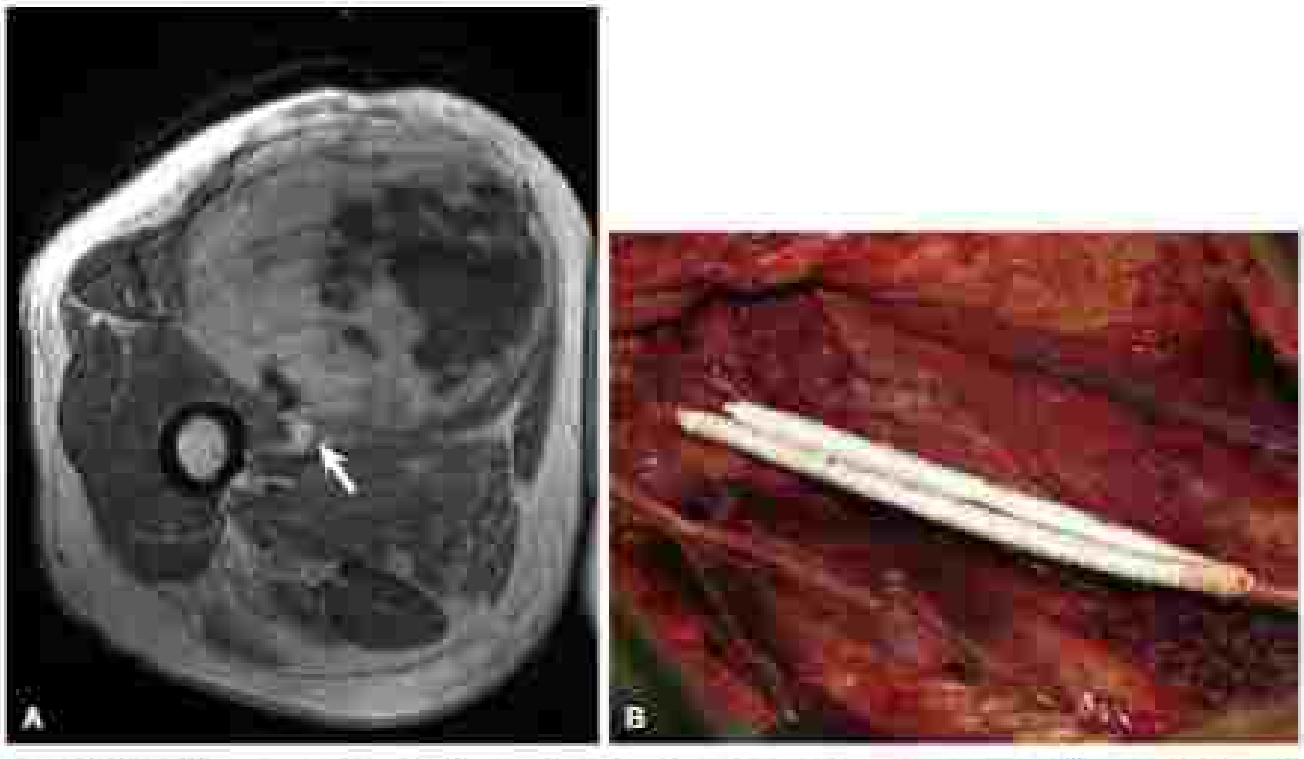

FIG. 6 (A) Axial MRI image of a monophasic synovial sarcoma of the thigh involving the femoral vessel (arrow). (B) Intraoperative image of the surgical field with vascular replacement, of both artery and vein.

(AJCC). Thus it is important for the surgeon to understand the different sarcoma histologic conditions, confirm the accuracy of the diagnosis with expert pathology review, and discuss the treatment plan in a multidisciplinary committee.

Wound closure should be meticulous to minimize risk of wound complications, which can be considerable as described in the next section. Drains may be necessary, particularly after preoperative radiation therapy or in the setting of recurrent tumors, as ongoing serous drainage may continue for weeks postoperatively. Flap reconstruction may be necessary for proper wound closure or if there is a large, potential dead space left behind (especially if preoperative radiation therapy had been administered).

Adjuvant/Neoadjuvant Radiation Therapy and Chemotherapy

Limb-sparing surgery generally relies on adjuvant/neoadjuvant radiation therapy to minimize risk of local recurrence, as demonstrated in the NCI trial. The goal of radiation is to treat the margin to minimize the risk of recurrence, not necessarily to reduce the size of the tumor per se. Radiation therapy reduces the risk of local recurrence from greater than 30% to less than 10% in most series but does not impact distant failure or overall survival rates.

Radiation therapy may be delivered as external beam radiation therapy (EBRT) or brachytherapy. EBRT may be delivered before or after surgery. One randomized trial, by O'Sullivan and colleagues, and sponsored by the Canadian NCI, compared preoperative EBRT with postoperative EBRT. There was no difference in local recurrence rates. Preoperative EBRT was associated with a doubling in the rate of wound complications (35% vs 17%) but essentially with a lower rate of late complications and tissue fibrosis and better functional outcomes. Postoperative EBRT generally covers a larger field (including drain sites) and to a higher dose than preoperative EBRT (approximately 66 Gy vs 50 Gy). This is particularly important in young adults of child-bearing age with proximal thigh STS; preoperative EBRT may spare the gonads whereas postoperative radiation may not. An ongoing North American trial is evaluating whether lower doses of postoperative radiation (50 Gy, matching the preoperative dose) provide equivalent rates of local control.

Brachytherapy may be delivered through afterloading catheters placed across the tumor bed at the end of surgery. The goal of brachytherapy is to deliver additional radiation to a close margin (including neurovascular structures) with minimal treatment to surrounding tissue, particularly when further EBRT is no longer feasible. When the final pathologic margins are confirmed, the appropriate catheters may be loaded with radioactive seeds once or twice a day for a defined treatment period concentrated over the close margins. To minimize wound complications, catheters should not be loaded until at least postoperative day 5. To minimize the risk of dislodging the catheters, any drains placed at the time of surgery should remain in place until the catheters have been removed.

Patients with small (<5 cm), superficial, well-circumscribed STS resected with an appropriately wide margin (>1 cm) of uninvolved tissue or biologic barrier (fascia) may not require radiation therapy, particularly if not high grade, provided that they can be reliably monitored.

Approximately 25% to 50% of patients with extremity STS develop distant metastatic disease. Those with large (>10 cm), deep, high-grade STS may be considered for preoperative or postoperative chemotherapy, usually with active agents such as doxorubicin and ifosfamide (response rates of 20% to 40% in patients with metastatic disease). A potential benefit in the more common histologic conditions at higher risk (i.e., synovial sarcoma, myxoid liposarcoma, leiomyosarcoma, undifferentiated pleomorphic sarcoma, malignant peripheral nerve sheath tumor) has been recently suggested, and longer follow-up is awaited to draw more definitive conclusions. The implementation of the nomogram predicted risk, as described above, in the decision making will be critical in selecting proper patients for adjuvant/neoadjuvant chemotherapy in the future. Of note, chemotherapy may also be administered concurrent with radiotherapy and may help with maximizing tumor response, when limb/function preservation is an issue or positive margins over a critical structure are anticipated. The administration of concurrent chemoradiotherapy has been shown to offset the negative prognostic impact of locally positive surgical margins on local recurrence and final outcome.

Hyperthermic isolated limb perfusion (ILP) and infusion (ILI) have been investigated in several institutions as treatment for patients with locally advanced STS in whom limb-sparing, function-sparing surgery may not be possible. These procedures involve placing vascular access catheters into the main artery and vein of the affected extremity and perfusing with high-dose chemotherapy (usually melphalan) and tumor necrosis factor alpha under hyperthermic conditions. ILP is generally performed as an open procedure with catheters directly onto the vessels. ILI uses percutaneously placed catheters and is conducted under hypoxic conditions. Although both have proven efficacy in melanoma, the data for STS are more limited. No randomized trials have compared either technique over aggressive limb-sparing resection with EBRT for STS. Arguably, patients under consideration for ILP and ILI usually have locally advanced or multifocal STS and are not necessarily candidates for surgery with EBRT at first evaluation. ILP and ILI should be considered as potential therapies in appropriately selected patients, and eligible patients should be referred to centers where this therapy is available.

The utility of (neo)adjuvant immunotherapy for resectable extremity STS is under investigation and should only be considered on protocol. There is an ongoing U.S. randomized trial evaluating neoadjuvant radiation therapy with or without neoadjuvant/adjuvant pembrolizumab for certain subtypes of extremity STS.

Retroperitoneal Soft Tissue Sarcoma

Clinical and Diagnostic Evaluation

Patients with retroperitoneal STS are often asymptomatic until the mass reaches a large size (often 15 cm or greater). Symptoms include a palpable mass, early satiety, abdominal discomfort, or occasionally a new varicocele in men. Others may be incidental findings during abdominal imaging for other reasons. Initial clinical evaluation should include a thorough history and physical examination, with attention directed to ruling out other diagnoses in the differential, including lymphoma, primary germ cell tumor and testicular cancer metastatic to retroperitoneal lymph nodes (if male). Although there are no tumor markers known for STS histologic conditions at present, screening studies exist for other diagnoses, including lactate dehydrogenase, human chorionic gonadotropin, and alpha fetoprotein. After a thorough examination, CT scanning of the abdomen and pelvis is indicated. Staging evaluation is completed by chest CT scanning. There is no need for routine head CT or PET scanning.

Imaging alone is rarely diagnostic of the specific sarcoma histologic condition, with the exception of well differentiated/dedifferentiated liposarcoma. As described in the extremity STS section above, well differentiated liposarcomas have a radiographic density similar to normal surrounding fat, but they tend to be well encapsulated, with thick internal septations. Giant lipomas are only identified incidentally in the retroperitoneum; therefore are mass consisting of very well differentiated fatty tissue should be considered as well differentiated liposarcoma and treated as such (Fig. 8). When a solid component is present within the fatty lesion, the diagnosis of dedifferentiated liposarcoma is very likely. However, all retroperitoneal masses should be biopsied to ensure the diagnosis before any treatment is undertaken. We prefer to obtain core needle biopsy specimens with coaxial needles, under radiographic guidance. Biopsy tract recurrences are exceedingly rare, usually associated with the use of the strong technique, and do not need to be resected during definitive surgery. Once the pathologic diagnosis is obtained, the strategy should be discussed within the multidisciplinary tumor board, which has to include at least a medical oncologist, radiation oncologist, radiologist, and pathologist. The first surgical approach is critical for cure and cannot be repeated, when inappropriate, by a second procedure.

Anatomic Features of Retroperitoneal Sarcomas (RPS)

In patients with extremity STS, distant failure is a common pattern of recurrence. In contrast, RPS most commonly recur in a locoregional manner, and mortality in RPS is more often associated with locoregional recurrence. Proper resection of RPS requires appreciation of the anatomic boundaries of the tumor. CT imaging should be reviewed to identify landmarks defining the extent of the mass to determine which structures may be safely resected and which must remain. The anterior margin of an RPS is generally the ipsilateral colon and mesocolon, pancreas, liver, or stomach. The posterior margin is generally the psoas and iliacus muscles inferiorly, the ipsilateral kidney and diaphragm superiorly, and the ipsilateral aorta and gonadal vessels medially. However, this may vary from tumor to tumor, and some or all of these structures could be anterior to the mass, in which case they would constitute a portion of the anterior margin. The medial margin usually includes the spine and paraspinous muscles, the inferior vena cava (for right sided tumors), and the aorta (for left sided tumors). The lateral margin is constituted by the lateral or flank musculoskeletal sidewall, although, depending on the size and location of the tumor, the kidney, colon, or both could also border the lateral portion of the mass. The superior margin is similarly dependent on the size and location of the mass and may include the diaphragm on either side, the right lobe of the liver, the duodenum, and the head/uncinate process of the pancreas for right sided tumors, and pancreatic tail, spleen, and splenic vessels for left sided tumors. The inferior margin may include the iliopsoas muscle, the femoral nerve, the common, internal, and external iliac vessels, and the pelvic sidewall. Clearly, the size and specific location of the mass determine which of the many structures mentioned above constitute which specific margin.

In general, the ipsilateral kidney, colon and mesocolon, and at least a portion of the psoas can be safely and routinely easily resected without much difficulty. Resection of the pancreatic tail and spleen can usually be performed with relatively low short term morbidity. Resection of other structures, including but not limited to the aorta, inferior vena cava, iliac vessels, femoral nerve, diaphragm, duodenum, pancreatic head or uncinate process, and liver, entail more significant resections, with entailing greater morbidity.

(D) Surgical specimen including right colon (*short arrow*) and right kidney (*big arrow*); psoas not shown but present.

Technical Aspects of Retroperitoneal Sarcoma Resection

Before surgery, contralateral renal function should be assessed with a nuclear scan if an epithelial nephrectomy is planned. Patients should undergo bowel prep. Patients may be placed in either a lithotomy or modified lateral decubitus position. The abdomen may be entered through a midline, oblique, flank, or thoracoabdominal incision, depending on the precise anatomic location. It is important to adjust the incision to the extent of tumor to provide optimal exposure.

The goal of primary surgery should be an extended resection, removing involved or adherent surrounding organs and retroperitoneal fat en bloc with the tumor in an effort to maximally clear the margins and avoid spilling tumor (Figs. 9 and 10). Special consideration may apply to histologic subtypes different from liposarcomas. A more conservative resection, albeit wide, can be considered, if visceral organs are not directly involved. This is typically the case of solitary fibrous tumors, as well as of leiomyosarcoma because they present as well circumscribed masses, readily distinguishable from the retroperitoneal fat/soft tissues (Figs. 11 and 12), and have a much more limited local recurrence risk. Due to the size of the tumors, exposure and retraction may need to be shifted periodically. Ideally, the operation is conducted with carefully circumferential dissection around the expected specimen, enabling optimistic exposure on a broad front. It is important to approach surgery with curative intent. A macroscopically incomplete resection is no more beneficial than nonoperative management. The resection specimen should be reviewed with the pathologist immediately after removal for orientation and identification of margins of concern.

Adjuvant/Neoadjuvant Radiation Therapy and Chemotherapy

The role of radiation therapy is controversial. Radiation therapy unquestionably reduces the risk of local recurrence in patients with extremity STS, but this has not been proven in RPS. Furthermore, the proximity of radiosensitive tissues and organs, such as liver and small intestine, together with the large size of the radiation field, limits its utility in some patients. Those who use radiation

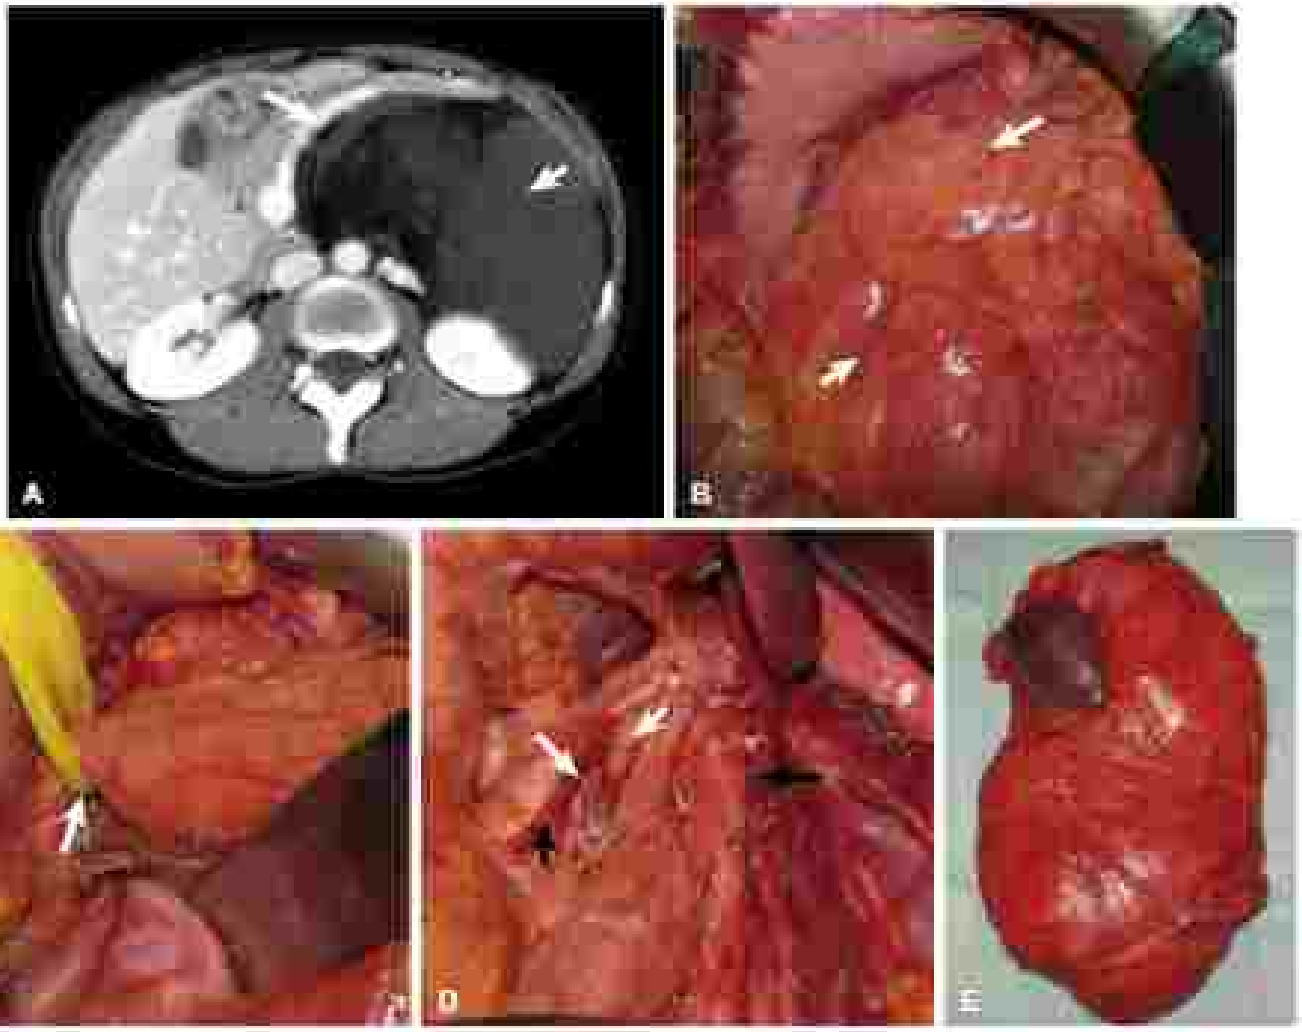

FIG. 10 Axial computed tomography (A) and intraoperative image (B) of a left retroperitoneal liposarcoma (short arrow) displacing the pancreas anteriorly (long arrow). (C) Preparation of pancreatic body for transection (arrow). (D) Surgical field after tumor removal demonstrating a clean left retroperitoneal space with visible ventral vein (long white arrow), superior mesenteric artery (short white arrow), pancreatic stump (short thin arrow), and aorta (long thin arrow). (E) Surgical specimen including left colon, left kidney, left psoas, distal pancreas, and spleen.

therapy generally favor delivering it before surgery, when the bulk of the tumor itself displaces uninvolved organs out of the radiation field. There is one recently completed randomized trial evaluating the utility of preoperative radiation therapy in patients with RPS, based in Europe and open to selected North American centers.

Similarly, the role of chemotherapy even for the subtypes at higher risk of distant spread (G3 dedifferentiated liposarcoma and leiomyosarcoma), is controversial. If considered, the neoadjuvant setting is usually preferable. There are no randomized trials addressing the role of standard chemotherapy in this disease as of yet. International collaboration is a key for maximizing the chance to enroll successfully in prospective studies for these rare diseases.

Breast Sarcoma

The most common sarcoma histologic conditions arising in the breast are angiosarcoma and phyllodes. Angiosarcoma may arise either primarily within the breast parenchyma or secondarily within the breast skin as a consequence of lymphedema or, more commonly, radiation therapy delivered as a part of breast conservation therapy for breast cancer. Each of these malignancies will be considered individually.

Primary Angiosarcoma

Primary angiosarcoma is a disease of the breast parenchyma arising in young women. Angiosarcoma, irrespective of site, is in general responsive to systemic chemotherapy. However, once chemotherapy is stopped, the disease tends to regrow. Furthermore, despite its sensitivity to chemotherapy, there is no proven survival benefit from systemic therapy. The only potentially curative therapy is surgery. Although breast cancer may be treated with breast conservation limited surgery due to the proven benefit of radiation therapy and hormonal therapy, there are no such proven beneficial adjuvant therapies for primary breast angiosarcoma. Therefore patients should be offered a simple mastectomy instead of lumpectomy. Partial resection of the pectoralis major may be necessary to achieve negative margins. The skin may be closed primarily. Before surgery, the patient should undergo staging with chest, abdomen, and pelvis CT scanning and an MRI of the breast. Initial physical examination should include a contralateral breast examination. The contralateral breast may be a site for metastatic disease, but, to date, there is no proven benefit from a contralateral prophylactic mastectomy.

Secondary Breast Angiosarcoma

Secondary breast angiosarcoma is a disease affecting older women. Historically, secondary angiosarcoma arose in the setting of

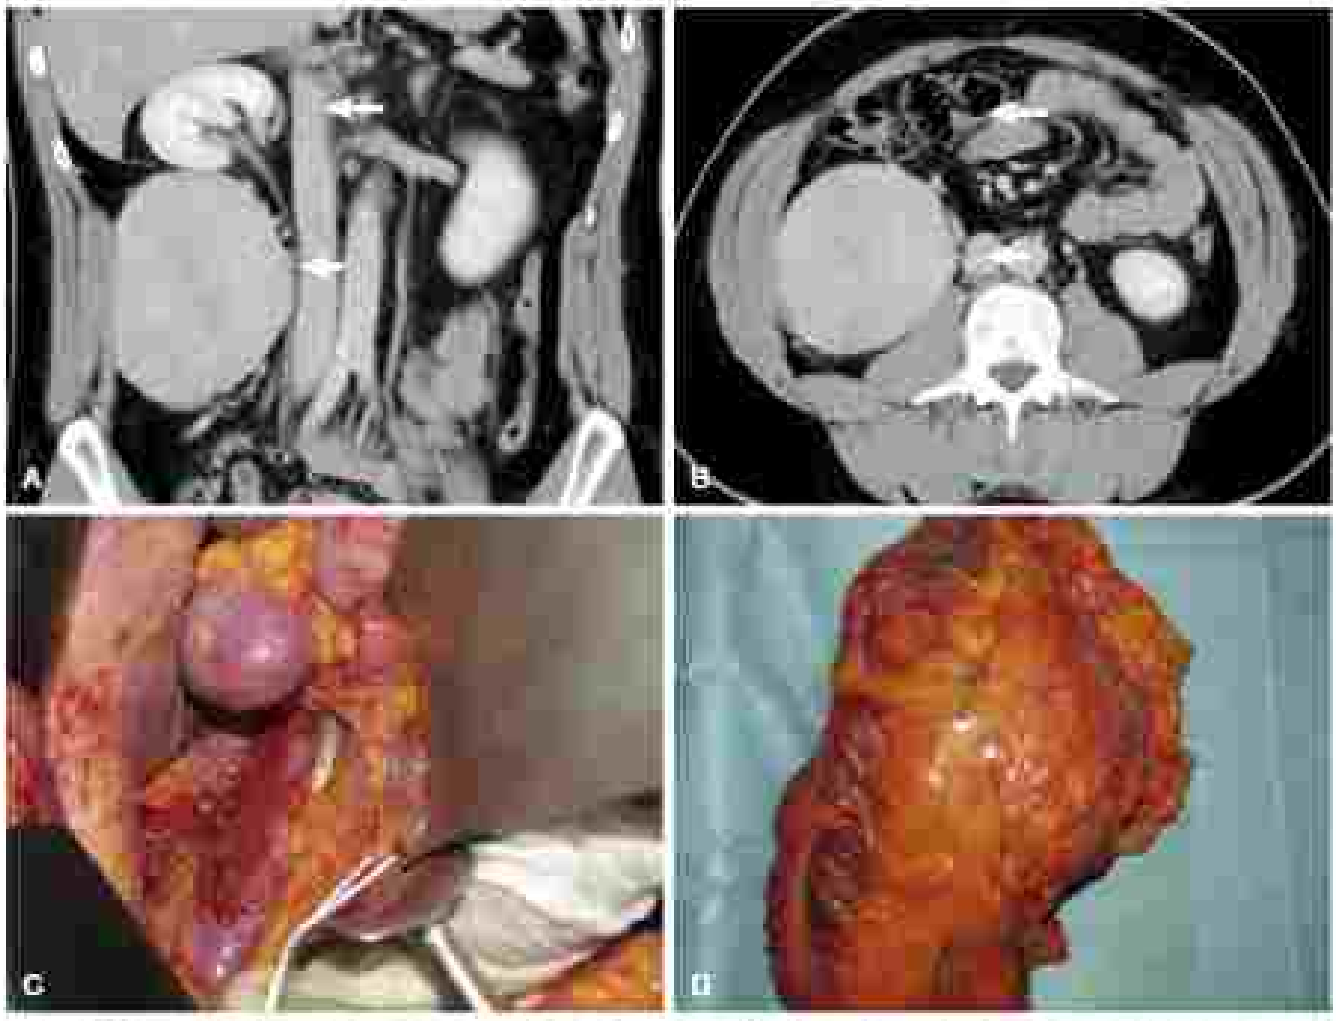

FIG. 11 (A–B) Coronal/axial computed tomography images of a right retroperitoneal solitary fibrous tumor (short arrow) displacing the right kidney and the right colon (long arrow). Surgical field (C) after tumor removal en bloc with peritoneal capsule, psoas muscle fascia, and right colon (D).

lymphedema. Now, it is more commonly seen as a consequence of RT. RT associated angiosarcoma is a cutaneous malignancy that may extend into breast parenchyma, whereas primary angiosarcoma is a disease of the breast parenchyma. Thus the operation for secondary angiosarcoma is different than that for primary angiosarcoma. Patients with secondary RT- associated angiosarcoma should undergo not only a total mastectomy but also, more importantly, resection of the affected organ—all of the breast skin. The disease is often multifocal, and therefore as much of the irradiated skin should be removed en bloc with the breast as possible. This is critical—a simple mastectomy alone does not remove the organ (skin) involved, and recurrence may be noted within weeks to months. If the tumor extends to the pectoralis major, then the muscle should be removed as well. All patients require extensive reconstruction, including skin grafting just to recover a flat, closed chest wall. Preoperative staging should include an MRI of the breast and a CT of the chest, abdomen, and pelvis. Follow up imaging should include CT of the chest, abdomen, and pelvis. MRI of the chest wall is not usually necessary because local recurrences are often apparent on clinical examination alone.

Phyllodes Tumor

Phyllodes tumors of the breast can grow to be quite large. Surgery alone is the primary therapy. Tumors should be resected with a negative margin; for smaller tumors, a lumpectomy may be possible, but, for larger tumors, a simple mastectomy may be necessary. Lymph node biopsy is not necessary. Recurrence may be observed in approximately 15% of patients, including local recurrence in the ipsilateral breast and distant recurrence in locations such as the lung and liver. Contralateral breast recurrences are exceedingly rare, and thus contralateral prophylactic mastectomy is not indicated.

HISTOLOGY-SPECIFIC TREATMENT

ALT/Well-Differentiated Liposarcoma

This low grade tumor, when arising in the extremity, has a relatively low rate of recurrence, may not recur for quite some time, and has no risk of distant metastatic spread and death, unless dedifferentiation occurs over its natural history. Dedifferentiation, if it occurs, in fact entails a risk of metastatic spread as high as 20%. In contrast, low-grade locally recurrent ALT may grow slowly for years. Therefore such tumors arising in the extremity can be resected with a limited negative or even a positive margin, especially when preserving limb function is an issue (Fig. 13). Radiographically, ALT may be difficult to distinguish from an intramuscular lipoma, a benign entity that can also arise in deep muscle tissue. ALT/well-differentiated liposarcoma is a more threatening neoplasm when located in the retroperitoneum, even in absence of areas of dedifferentiation. In fact, as discussed above, local control is an issue at this site, and patients often die of locoregional failure, without developing distant metastases (Fig. 14).

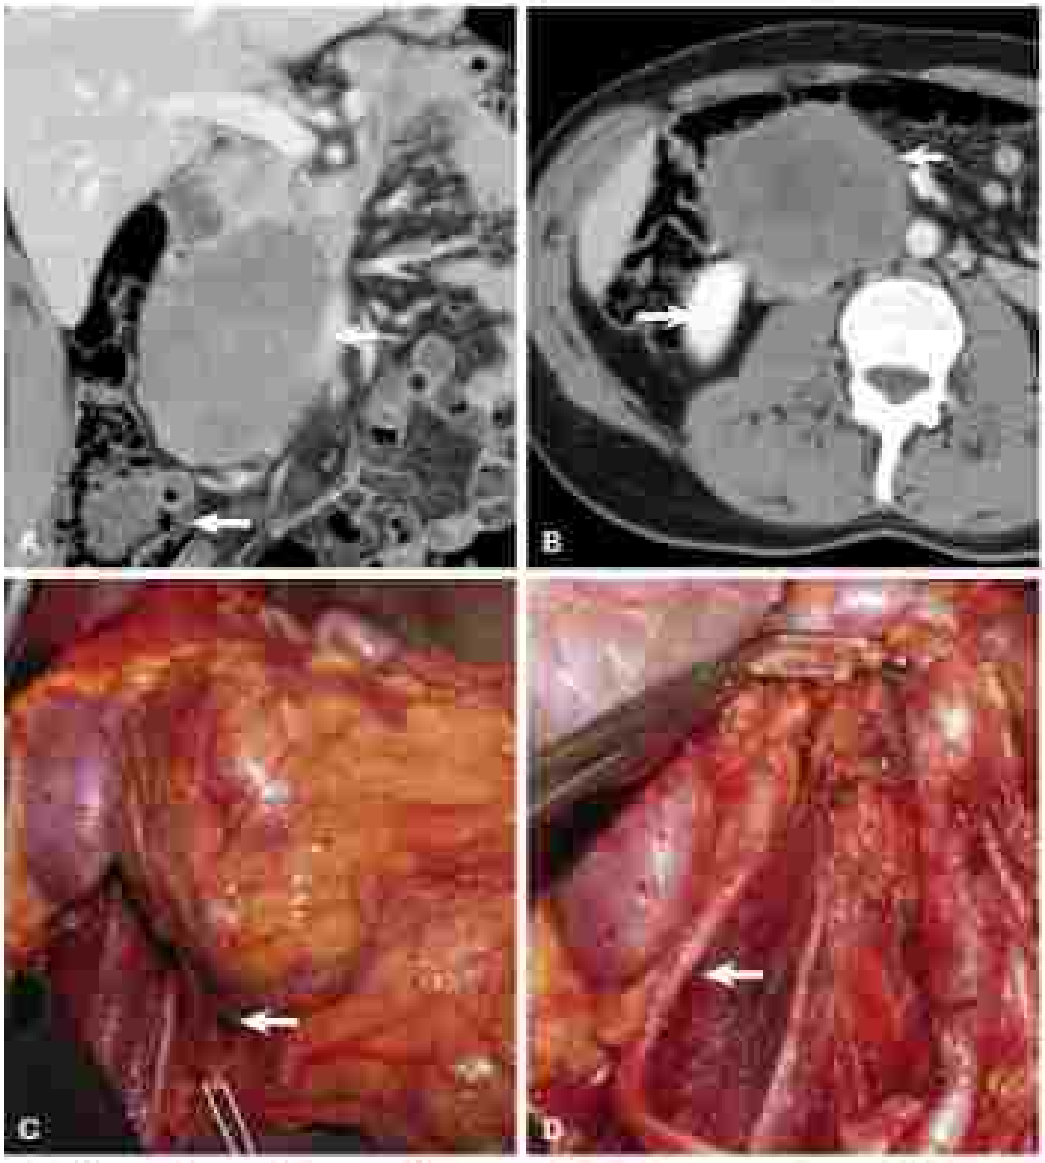

FIG. 12 (A–B) Contrast-enhanced computed tomography images of a leiomyosarcoma of the inferior vena cava (short arrow) displacing the right kidney and the right colon (long arrow). Intraoperative images showing displacement (C, arrow) and preservation of the right ureter and kidney (D, arrow).

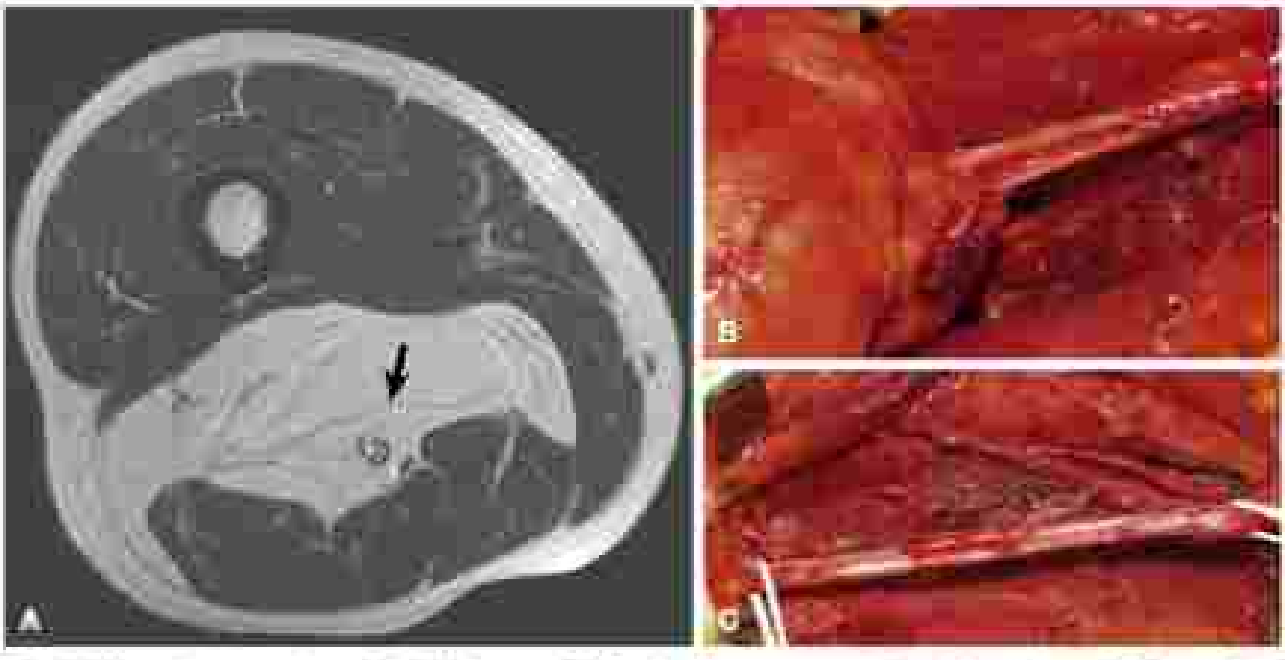

FIG. 13 (A) Axial magnetic resonance image of the thigh shows a well-differentiated liposarcoma encasing the sciatic nerve (arrow). (B) Tumor pushed off the sciatic nerve. (C) Surgical field after resection of the tumor with demonstrated nerve.

Myxoid Liposarcoma

Myxoid liposarcoma is a subtype of liposarcoma, commonly arising in extremities and notable for two key unusual characteristics that impact treatment and surveillance. First, it is particularly sensitive to chemotherapy and radiation therapy, such that the use of either or both in the neoadjuvant setting can result in significant tumor shrinkage (Fig. 13). This can be particularly beneficial if the tumor is abutting a critical structure, such as bone, vessel, or nerve. In fact, the sensitivity of this histologic subtype to radiation serves as the basis of an ongoing noninferiority trial evaluating lower doses of neoadjuvant radiation (36 Gy) instead of the traditional neoadjuvant dose (50 Gy). Second, myxoid liposarcoma has a propensity to metastasize to unusual sites, including extraspinal tissue. Therefore we recommend periodic imaging of extraspinal tissue (including muscle and bone).

FIG. 14 Locally advanced well-differentiated liposarcoma.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a superficial tumor that infiltrates soft tissue for centimeters beyond the obvious margins of the lesion and can recur locally after an inadequate resection. However, the more common variety of DFSP does not display metastatic behavior. Therefore the goal of surgery should be negative margins, often necessitating reconstruction by plastic surgery. When cosmesis is an issue, limited positive margins may be accepted, and a wider resection postponed until DFSP locally recurs. Due to the relatively indolent nature of the growth of DFSP, a tissue expander may be placed, and resection may be delayed to allow a single stage resection and reconstruction (Fig. 16). Because DFSP is usually a relatively superficial tumor, resection of muscle deep to the tumor is not often necessary. Intraoperative frozen section margin analysis is not generally helpful because the surrounding fat rarely freezes well for analysis. Mohs' micrographic surgery has been reported as a treatment for this neoplasm, but long-term results are lacking. Follow-up should consist of a physical examination, and imaging may be reserved for patients with a suspicious mass in the tumor bed. Approximately 5% to 10% of patients with DFSP have a more aggressive fibrosarcomatous variant that may recur locally and potentially spread. These individuals should be treated as a "conventional" sarcoma and followed up with systematic imaging. Radiation therapy is not usually recommended. Imatinib is approved for the management of locally advanced/metastatic DFSP. However, it should be noted that neoadjuvant imatinib does not change the original extent of the resection, even after shrinkage. In locally advanced disease, it is usually given as a bridge therapy when tissue expansion (for subsequent flap reconstruction) is required before performing the excision, especially when a fibrosarcomatous component is present.

Myxofibrosarcoma

This tumor, when located superficially, infiltrates through soft tissue (subcutaneous fat and investing fascia) centimeters beyond the macroscopic margins of the visible or palpable mass (Fig. 17). When located intramuscularly, the extension of the infiltration is usually limited by anatomic barriers, although it has a higher propensity to invade into these anatomic boundaries compared with other histologic subtypes. Myxofibrosarcoma most commonly arises in the extremities of elderly individuals. It demonstrates a 30% rate of local recurrence

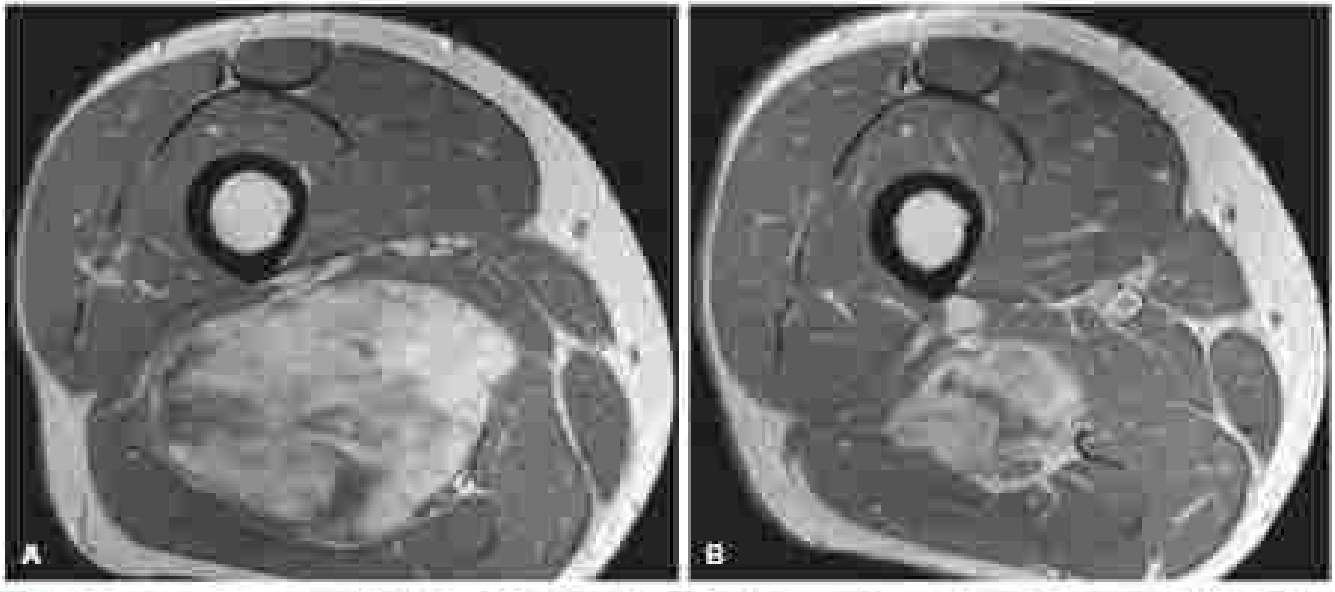

FIG. 15 High-grade myxoid liposarcoma of the right thigh. Contrast-enhanced T1-weighted magnetic resonance image, axial view at baseline (A) and after administration of neoadjuvant chemotherapy (B) (three courses of anthracycline + ifosfamide) and radiotherapy (to a total dose of 50 Gy).

FIG. 16 Dermatofibrosarcoma protuberans repaired by a rotational flap after prior tissue expander placement. Residual tan of incision line marked in black (arrow).

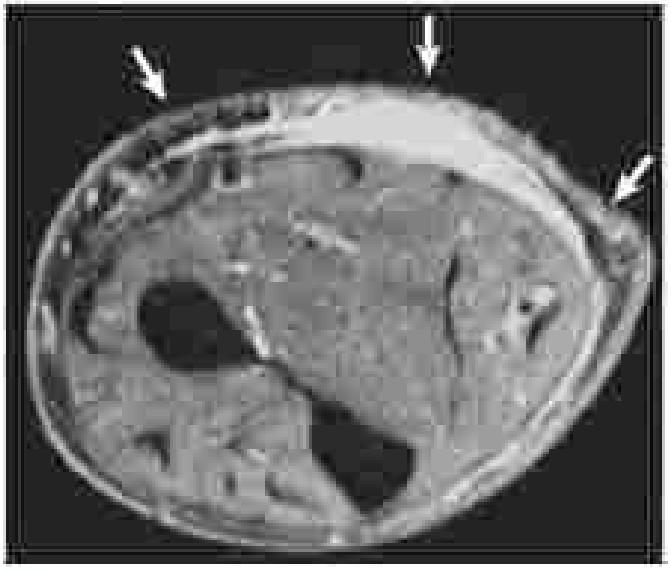

FIG. 17 Superficial myxofibrosarcoma of the forearm, with infiltration of the surrounding tissue extending 2 to 3 cm from the mass. The effect is shown by arrows.

and 10% rate of distant recurrence. Multiple local recurrences have been associated with eventual amputation. Therefore it is critical to pursue aggressive local therapy. Wide surgical margins (2- to 4-cm radial margins beyond the clinical boundaries of the palpable mass, especially in more superficial tumors) should be the goal of surgery, which often requires complex wound closure or flap reconstruction by a plastic and reconstructive surgeon, as well as resection and reconstruction of vessels, nerves, or both. Radiation therapy, either before or after surgery (described below), may be considered because this specific histology is one of the most sensitive to this treatment modality. Follow-up imaging should include the primary site (usually with an MRI), as well as the lungs (chest CT).

Angiosarcoma

Management of primary and radiation-associated (secondary) angiosarcoma of the breast is discussed in the section on breast carcinoma above. Scalp angiosarcoma (Fig. 18) is a particularly insidious malignancy. Scalp angiosarcomas are commonly multifocal, by both clinical examination and CT or MRI imaging. Although radical surgery is possible (requiring complex flap reconstruction), it is not uncommon for patients to develop local recurrences immediately outside the margins of resection, even if the margins of the initial resection were widely negative and with or without radiation therapy. Angiosarcoma is sensitive to systemic chemotherapy and to radiation therapy. Because surgery is rarely curative, it should not be considered first-line therapy for scalp angiosarcoma. Surgery may be reserved for patients who are experiencing problems with local control (bleeding from a fungating tumor) or who only appear to have a solitary site of disease by both clinical examination and imaging while undergoing systemic therapy.

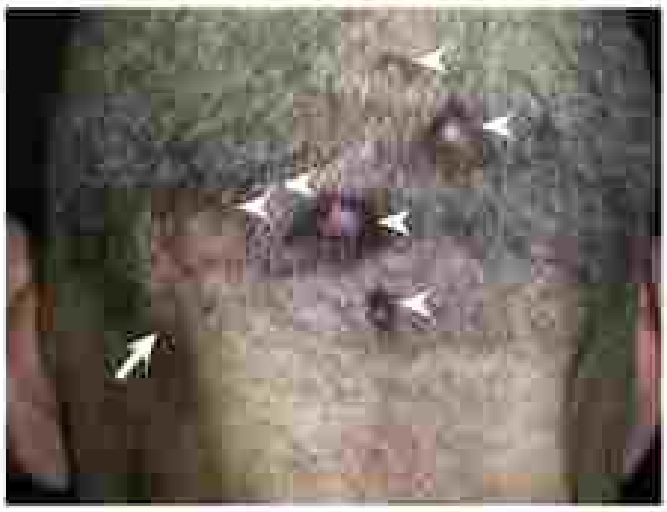

FIG. 18 Multifocal angiosarcoma (arrow) on scalp with necrotic tumor rarely penetrated.

Radiation-Induced Sarcomas

Radiation-induced sarcomas are rare and include a variety of histologic subtypes, the most common of which are undifferentiated pleomorphic sarcoma, angiosarcoma, malignant peripheral nerve sheath tumors, and leiomyosarcoma. In addition to the intrinsic characteristics of each histologic subtype, all characterized by a high propensity to locally recur, given the difficulty of obtaining clear margins. This is due in part to the difficulty in distinguishing tumor infiltration of healthy tissues from radiation-induced soft tissue changes around the tumor site and in part to the discontiguous and multifocal involvement of tissue within the radiation field (Fig. 19). The tumor should be excised with as much tissue around it as possible. This often, if not always, requires reconstruction and coverage by a plastic surgeon and potentially a more liberal policy of neurovascular resection and reconstruction. Systemic chemotherapy and reirradiation are often considered, given the overall dismal prognosis, although the use of the latter must be weighed with caution.

Malignant Peripheral Nerve Sheath Tumors

Malignant peripheral nerve sheath tumors (MPNSTs) often arise from a major peripheral nerve, which can be identified macroscopically. They can occur sporadically or in the context of neurofibromatosis type 1. The high-grade variant is marked by an early propensity for distant metastasis. When originating from a peripheral nerve, MPNST also may spread along the nerve fibers proximally or distally. Wider margins at this level should be obtained (if possible, at least 4 cm of macroscopic healthy nerve, Fig. 20) to limit locoregional failure, which eventually may reach the spinal cord. Intraoperative

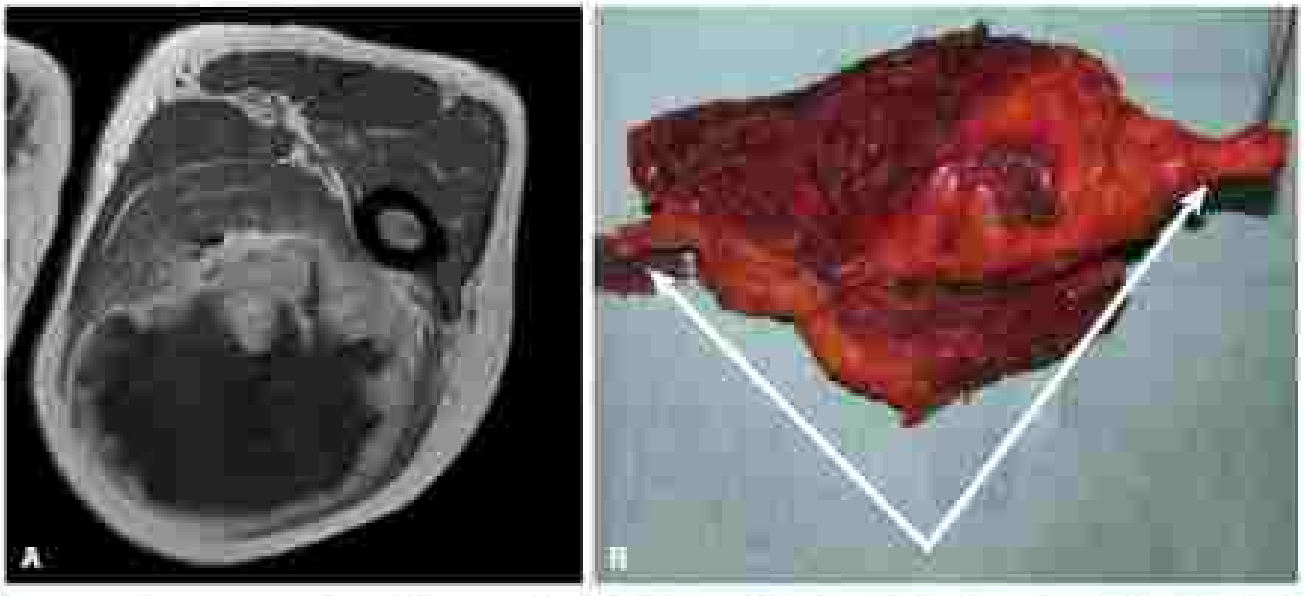

FIG. 20 Preoperative magnetic resonance image (A) and surgical specimen (B) demonstrating malignant peripheral nerve sheath tumor arising from the sciatic nerve (arrows indicating nerve margin).

tissue sarcoma analysis may help ensure clear margins. Systemic chemotherapy is used in an individualized basis.

Desmoid Fibromatosis

Desmoid fibromatosis is a noninvasive neoplasm that displays malignant local behavior. Desmoids may arise in the context of familial adenomatous polyposis (FAP), concurrent with a pregnancy, or sporadically. Those arising in the context of FAP may be quite aggressive, often involving the bowel mesentery and occasionally encasing the mesenteric vessels. In fact, local complications secondary to desmoids are the most common cause of death after colon cancer in individuals with FAP. Those arising during pregnancy may grow during pregnancy, but often this growth stabilizes postpartum.

Recently, there has been a trend toward less radical surgery and more nonoperative management. The natural history of desmoids may vary, and often tumors stop growing or even shrink without intervention (Fig. 21). Therefore primary nonoperative management is now considered the primary approach, particularly for tumors situated in difficult locations. In case of persistent progression, different management is considered, depending on the location. Systemic therapy, including cytotoxic intravenous chemotherapy with different agents and schedules, oral tyrosine kinase inhibitors (imatinib,

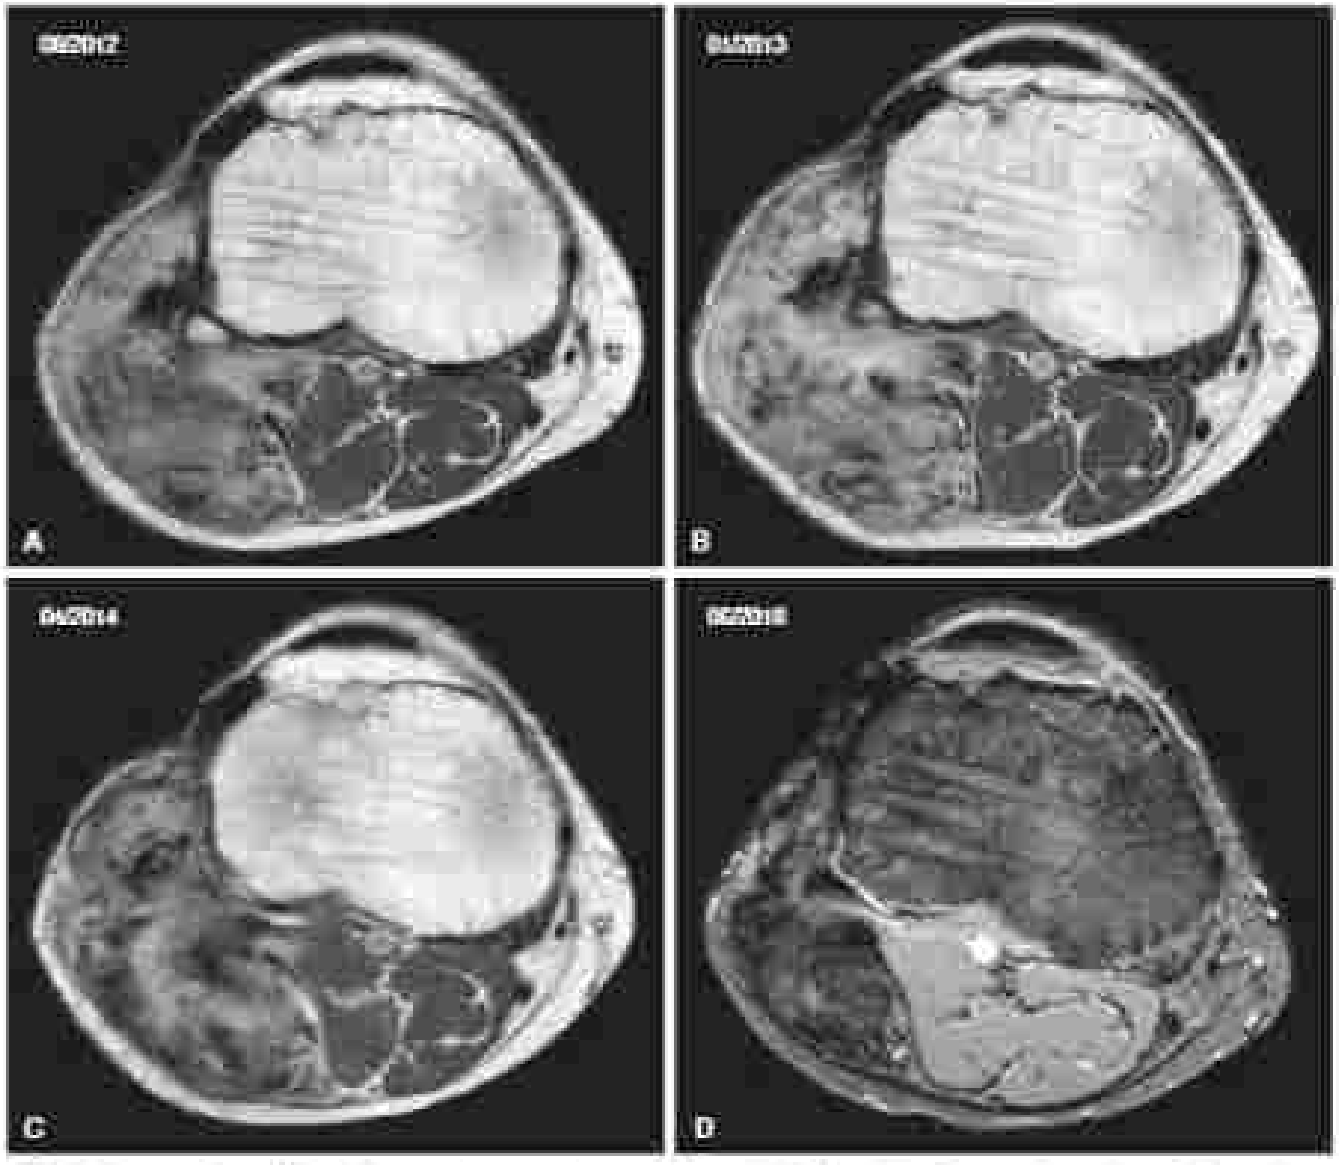

FIG. 21 Axial contrast-enhanced T1-weighted magnetic resonance images of right proximal leg dermatofibrosarcoma on active surveillance only at baseline (A), 6 months (B), 12 months (C), and 20 months (D) later. A lack progression after initial slight progression and subsequent stabilization is clearly seen.

steroids), nonsteroidal antiinflammatory drugs, and hormonal agents such as tamoxifen have varying degrees of efficacy and are often considered before resorting to surgery, with the only possible exception of sporadic abdominal wall desmoids, which are characterized by an optimal postsurgical outcome.

When surgery is undertaken, it is important to avoid compromising function when possible. Mesenteric desmoids may be particularly problematic to resect, especially those associated with FAP, and surgery should be approached with caution. Every care should be taken to avoid a modality that determines higher morbidity than the one determined by the presence of the disease itself.

SUMMARY

Soft tissue sarcomas may arise in a variety of body sites and within a variety of tissues. The management of STS requires a thorough understanding of the biology of the different histologic conditions. Limb- and function-sparing approaches should be used when feasible, but extent of surgery should not be compromised for sake of chosen. Margins of resection and use of adjuvant radiation therapy and chemotherapy are contingent on accurate histologic diagnosis. However, adjuvant therapy after a marginal resection is not an appropriate substitute for a margin negative operation. Treatment planning should include multidisciplinary consultation to determine optimal therapy, taking into consideration the size and extent of the disease, its natural history and sensitivity to available treatments, surgical challenges, and, of course, the wishes of the patient.

MANAGEMENT OF SOLITARY NECK MASS

Allison N. Martin, MD, MPH, John B. Hanks, MD, and Philip A.S. Ash, MD

A isolated neck mass is a common clinical scenario in patients of all ages. Management varies widely with the multiple etiologies. Success in this scenario requires familiarity with cervical anatomy, an organized approach to differential diagnosis, and a stepwise evaluation as summarized in Fig. 1. Tissue acquisition for diagnosis often is required, and surgical treatment is indicated for many etiologies of neck mass. Therefore the prepared surgeon is well positioned to play a central role in the clinical evaluation, diagnostic workup, and management of neck masses.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the isolated neck mass is broad and includes congenital, inflammatory, and neoplastic processes (Box 1). Between 2% and 9% of head and neck cancers present as cervical masses without a known primary. Although malignancy must be considered in all cases of neck mass, the likelihood varies significantly with age. In the pediatric population, less than 10% of neck masses are neoplastic, whereas as many as 80% of neck masses that occur outside of the thyroid are neoplastic in adults over the age of 40 years. Additionally, human papillomavirus (HPV) has been increasingly associated with the development of head and neck cancers in the United States.

WORKUP

History

The clinical history gives indications regarding the likelihood that a given neck mass is benign or malignant. The importance of patient age helps to stratify the most likely cause of the neck mass: young patients (<16 years) are most likely to have an inflammatory or congenital lesion; the cause of a neck mass in patients ages 16 to 40 is still most often inflammatory or congenital but may also be malignant; masses in patients older than 40 years should be considered malignant until proven otherwise. Other history items concerning for malignancy include a personal history of malignancy, family history of malignancy, smoking or other tobacco use, heavy alcohol use, sun exposure, and radiation exposure. Neck specific history items that are concerning for malignancy include persistent mass, dysphagia, hoarseness or other neurologic deficit, epistaxis, and radiating pain, including otalgia. Constitutional symptoms such as sweats, fevers, fatigue, and weight loss are concerning for lymphoma or other malignancy but also may be present with infectious etiologies. Rapidly developing tender masses are often infectious or inflammatory. It is important to fully characterize the timing of onset of the mass and how it has changed over time, in either size or character, since it was first noted.

One also should ask about prior treatments, biopsies, and surgical interventions. More often in children, but also in adults, lymphadenopathy may already have been treated with antibiotics. Persistence of lymphadenopathy after antibiotics should be considered concerning for malignancy. Retrieval of relevant prior imaging, operative reports, pathology reports, and pathology specimens is imperative whenever possible.

A history of severe or episodic hypertension rarely may be associated with a head and neck paraganglioma, although only a small minority of head and neck paragangliomas are functional. Cough provoked by pressure on the mass has been associated with schwannomas of the vagus nerve. This can be confirmed with palpation on physical examination.

Finally, the incidence of HPV-associated oropharyngeal squamous cell carcinomas has more than doubled in recent years. Diagnostic delay for these lesions is typically due to differential epidemiology and presentation compared with classical head and neck cancers in that affected individuals are (1) younger and lack exposure to tobacco, alcohol, or both and (2) present as neck metastases without a known primary and can be cystic in nature, causing diagnostic confusion with branchial cleft cysts.

Physical Examination

A focused physical examination of the head and neck is essential to properly evaluate a neck mass. Important examination findings include firmness, nonmotion, asymmetry in the contralateral neck, fixation to surrounding structures, midline mass, and neurologic deficit, including cranial nerve (CN) function (see the "Surgical Considerations" section for a detailed discussion of CNs at risk for injury). All other aspects of the neck also should be examined, including the thyroid and salivary glands, as well as all nodal basins. The examiner can typically distinguish thyroid from nonthyroid tissue on physical examination, otherwise ultrasonography can make this clear. Visualization of the mucosal surface of the upper aerodigestive tract is important, as is evaluation of the skin of the head and neck, including the scalp and auditory canal. Palpation with the gloved hand, including bimanual palpation of the floor of the mouth, may help with identification of abnormalities that exist deep to normal-appearing mucosa. Examination of dentition could reveal dental infection that can result in cervical lymphadenopathy.

Management of Solitary Neck Mass

Allison N. Martin, MD, MPH, John B. Hanks, MD, and Philip W. Smith, MD

An isolated neck mass is a common clinical scenario in patients of all ages. Management varies widely with the multiple etiologies. Success in this scenario requires familiarity with cervical anatomy, an organized approach to differential diagnosis, and a stepwise evaluation as summarized in Fig. 1. Tissue acquisition for diagnosis often is required, and surgical treatment is indicated for many etiologies of neck mass. Therefore the prepared surgeon is well positioned to play a central role in the clinical evaluation, diagnostic workup, and management of neck masses.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the isolated neck mass is broad and includes congenital, inflammatory, and neoplastic processes (Box 1). Between 2% and 9% of head and neck cancers present as cervical masses without a known primary. Although malignancy must be considered in all cases of neck mass, the likelihood varies significantly with age. In the pediatric population, less than 10% of neck masses are neoplastic, whereas as many as 80% of neck masses that occur outside of the thyroid are neoplastic in adults over the age of 40 years. Additionally, human papillomavirus (HPV) has been increasingly associated with the development of head and neck cancers in the United States.

WORKUP

History

The clinical history gives indications regarding the likelihood that a given neck mass is benign or malignant. The importance of patient age helps to stratify the most likely cause of the neck mass: young patients (<16 years) are most likely to have an inflammatory or congenital lesion; the cause of a neck mass in patients ages 16 to 40 is still most often inflammatory or congenital but may also be malignant; masses in patients older than 40 years should be considered malignant until proven otherwise. Other history items concerning for malignancy include a personal history of malignancy, family history of malignancy, smoking or other tobacco use, heavy alcohol use, sun exposure, and radiation exposure. Neck specific history items that are concerning for malignancy include persistent mass, dysphagia, hoarseness or other neurologic deficit, epistaxis, and radiating pain, including otalgia. Constitutional symptoms such as sweats, fevers, fatigue, and weight loss are concerning for lymphoma or other malignancy but also may be present with infectious etiologies. Rapidly developing tender masses are often infectious or inflammatory. It is important to fully characterize the timing of onset of the mass and how it has changed over time, in either size or character, since it was first noted.

One also should ask about prior treatments, biopsies, and surgical interventions. More often in children, but also in adults, lymphadenopathy may already have been treated with antibiotics. Persistence of lymphadenopathy after antibiotics should be considered concerning for malignancy. Retrieval of relevant prior imaging, operative reports, pathology reports, and pathology specimens is imperative whenever possible.

A history of severe or episodic hypertension rarely may be associated with a head and neck paraganglioma, although only a small minority of head and neck paragangliomas are functional. Cough provoked by pressure on the mass has been associated with schwannomas of the vagus nerve. This can be confirmed with palpation on physical examination.

Finally, the incidence of HPV-associated oropharyngeal squamous cell carcinomas has more than doubled in recent years. Diagnostic delay for these lesions is typically due to differential epidemiology and presentation compared with classical head and neck cancers in that affected individuals are (1) younger and lack exposure to tobacco, alcohol, or both and (2) present as neck metastases without a known primary and can be cystic in nature, causing diagnostic confusion with branchial cleft cysts.

Physical Examination

A focused physical examination of the head and neck is essential to properly evaluate a neck mass. Important examination findings include firmness, nonmotion, asymmetry in the contralateral neck, fixation to surrounding structures, midline mass, and neurologic deficit, including cranial nerve (CN) function (see the "Surgical Considerations" section for a detailed discussion of CNs at risk for injury). All other aspects of the neck also should be examined, including the thyroid and salivary glands, as well as all nodal basins. The examiner can typically distinguish thyroid from nonthyroid tissue on physical examination, otherwise ultrasonography can make this clear. Visualization of the mucosal surface of the upper aerodigestive tract is important, as is evaluation of the skin of the head and neck, including the scalp and auditory canal. Palpation with the gloved hand, including bimanual palpation of the floor of the mouth, may help with identification of abnormalities that exist deep to normal-appearing mucosa. Examination of dentition could reveal dental infection that can result in cervical lymphadenopathy.

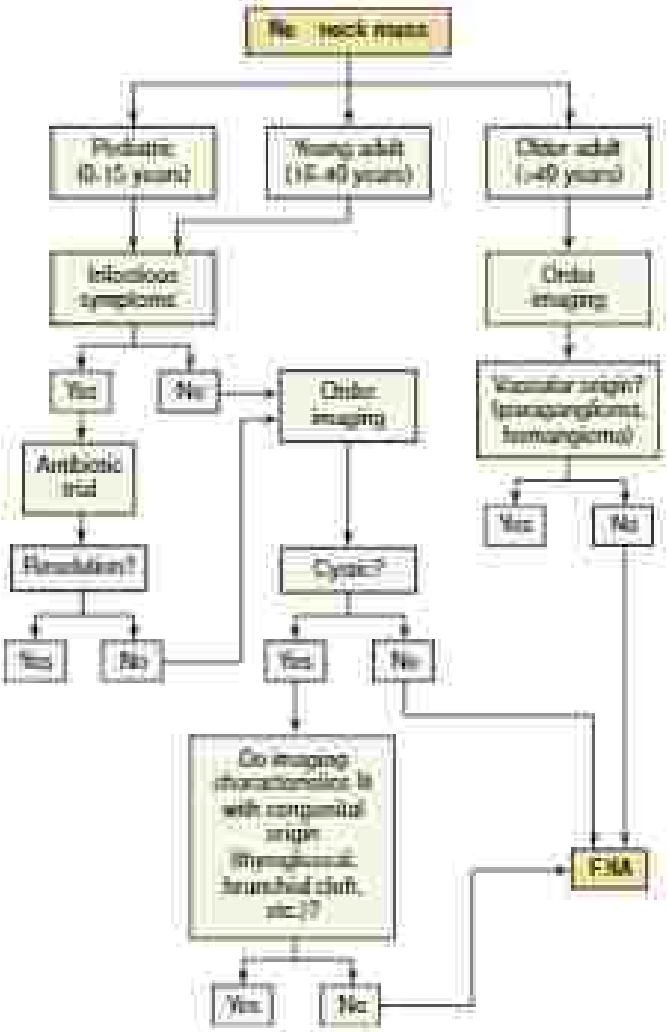

FIG. 1 Diagnostic algorithm for a new neck mass. The distinction made based on age of 40 years should be taken as a general guideline to be adjusted based on clinical evaluation and not as an absolute rule. FNA, fine-needle aspiration. *(Modified from Hui FW, Hughes RJ, Lund VJ, et al. Infra-Carotid Digastric Triangle Lymphadenopathy: A New Classification. Philadelphia: Elsevier; 2010.)*

BOX 1 Differential Diagnosis of Neck Masses

Developmental

Inclusion cyst
Thyroglossal duct cyst
Congenital vascular malformations
Branchial cleft cyst
Cystic hygroma
Laryngocele
Teratoma
Bronchogenic cyst
Infections
Bacterial lymphadenitis (*Staphylococcus aureus*, *Streptococcus pyogenes*, *Bartonella*, *Brucella*)
Viral (Epstein-Barr, HIV, other common viruses)
Protozoal (toxoplasmosis, leishmaniasis)
Fungal (histoplasmosis, blastomycosis, coccidioidomycosis)

Inflammatory

Sarcoidosis, tuberculosis
IgG4 disease
Sarcoidosis
Aneurysm

Benign Neoplasia

Lipoma
Thyroid nodule/diffuse goiter
Parathyroid adenoma (rarely palpable)
Fibroma
Neurofibroma
Schwannoma (cyst)
Benign salivary tumors (pleomorphic adenoma, Warthin's tumor)

Malignancies

Lymphoma
Carotid body tumor
Thyroid cancer
Malignant salivary tumors (mucoepidermoid, adenoid cystic)
Parathyroid cancer
Pheochromocytoma
Carcinoid
Metastasis to cervical lymph nodes (thyroid, squamous cell carcinoma, adenocarcinoma, melanoma)

Patients and even referring physicians may mistake normal structures for pathology. Such structures may include gnathic salivary glands, the horn of the thyroid cartilage, the hyoid bone, or spinal transverse processes (particularly C2). Therefore examination of the neck should first confirm the presence of a pathologic finding. If an abnormality is present, a detailed examination ensues. The mass should be measured in at least two dimensions with a tape measure and the findings documented. Photographs for the medical record may also be valuable. The location of the mass should be precisely defined. The location should be defined not only in a descriptive fashion relative to normal anatomy (e.g., "at the anterior border of the sternocleidomastoid muscle [SCM] at the level of the cricothyroid") but also by the nodal level based on the system outlined in Fig. 2A and Table 1. This system of nodal levels is of value for several reasons: (1) it allows reproducible communication between caregivers and referral boundaries with physical examination, imaging, and operative anatomy; (2) nodal levels are diagnostically important because malignancies of different origins spread characteristically to different nodal levels (see Table 1); and (3) lymph node levels are important therapeutically because lymph node dissection typically proceeds based on nodal level compartment dissection. The location of a neck lesion may also be noted in reference to the anatomic triangles of the neck as delineated by the SCM (Fig. 2B).

Mirror examination or flexible fiberoptic laryngoscopy allows significantly improved visualization and can be performed in the office setting. Evaluation of all mucosal surfaces is possible, from the nasal cavity to the vocal cords. The location of the neck lesion that is concerning for metastatic lymphadenopathy helps to determine the most likely primary sites and can guide this evaluation. Attention should be paid to all visible surfaces, especially the lymphoid regions of the nasopharynx, base of the tongue, and oropharynx (Waldeyer's ring).

In addition to examination of the head and neck, a thorough physical examination is warranted in all cases of neck mass. One should note the presence of cachexia and stigmata of alcoholism or tobacco abuse. Examination of skin, lungs, and abdomen may provide clues with regard to a primary source of metastatic disease in the neck. Axillary and femoral lymph node basins should be examined and may be revealing in a systemic disease process. General examination also helps the surgeon understand a patient's general fitness to tolerate medical and surgical interventions. The clinician also should look for any prior incisions that indicate diagnostic or therapeutic interventions that the patient may have neglected to describe.

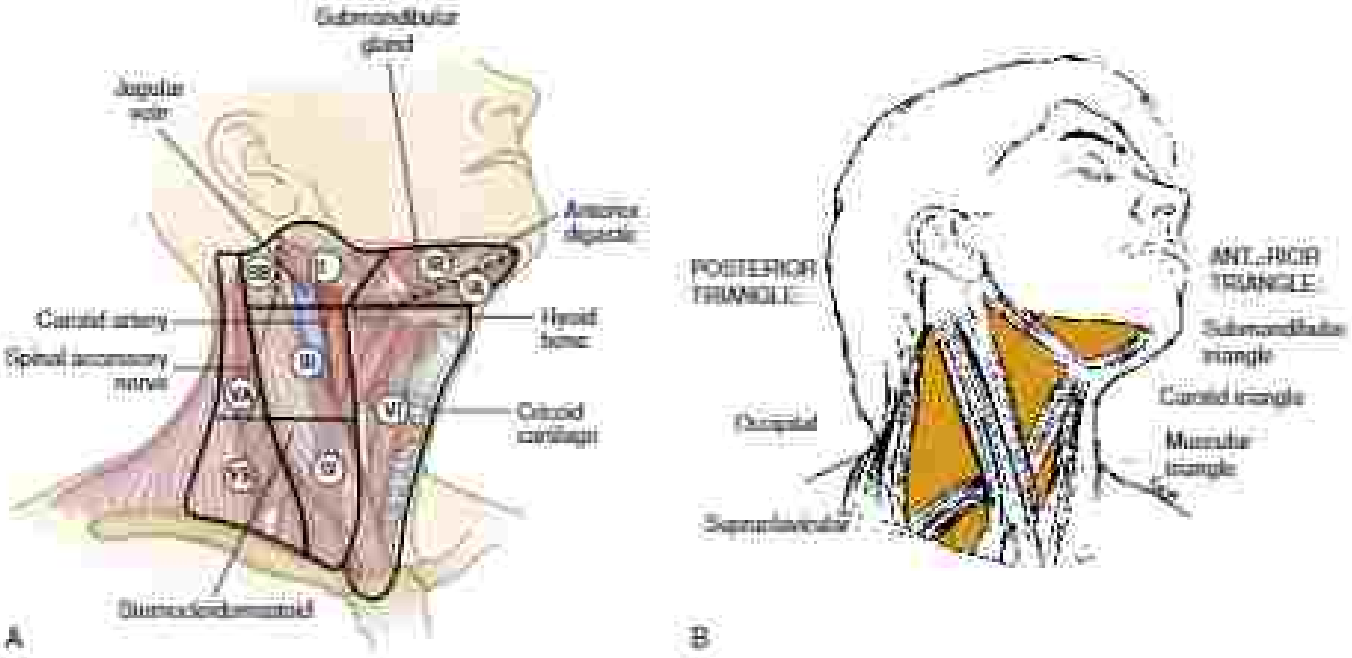

FIG. 2. (A) Head and neck lymph node levels of the neck. Boundaries are given in Table 1. Criteria exist to define these levels clinically, radiographically, and surgically. (B) The neck is divided into two major triangles, anterior and posterior, by the sternocleidomastoid muscle. The anterior triangle may be further subdivided into the carotid, submandibular, submental, and muscular triangles; the posterior belly of the omohyoid divides the posterior triangle into occipital and supraclavicular triangles. (A, From Smith PW, Saboorian MH, Haffty B, Ogunbiyi O. Cancer control in the United States. Lancet Oncol. 2002;3:698–707. Modified from Lingeman RE. Surgical anatomy. In: Cummings CW, et al, eds. Otolaryngology—Head & Neck Surgery. 2nd ed. St Louis: Mosby; 1993.)

TABLE 1 Boundaries of Cervical Lymph Node Levels and Considerations for Primary Site for Metastatic Disease

Boundaries and Contents		Metastatic Primary Sites
Level I	Submandibular and submental nodes. Bounded by the mandible superiorly, the midline anteriorly, the hyoid inferiorly, and the stylohyoid muscle posteriorly. Subdivided into IA and IB by the anterior belly of the digastric muscle. IA crosses the midline to the contralateral anterior belly of the digastric.	IA: Floor of mouth, lower lip, anterior tongue, lower gum. IB: Oral cavity, anterior nasal cavity, submandibular gland, midface soft tissues.
Level II	Upper jugular nodes. Bounded by the skull base superiorly, the stylohyoid muscle anteriorly, the inferior border of the hyoid bone inferiorly, and the posterior border of the SCM posteriorly. Subdivided into IIA and IIB by the spinal accessory nerve.	Oral cavity, nasal cavity, nasopharynx, oropharynx, hypopharynx, larynx, parotid gland
Level III	Middle jugular nodes. Bounded by the inferior border of the hyoid bone superiorly, the sternohyoid muscle anteriorly, the inferior border of the cricoid cartilage inferiorly, and the posterior border of the SCM posteriorly.	Oral cavity, nasopharynx, oropharynx, hypopharynx, larynx, cervical esophagus, thyroid
Level IV	Lower jugular nodes. Bounded by the inferior border of the cricoid cartilage superiorly, the sternohyoid muscle anteriorly, the clavicle inferiorly, and the posterior border of the SCM posteriorly.	Hypopharynx, thyroid, cervical esophagus, larynx, Virchow's node (lung or abdominal malignancy)
Level V	Posterior triangle nodes. Bounded by the junction of the trapezius and SCM superiorly, the posterior border of the SCM anteriorly, the clavicle inferiorly, and the anterior border of the trapezius laterally. Subdivided into VA and VB by the plane of the inferior border of the cricoid cartilage.	Nasopharynx, oropharynx, thyroid, cutaneous structures of scalp and neck, breast
Level VI	Also known as the central compartment. Prelaryngeal, pretracheal, delphian, paratracheal nodes, and parathyroidal nodes. Bounded by the hyoid bone superiorly, the carotid sheath laterally, and the sternum inferiorly.	Thyroid, glottic and subglottic larynx, piriform sinus, cervical esophagus
Level VII (variably defined)	This level is variably defined and is the substernal extension of level VI to the level of the innominate artery.	Similar to level VI

SCM, Sternocleidomastoid muscle.

Two congenital lesions are worth highlighting for their specific physical examination findings: thyroglossal duct cysts and branchial cleft cysts. Thyroglossal duct cysts are found in or near the midline of the neck and typically just below the hyoid bone and occur along the thyroglossal tract between the thyroid and the base of the tongue. They may become infected, which frequently follows an upper respiratory infection, or they may present as an asymptomatic mass. Most are diagnosed before adulthood, but initial presentation to adults is not uncommon. Protrusion of the tongue typically results in cephalad movement of the mass. This feature may be more easily appreciable by first applying inferior digital pressure on the mass before tongue protrusion. Thyroglossal duct cysts may create a mass effect or develop recurrent infections, and about 1% harbor malignancy. Therefore, when these cysts are found, excision of the cyst, presumptive labs, if present, and the tract up to the base of the tongue, including the central portion of the hyoid bone, is indicated (the Sistrunk procedure). Confirmation of the presence of normal thyroid tissue in the thyroid bed with examination or imaging before excision is important.

Branchial cleft cysts are also congenital lesions and, similar to thyroglossal duct cysts, may present with an inflammatory picture after an upper respiratory infection. These cysts are almost always diagnosed before age 30 years and account for 20% of pediatric neck masses. First branchial cleft cysts present inferior to the auricle or just below the angle of the mandible. These may communicate with the auditory canal and may be closely associated with the facial nerve. Second branchial cleft cysts are the most common (95%). They are found inferior to the angle of the mandible on the anterior border of the SCM and communicate with the tonsillar fossa. Third branchial cleft cysts also present on the anterior border of the SCM, lower than a second cleft cyst, and communicate with the pharynx at the thyrohyoid membrane or piriform sinus. Branchial cleft cysts and their tracts are typically excised with care given the relationship of these tracts to cranial nerves and other deep structures.

Imaging

Imaging of a neck mass may be valuable in characterizing the primary lesion, in searching for a primary source of a metastasis, and in follow up after an intervention. Anteroposterior and lateral chest radiographs should be obtained if concern exists that the neck mass is related to an atypical infectious or inflammatory source and in those with a history of cough or recent travel. Chest imaging also is indicated for those masses whose location and biopsy findings are concerning for a primary thoracic malignancy, such as lung cancer, and for patients with a new diagnosis of cancer to evaluate for pulmonary metastasis.

CT scanning of the neck requires ionizing radiation to the thyroid and is most valuable if performed with intravenous contrast. Contrast may be contraindicated because of renal disease or allergy. Despite this, contrast CT scanning is an excellent and widely available imaging modality and is superior to ultrasound scanning in providing three-dimensional resolution of the anatomy of the lesion and evidence of invasion or distortion of normal anatomy. Also, if the presenting lesion is thought to be nodal metastasis from a head and neck primary malignancy, high-quality CT scanning of the head and neck can identify a primary source in 20% of cases. Therefore contrast CT scanning of the head and neck is valuable and is indicated in many neck masses to which the diagnosis or primary source is not already defined.

Magnetic resonance imaging (MRI) is often better than CT scanning in defining the presence or absence of invasion by the mass into surrounding structures, particularly vascular and neural structures. It may also be helpful in patients with significant dental artifact, in pregnant patients, or in those with indicated contrast reactions. MRI is helpful in the diagnosis and evaluation of carotid body tumors, glomus tumors, and schwannomas.

Ultrasound scanning can serve as an extension of the physical examination during the initial office evaluation of the mass or through formal radiology performed scan. Ultrasound scanning avoids exposure to ionizing radiation or contrast and allows precise measurements of size and definition of the relationship to normal anatomy; distinguishes cystic from solid lesions; allows assessment of vascularity; characterization of lymph nodes and may help distinguish whether the mass is invasive into surrounding structures. Ultrasonographic features that suggest malignancy include loss of the normal hyperechoic fatty hilum, hyperechogenicity or hypoechogenicity, cystic degeneration, punctuate calcifications, unclear borders with surrounding structures, and perinodal edema (Fig. 3). Ultrasound scanning also is ideal for evaluation of thyroid nodules.

The role of positron emission tomography (PET) or fusion imaging of PET with CT scan (PET/CT) continues to be elucidated. PET and PET/CT are not appropriate first line studies for the initial evaluation of a neck mass. However, PET is an appropriate secondary imaging technique for patients who are being evaluated for a metastatic squamous cell carcinoma of unknown primary when CT scanning or MRI have been unrevealing.

With improvements in the capabilities of CT scanning and MRI, diagnostic arteriography is rarely necessary for neck masses. Arteriography may be indicated therapeutically, particularly for embolization of some highly vascular lesions before resection.

Tissue Diagnosis

The presence of an isolated neck mass in an adult over age 40 years should be considered malignant until proven otherwise. These masses may represent metastatic squamous cell carcinomas from the upper aerodigestive tract. Fine needle aspiration (FNA) biopsy plays a central role in the diagnostic evaluation of neck masses and should be considered the standard of care in undiagnosed adult neck masses. FNA can be performed with simple equipment, is widely available, is generally safe, and is diagnostic in 90% or more of cases. Samples can be evaluated for both pathology and microbiology, depending on the clinical scenario. Risks associated with this procedure include bleeding and sampling error. Furthermore, FNA can provide tissue for microbiologic testing, which is essential in the diagnosis and management of infectious processes, such as infectious lymphadenitis or HPV/Epstein-Barr virus–positive nodules.

Readily palpable lesions may be amenable to simple manual biopsy, but ultrasound scanning is now readily available, and real-time ultrasound guidance should most often be used to decrease risk and increase diagnostic yield. In cases of a cystic lymph node, ultrasound scanning should be used to ensure that the wall is sampled. Ultrasound guidance also helps to avoid needle biopsy of vascular lesions that are mistaken as a solid mass with examination if imaging is not already completed.

FNA typically can be performed on an outpatient basis. Because multiple passes should be taken, the use of local anesthetic is suggested. If manual palpation guidance is used, the mass should be transfixed between the thumb and forefinger of the nondominant hand. If ultrasound scanning is used, a 22- to 30-gauge is appropriate in most cases (Fig. 4). The needle should be passed along the long axis of the probe at an oblique angle so that the entire needle course can be imaged in real time. A short-axis technique also can be used, in which the needle is inserted perpendicular to the probe and is lateral by some. Needle guides are available with some ultrasound equipment and may be used if desired. A 22-gauge or 25-gauge needle is affixed to a 10-mL syringe with several milliliters of air already in the syringe. The syringe may be placed in a special control handle, but this is not required. The mass should be entered with negative pressure on the syringe. There is four aspirates should be made per pass, and multiple angled passes should be made to ensure adequate sampling. Suction on the syringe plunger should be released before exiting the mass to avoid aspiration of the sample into the body of the syringe. The syringe is then removed from the needle, filled with air, and placed back on the needle. The specimen is then expelled from the needle onto a glass slide. The slide containing the specimen is immediately

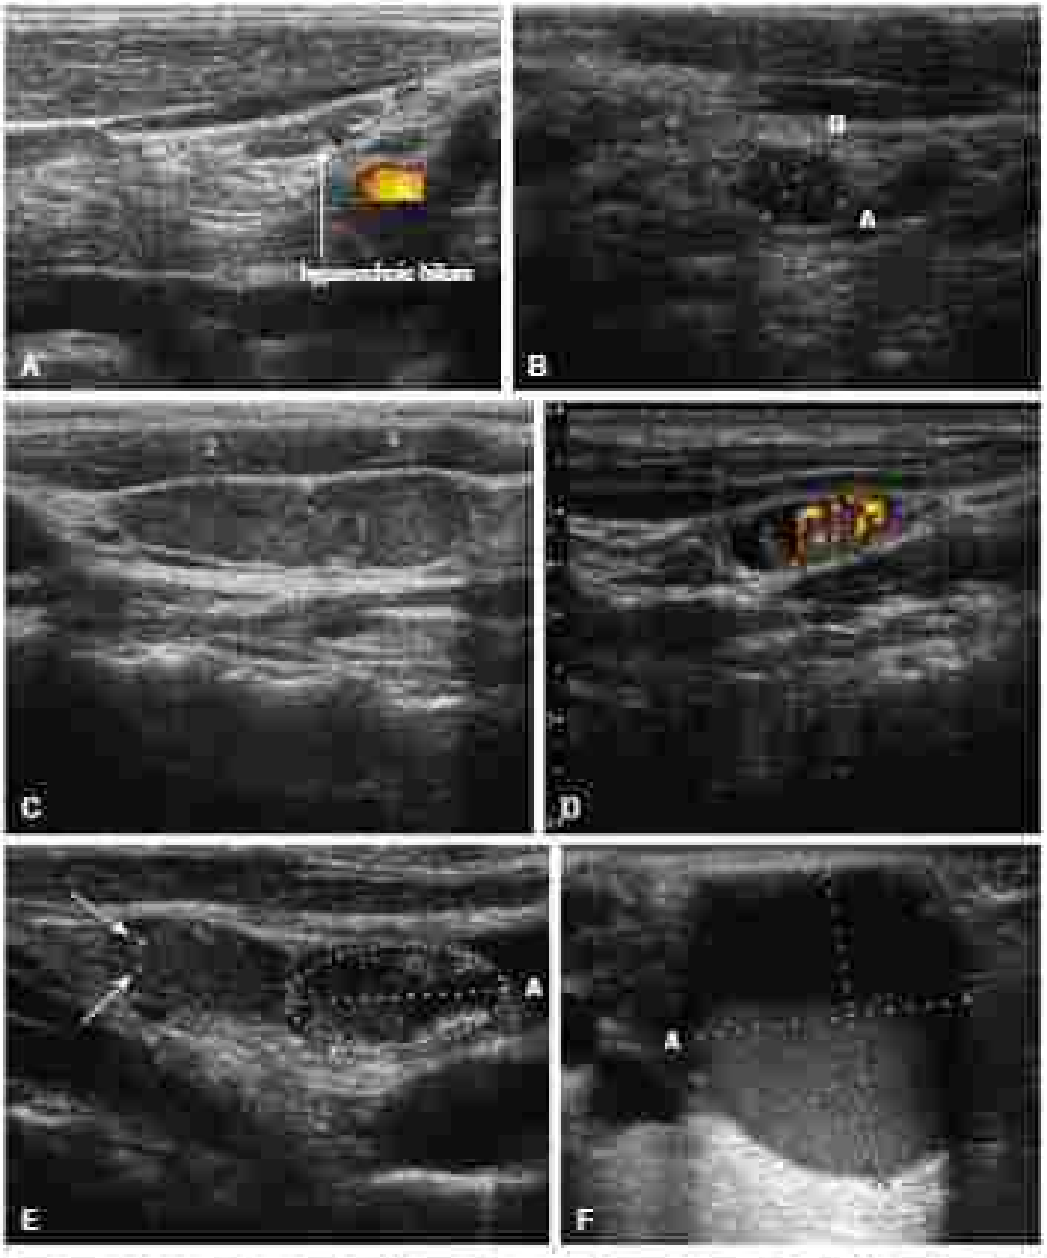

FIG. 3. (A) Benign lymph node shows hyperechoic fibers. (B) Malignancy mixed cystic and hyperechoic lymph node. (C) Malignant lymph node with loss of hyperechoic fatty fibers. (D) Malignant lymph node with peripheral and central vascularization. (E) Malignant lymph node with hyperechoic punctuate calcifications. (F) Malignant lymph node with cystic degeneration. (From Ghaedian T, Ozaki T, Ryan M, et al. Ultrasound features of malignancy for cervical lymph nodes in patients followed up for differentiated thyroid cancer. Clin Endocrinol Meta. 2020;92:690–694.)

smeared with another slide. The specimen is then promptly placed in formalin or ethanol to prevent desiccation. The presence of a cytologist for immediate review of the slides helps ensure that adequate specimen is achieved and increases diagnostic yield.

If initial FNA biopsy results are nondiagnostic, the surgeon should communicate with the pathologist to determine whether the specimen is inadequate or whether a different type of biopsy is needed. If inadequate biopsy is the problem, then repeat FNA with ultrasound guidance and immediate cytopathology review is indicated.

FNA biopsy provides the cytopathologist with the opportunity to comment on abnormalities at the cellular level but with minimal ability to comment on architectural characteristics. This may render specific diagnosis impossible, which is particularly a challenge for lymphoma and follicular thyroid cancer. In situations in which FNA biopsy is inadequate, core needle biopsy provides a small plug of tissue with some preservation of architectural features. A conversation with the pathologist familiar with the case is the best approach to ascertain whether a core needle biopsy is expected to be helpful beyond an FNA and therefore worth the slightly increased risk of hematoma or other injury. Core biopsy also typically should be performed with real-time ultrasound guidance. If lymphoma is suspected, this should be communicated to the pathologist to ensure appropriate specimen handling, including sending the specimen unfixed.

Excisional biopsy may be necessary in a minority of cases, roughly 10% of those with malignant neck mass. Advantages include excellent tissue acquisition for pathologic analysis and the potential of therapeutic benefit in some cases. Excisional biopsy also allows the surgeon to allocate a significant sample of tissue for culture. It is important to communicate directly with the pathologist so that the fresh tissue is handled appropriately, because incorrect processing in formalin

FIG. 4 Ultrasound-guided fine-needle aspiration biopsy of a neck mass lying posterior to the jugular vein. The biopsy was performed with a 22-gauge needle and confirmed metastatic papillary thyroid cancer. SCM, Sternocleidomastoid muscle.

can rule the sample for culture or cytology. Disadvantages include soreness, potential poor wound healing, particularly if therapeutic radiation may ensue, potential spread of disease, need for anesthesia, risk of surgical complication, such as nerve injury, and creation of a cooperative field if subsequent compartment-based dissection proves necessary. With the excellent success of FNA in diagnosis of squamous cell cancer, open biopsy should rarely be necessary. Not only does it expose the patient to anesthetic and procedural risks, but it may worsen the prognosis and increase the local failure rate. If squamous cell cancers remain a possibility and an excisional biopsy is planned, the surgeon should discuss proceeding directly to formal compartment-oriented neck dissection with the same anesthetic if squamous cell carcinoma ultimately is identified. Obviously, a thorough examination for a primary malignancy should be completed before this approach.

Although most thyroid masses are benign, a thorough and thoughtful evaluation of thyroid nodules should be pursued. This workup is detailed elsewhere in this text, but FNA also plays a prominent role for thyroid lesions and is particularly effective in diagnosis of papillary thyroid cancer. On occasion, a biopsy of a lateral neck mass shows thyroid follicular cells in a patient without known thyroid disease. This finding should be construed as indication for a primary thyroid malignancy within the thyroid, most often a papillary thyroid cancer.

Carotid body paragangliomas typically can be diagnosed on the basis of classic imaging features on CT/CT angiography, MRI, or angiography, including splaying of the internal and external carotid arteries. These lesions are highly vascular. Biopsy of carotid body tumors is not needed and should be discouraged.

Endoscopy and Biopsy

When FNA of a neck mass reveals squamous cell cancer, the surgeon must seek the primary lesion. As previously reviewed, the nodal level may direct the initial evaluation. A thorough history and physical examination, including mirror examination or flexible fiberoptic laryngoscopy, should be completed. Initial imaging consists of CT scanning of the neck, which results in identification of a primary malignancy in 20% of cases. Chest imaging (plain x-ray or CT scanning) aids in the search and is particularly useful for lower neck nodal disease. PET may be a useful secondary imaging study. If PET is used as part of the diagnostic approach, it should be completed before endoscopy and biopsy, both to aid in targeting the evaluation and to prevent false-positive PET findings from recently manipulated tissue.

When the primary tumor site remains occult after these studies, panendoscopy and biopsy should follow. Panendoscopy includes laryngoscopy, bronchoscopy, and esophagoscopy. If a primary tumor still is not identified, then at the same setting, biopsy should be performed. If the tonsils are still present, ipsilateral tonsillectomy should be performed; tonsils are found to be the primary source in 20% to 40% of these patients. Bilateral tonsillectomy also is reasonable, but, if this is not performed, then the contralateral tonsil should at least be biopsied. Directed biopsy also should be performed of the nasopharynx, hypopharynx, tongue base, and piriform sinus. Special attention should be paid to any area that was at all suspicious on the imaging evaluation.

SURGICAL CONSIDERATIONS

Anesthesia and Airway Considerations

Many neck masses feel superficial or prominent but can be misleading. Neck masses usually lie deep to the platysma, and major neurovascular structures are often within the intended operative field. Local anesthetic can impair motor response of nerves at risk. Therefore most neck mass surgical biopsies or excisions are performed with general anesthetic. In cases in which clinical or radiographic evaluation suggests significant airway compromise or distortion, communication with the anesthesiologist is imperative to plan for difficult airway management. If the airway is markedly compromised, a planned tracheostomy may be appropriate and should be performed before patient decline develops. Communication again is important regarding avoidance of long-acting paralytics to permit monitoring of motor nerve response.

Incisions

Transverse skin incisions that are placed in a preexisting skin crease are preferred for optimal cosmetic results. When possible, the incision should be placed along the same line as would be used if a subsequent more radical procedure, such as neck dissection, followed the initial procedure. If a small incision is initially used and a need for more exposure occurs, neck incisions can be widened with either transverse or oblique extensions (e.g., along the anterior border of SCM) for better visibility. Although cosmesis is important, it is more important to have adequate exposure to identify anatomic landmarks and protect vessels and nerves.

Potential Nerve Injuries

Neurologic injury may occur with both diagnostic and therapeutic interventions. An understanding of the anatomy is essential to minimize the rate of injury, as is discussion of potential temporary dysfunction or permanent injury with the patient before intervention. Low-energy nerve stimulating devices may aid in identification of motor nerves in the course of dissection but cannot substitute for knowledge of anatomy and meticulous technique. Among the most frequently at risk and commonly injured nerves in the neck are the spinal accessory nerve (cranial nerve [CN] XI) and the marginal mandibular branch of the facial nerve (CN VII). Both injuries cause significant morbidity.

The marginal branch of CN VII is at risk below the body of the mandible. It courses from the main trunk of the nerve in the parotid gland over the body of the mandible (at the area of the facial artery) into the fascia of the submandibular gland, deep to the platysma. The nerve then courses superiorly to cross over the mandible and ultimately becomes more superficial at the level of the platysma and innervates the depressors of the lower lip. The nerve thus lies below the inferior aspect of the mandible for several centimeters. Avoiding the region of the body of the mandible can minimize chances of injury to this nerve. To avoid injury to this nerve, which may be diminutive in size, incisions should be made at least two fingerbreadths below the inferior edge of the body of the mandible. In dissection of the submandibular region, the fascia of the gland should be elevated with the skin flap and the facial vein should be ligated and divided low. Dissection should proceed bluntly, spreading in the expected direction of the nerve.

The vagus nerve (CN X) descends within the carotid sheath, typically posterior to the vascular structures. Unlike division of the vagus in the chest or abdomen, a vagal injury or sacrifice in the neck carries the added morbidity of creating an ipsilateral vocal fold paralysis. This occurs because the recurrent laryngeal nerve has not branched from the vagus nerve until after the latter has descended from the neck. If a vagus nerve injury occurs, neurorrhaphy is not expected to restore normal function but may help to prevent atrophy of the vocal fold complex, which improves the functional result of subsequent vocal cord medialization procedures. In the right neck, the potential exists for a nonrecurrent laryngeal nerve that courses directly medially from the vagus. This aberrant nerve may course with the superior thyroid artery or more inferiorly. Nonrecurrent right laryngeal nerves occur in the setting of an aberrant right subclavian artery (arteria lusoria), and could be injured in the carotid sheath or central compartment if not recognized.

The spinal accessory nerve (CN XI) is at risk for surgical injury in cervical levels II and V. It exits the jugular foramen together with the vagus and glossopharyngeal nerves and courses inferior laterally deep to the posterior belly of the digastric. It passes either superficial or deep to the internal jugular vein. It gives off branches to the SCM and passes either through or deep to the SCM into the posterior triangle. It exits the posterior border of the SCM at approximately the junction of the upper and middle third of the posterior border of the SCM, typically 5 to 8 cm from the mastoid tip. This is approximately 1 cm cephalad to Erb's point, where cutaneous nerves including the greater auricular nerve can be found at the posterior border of the SCM. CN XI then runs superficially overlying the levator scapula muscle in the posterior triangle to the trapezius and courses and may connect with branches of the cervical plexus in its course. It frequently has a more distal course in level V, and the absence of a defined platysma in the posterior triangle renders it even more susceptible to injury.

The hypoglossal nerve (CN XII) provides motor innervation to the tongue. It traverses levels I and II. It descends between the internal jugular vein and the carotid artery and then courses medially. It runs deep to the posterior belly of the digastric muscle, where it is surrounded by the ranine veins. Injuries to this nerve may occur during attempts to control bleeding from these veins.

Other Potential Complications

Although these procedures are usually clean, wound infection sometimes occurs and may be related to the smoking and nutritional status of the patient or irradiated tissue. Chyle leak also may occur and is most likely with procedures on the left side at level IV. The thoracic duct runs deep to the carotid artery low in the left neck and empties into the internal jugular vein deep to its junction with the subclavian vein. All tissue divided in this area lying between the pleura and vagus nerves should be carefully ligated. When they occur, chyle leaks are initially managed conservatively with a low fat diet and medium chain triglyceride diet. High volume or persistent leaks occasionally require reoperation for definitive repair, which usually is accomplished with the placement of Weck clips once the leak is identified and isolated from other structures.

Surgical Infections of the Hand

E. Gene Deune, MD, and Nicholas A. Caloras, MD

BACKGROUND

The hand is continuously subjected to insults that could result in serious infections. With all these sources, it is a wonder that the hands and fingers are not infected more often. Cases of suspected hand or finger infections demand accurate diagnosis, appropriate and timely antimicrobial drugs, and well-thought-out surgical interventions, when necessary. Failure to do so can result in significant functional and cosmetic deficits caused by contractures, stiffness, or amputations.

General Principles

Initial management of hand infections depends on a thorough history regarding the mechanism and the environment of the injury, duration of the infection, possible inciting organisms, and any contributing systemic illness. The occupation, location, and circumstance of the injury can be exceptionally informative regarding the causative organism, such as herpes simplex in dental and healthcare workers or *Pasteurella multocida* in cat and dog bites. Diabetes, injection drug use, or an acquired immunocompromised state (for example, active chemotherapy, human immunodeficiency virus, or long-term steroid use) may potentiate infections by an otherwise nonvirulent organism.

Examination

Remove all clothing, jewelry, and dressings from the fingers to the shoulder, bilaterally so that nothing interferes with the visual inspection of the hand. This is one of the most important aspects of assessing hand infections. Note the skin color, size, shape, and position of the hand and fingers. Look for any cuts or wounds on the hand and any deformities that may indicate a structural injury. Assess motion of the hand and fingers at each joint to evaluate for functional integrity. Hand infections oftentimes result from an injury that may be associated with tendon lacerations, fractures, or foreign objects, conversely, infections often lead to pain and limited range of motion.

Tests and Studies

Laboratory tests should include a complete blood count and electrolytes; sedimentation rate and C-reactive protein are helpful in cases

The marginal branch of CN VII is at risk below the body of the mandible. It courses from the main trunk of the nerve in the parotid gland over the body of the mandible (at the area of the facial artery) into the fascia of the submandibular gland, deep to the platysma. The nerve then courses superiorly to cross over the mandible and ultimately becomes more superficial at the level of the platysma and innervates the depressors of the lower lip. The nerve thus lies below the inferior aspect of the mandible for several centimeters. Avoiding the region of the body of the mandible can minimize chances of injury to this nerve. To avoid injury to this nerve, which may be diminutive in size, incisions should be made at least two fingerbreadths below the inferior edge of the body of the mandible. In dissection of the submandibular region, the fascia of the gland should be elevated with the skin flap and the facial vein should be ligated and divided low. Dissection should proceed bluntly, spreading in the expected direction of the nerve.

The vagus nerve (CN X) descends within the carotid sheath, typically posterior to the vascular structures. Unlike division of the vagus in the chest or abdomen, a vagal injury or sacrifice in the neck carries the added morbidity of creating an ipsilateral vocal fold paralysis. This occurs because the recurrent laryngeal nerve has not branched from the vagus nerve until after the latter has descended from the neck. If a vagus nerve injury occurs, neurorrhaphy is not expected to restore normal function but may help to prevent atrophy of the vocal fold complex, which improves the functional result of subsequent vocal cord medialization procedures. In the right neck, the potential exists for a nonrecurrent laryngeal nerve that courses directly medially from the vagus. This aberrant nerve may course with the superior thyroid artery or more inferiorly. Nonrecurrent right laryngeal nerves occur in the setting of an aberrant right subclavian artery (arteria lusoria), and could be injured in the carotid sheath or central compartment if not recognized.

The spinal accessory nerve (CN XI) is at risk for surgical injury in cervical levels II and V. It exits the jugular foramen together with the vagus and glossopharyngeal nerves and courses inferior laterally deep to the posterior belly of the digastric. It passes either superficial or deep to the internal jugular vein. It gives off branches to the SCM and passes either through or deep to the SCM into the posterior triangle. It exits the posterior border of the SCM at approximately the junction of the upper and middle third of the posterior border of the SCM, typically 5 to 8 cm from the mastoid tip. This is approximately 1 cm cephalad to Erb's point, where cutaneous nerves including the greater auricular nerve can be found at the posterior border of the SCM. CN XI then runs superficially overlying the levator scapula muscle in the posterior triangle to the trapezius and courses and may connect with branches of the cervical plexus in its course. It frequently has a more distal course in level V, and the absence of a defined platysma in the posterior triangle renders it even more susceptible to injury.

The hypoglossal nerve (CN XII) provides motor innervation to the tongue. It traverses levels I and II. It descends between the internal jugular vein and the carotid artery and then courses medially. It runs deep to the posterior belly of the digastric muscle, where it is surrounded by the ranine veins. Injuries to this nerve may occur during attempts to control bleeding from these veins.

Other Potential Complications

Although these procedures are usually clean, wound infection sometimes occurs and may be related to the smoking and nutritional status of the patient or irradiated tissue. Chyle leak also may occur and is most likely with procedures on the left side at level IV. The thoracic duct runs deep to the carotid artery low in the left neck and empties into the internal jugular vein deep to its junction with the subclavian vein. All tissue divided in this area lying between the pleura and supraclavicular should be carefully ligated. When they occur, chyle leaks are initially managed conservatively with a low fat diet and medium chain triglyceride diet. High volume or persistent leaks occasionally require reoperation for definitive repair, which usually is accomplished with the placement of Weck clips once the leak is identified and isolated from other structures.

Surgical Infections of the Hand

E. Gene Deune, MD, and Nicholas A. Caloras, MD

Background

The hand is continuously subjected to insults that could result in serious infections. With all these sources, it is a wonder that the hands and fingers are not infected more often. Cases of suspected hand or finger infections demand accurate diagnosis, appropriate and timely antimicrobial drugs, and well thought out surgical interventions, when necessary. Failure to do so can result in significant functional and expressive deficits caused by contractures, stiffness, or amputations.

General Principles

Initial management of hand infections depends on a thorough history regarding the mechanism and the environment of the injury, duration of the infection, possible inciting organisms, and any contributing systemic illness. The occupation, location, and circumstance of the injury can be exceptionally informative regarding the causative organism, such as herpes simplex in dental and healthcare workers or *Pasteurella multocida* in cat and dog bites. Diabetes, injection drug use, or an acquired immunocompromised state (for example, active chemotherapy, human immunodeficiency virus, or long-term steroid use) may potentiate infections by an otherwise nontributed organism.

Examination

Remove all clothing, jewelry, and dressings from the fingers to the shoulder, bilaterally so that nothing interferes with the visual inspection of the hand. This is one of the most important aspects of assessing hand infections. Note the skin color, size, shape, and position of the hand and fingers. Look for any cuts or wounds on the hand and any deformities that may indicate a structural injury. Assess motion of the hand and fingers at each joint to evaluate for functional integrity. Hand infections oftentimes result from an injury that may be associated with tendon lacerations, fractures, or foreign objects, conversely, infections often lead to pain and limited range of motion.

Tests and Studies

Laboratory tests should include a complete blood count and electrolytes; sedimentation rate and C-reactive protein are helpful in cases

of suspected osteomyelitis. Cultures and gram stains are rarely useful for chronic cutaneous infections but are vital in cases of abscess or deep space infections. If there is a strong suspicion, cultures should also be sent for atypical bacteria, mycobacteria, fungi, and viruses. All patients should have three plain radiographs of the hand to look for foreign bodies, subcutaneous air, or fractures. Arthrocentesis should be strongly considered when septic arthritis is a prominent feature of the differential diagnosis. Computed tomography is indicated in cases of multiple fractures or when there is concern for abscess, deep space collection, or concomitant vascular injury. Magnetic resonance imaging is most useful in the evaluation of osteomyelitis.

Treatment

Treatment in the first 24 to 48 hours consists of antibiotics, immobilization, and elevation. Elevation is especially useful in greatly edematous infections. In a stable patient, antibiotics can be delayed if meaningful cultures can be obtained promptly. A bedside procedure, under local anesthetic infiltration or nerve block, is often indicated in cases of superficial abscess, easily extractable foreign body, or grossly contaminated lacerations. If there is no improvement after the first 48 hours, it is highly unlikely that prolonged antibiotics alone will be effective. Thrombosis of local vessels at the infection site prevents adequate circulation; furthermore, compartments and closed spaces of the hand tend to wall off infections, preventing systemic antibiotics from reaching the infection.

Progression of the symptoms, delayed presentation (>48 hours), or deep abscess formation are all indications for operative intervention. When operating in the hand, placement of incisions is crucial to long-term success. General principles of operative treatment consist of thorough irrigation and debridement of nonviral tissue. Even after thorough debridement, the wound may still require closed or open postoperative drainage. We recommend using tourniquet control without limb exsanguination, the latter of which risks propagating bacteria into systemic circulation. Instead, the arm should be elevated and direct pressure applied to the brachial artery for 1 minute before tourniquet inflation. Intraoperative cultures should be acquired and the hand then splinted for at least 3 days. Occasionally, more debridement may be necessary to control the infection.

MINOR INFECTIONS

Cellulitis

Cellulitis is infection of the dermis; it may be the cutaneous representation of a deeper or distant infection or abscess. Inciting causes can be a skin abrasion, a puncture, or a retained foreign object. The most common organisms are *Staphylococcus aureus* and group A β-hemolytic *Streptococcus*.

Symptoms

Warmth, erythema, swelling, lymphangitis, and adenopathy are all common. Moderate to severe discomfort on palpation or range of motion in the involved region is also typical.

Treatment

Initial management involves marking the extent of infection, hand immobilization, elevation, antibiotics, and removal of the offending agent (e.g., foreign object, distant source of infection, or an unlikely drug allergen). It is of utmost importance not to use the affected limb for venipuncture. The severity of the cellulitis dictates whether the patient receives treatment as an outpatient or an inpatient. If the cellulitis increases, if there is no response to oral antibiotics, or if there is purulence, the patient needs to be hospitalized. Anti-staphylococcal penicillins or first generation cephalosporins should be the first-line antibiotics. Clindamycin or a quinolone may be used in cases of penicillin allergy. Vancomycin is indicated if there are risk factors for methicillin-resistant *Staphylococcus aureus* (MRSA). Failure of first-line antibiotics is most often due to bacterial resistance or perpetuation of an underlying abscess.

Paronychia

Although it is the most common hand infection, paronychia is usually seen first by either the patient's primary care physician or the emergency room physician. Paronychia is an infection along the paronychium, the lateral folds of the fingernail. The eponychium is the proximal boundary, and the hyponychium is the distal boundary. Thus an eponychia that occurs at the base of the nail refers to the infection along the eponychium. If both the paronychium and the eponychium are involved, it is called a *circumferential infection*. A paronychia is caused by bacteria introduced into the soft tissue through a break in the nailfold from a hangnail, manicure, nail biting, or penetrating trauma. Common organisms are *S. aureus* or oral anaerobes. A ruptured ganglion cyst emanating from the distal interphalangeal (DIP) joint can also be a cause for an infection along the nailfold.

Symptoms

The symptoms vary depending on the severity and duration of the paronychia. Initially there is mild swelling and erythema at the site of the inciting source, with involvement of the adjacent nailfold. If neglected, the infection may progress to fluctuance and local purulence with spontaneous drainage. Purulence distal to the nail plate indicates that there is involvement of the nail matrix. With severe infections an accompanying cellulitis involving the finger and the hand may occur.

Treatment

The treatment is tailored to the severity of the infection. Prevention is the major deterrent, particularly if the cause is nail biting or manicures. In early paronychia, when there is no purulence and only erythema and swelling, oral antibiotics, warm soapy soaks, and splint immobilization can be successful.

When surgical drainage becomes necessary, the finger needs to be anesthetized with a digital block. A Penrose drain is placed around the base of the finger as a digital tourniquet. Next, a large-bore intravenous needle (19- or 18-gauge) is inserted beneath the nailfold with the bevel side down and gently passed back and forth to lift the nailfold off the nail plate (Fig. 1). This action allows for localization and puncturing of the abscess. Once the location of the abscess is noted, the needle can be turned 90 degrees and the sharp beveled edge used as a knife. With this technique, the nailfold is incised directly over the abscess to allow for drainage. If the abscess is underneath the nail plate, or an ingrown nail is the causative factor, a portion of the nail plate can be elevated off the nail bed. The nail is then cut longitudinally with sharp scissors or scalpel and gently removed. We recommend routinely obtaining cultures if a paronychia requires intervention for drainage. The wound should be packed with ¼ 25 inch ribbon gauze and the finger wrapped. Other wound care includes twice daily warm soapy soaks and replacement of the packing twice a day. An oral anti-staphylococcal antibiotic should be administered for at least 5 days, with a plan to follow up in 1 week.

Chronic paronychia is a clinically different entity than acute paronychia. It occurs in patients whose hands are constantly exposed to water containing irritants, alkali, or microorganisms. Its treatment involves the removal of the overlying dorsal skin as a nonpainful outpatient procedure. The reader is referred to the references listed below for more information.

Herpetic Whitlow

Herpetic whitlow is a cytolytic skin infection of the pulp and nailfold of the fingers. The causative agent is herpes simplex virus, type 1 or type 2. Infection occurs from direct contact with another infected individual or from self-inoculation by an infected body part. Dental and medical personnel are at slightly higher risk of infection because of the increased contact with potentially infected secretions. Immunocompromised patients are also at high risk. It is important to distinguish between a paronychia and herpetic whitlow because incision and drainage of a herpetic whitlow is not recommended for fear of a bacterial superinfection.

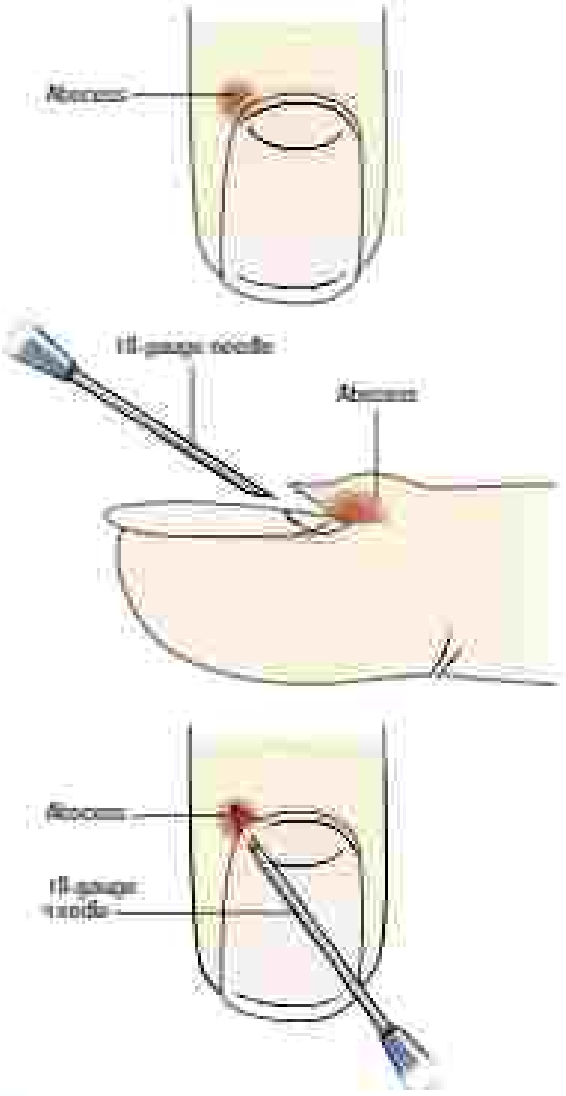

FIG. 1 Paronychia drainage. A large-bore intravenous needle (16- or 18-gauge) is inserted beneath the eponychium with the bevel side down and gently passed back and forth to lift the margin of the nail plate (A). The abscess is then entered with the needle tip, and pus is drained (B). The nail plate may be removed to expose the entire abscess cavity (C).

Symptoms

After the inoculation, there is usually a 48- to 72-hour prodrome of severe pain, followed by erythema. Ten to 14 days later, small clear vesicles, which may be turbid, appear and then coalesce. The overlying skin sloughs and ulcerates. Fever, malaise, and lymphangitis may occur. In susceptible hosts, signs and symptoms of disseminated virus can be observed.

Diagnosis and Treatment

Tzanck smear or viral cultures of the vesicle fluid will secure the diagnosis. Often these tests are unnecessary because the diagnosis can be made on the symptoms alone. The infection is usually self-limiting and lasts 3 to 4 weeks, so antiviral medication is not indicated, unless there is concern for visceral and disseminated infection. Removing the nail plate has been advocated to relieve pain if the nail plate is involved, but surgical intervention increases the risk of bacterial superinfection and systemic viral infection. Patients should cover the area with a clean, dry dressing at all times to prevent spread of the virus. Twenty percent of patients will experience a recurrence, which is usually milder and of shorter duration than the initial infection.

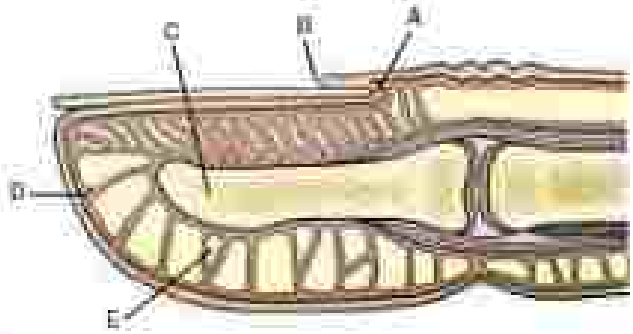

FIG. 2 Anatomy of the distal fingertip. Note the compartments formed by the vertical septae. A, nail matrix. B, eponychium. C, distal phalanx. D, septum. E, fingertip pulp.

Felon

A felon is a subcutaneous abscess in the volar fingertip pulp, within the multiseptated compartments created by vertical fibers extending from the distal phalangeal periosteum into the epidermis (Fig. 2). Felons are usually due to penetrating trauma from a needle, wood splinter, or minor cut. Iatrogenic trauma from finger sticks for blood glucose monitoring can also be a cause. The most common organism is *S. aureus*. Gram-negative rods or polymicrobial infections should also be suspected in immunocompromised patients. Left untreated, a felon may progress to localized tissue necrosis, septic destruction, cellulitis, distal phalangeal osteomyelitis, and DIP joint septic arthritis. Proximal spread may also result in pyogenic flexor tenosynovitis.

Symptoms

Usually, the patient presents a few days after the injury with a rapid onset of pain, erythema, and tense swelling of the entire pulp. The swelling does not usually extend to the DIP crease unless there is an associated cellulitis, pyogenic flexor tenosynovitis, or septic arthritis of the DIP joint.

Treatment

If seen in the first 24 to 48 hours, oral antibiotics, warm soapy soaks, and elevation may abort the progression. Failure to improve, worsening symptoms, or fluctuance in the finger pulp are all indications for drainage. There are several locations for the surgical incision (Fig. 3). Regardless of which one is used, the digital neurovascular structures (found in the midline of the volar-distal dimension), the flexor tendons, nail matrix, and the DIP joint space should be protected to avoid injuries. The two preferred incisions are the single longitudinal palmar incision and the unilateral longitudinal incision. The abscess should be drained, irrigated, and packed; cultures should be obtained from any discrete infectious collections. A first-generation cephalosporin or clindamycin (penicillin allergy) is recommended and wound care continued until the felon has resolved.

MAJOR INFECTIONS

Pyogenic Flexor Tenosynovitis

Pyogenic flexor tenosynovitis is infection within the potential space formed by the visceral and parietal layers of the synoviovium that constitute the flexor tendon synovial sheath. The visceral layer invests the flexor tendon, which is then surrounded by the parietal layer. The synovial sheath begins just proximal to the first annular pulley (A1) at the distal metacarpal neck and ends at the insertion of the flexor digitorum profundus distal to the A1 pulley. The small finger sheath

Deep Space Infections

[illegible]

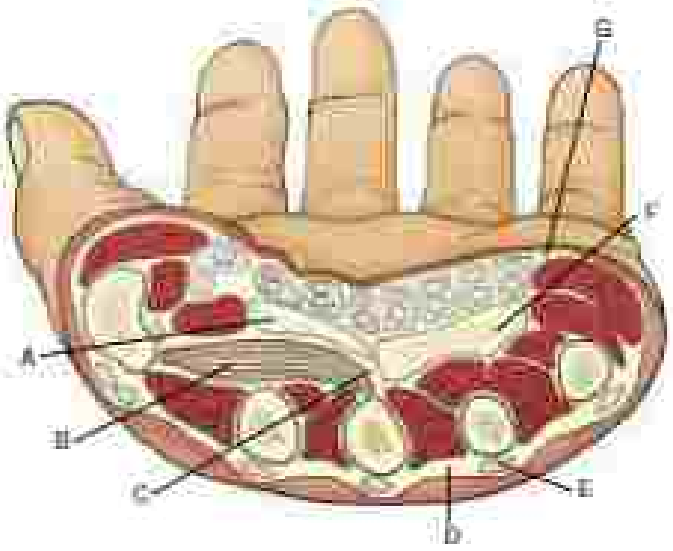

FIG. 3 Anatomy of the hand, cross-sectional view. The deep spaces are demonstrated: thenar space, midpalmar space, hypothenar space, and the dorsal subaponeurotic space. The interdigital web spaces and the space of Parona are not shown. A, Thenar space; B, adductor pollicis muscle; C, midpalmar space; D, dorsal subaponeurotic space; E, extensor tendon surrounded by dorsal aponeurosis; F, midpalmar space; G, palmar aponeurosis.

space, and interdigital webspaces, one in the dorsal hand (the dorsal subaponeurotic space), and the sixth in the volar forearm (space of Parona). The most hand infections, the most common organisms are *S. aureus* and Streptococcus species. Penetrating trauma is the most common cause of infection. In the absence of trauma, the most likely cause for the infection is contiguous spread from an adjacent deep space infection, a concurrent subcutaneous abscess, or pyogenic flexor tenosynovitis. Swelling and tenderness are symptoms shared by all deep space infections. A deep space infection requires surgical incision, drainage, irrigation, and debridement of all necrotic tissue, followed by elevation, immobilization, and intravenous antibiotics. Gram stains and culture are essential at the time of the incision and drainage.

Thenar Space

The thenar space is located on the radial palmar aspect of the hand just distal to the thenar eminence. The dorsal floor is defined by the first metacarpal muscles and the adductor pollicis longus, which inserts into the volar aspect of the long finger metacarpal. Ulnarly, it is separated by the oblique fascial septum from the midpalmar space (see diagram), which also inserts into the long finger metacarpal at the same place as the adductor pollicis longus fascia. Radially the border is formed by the convergence of the adductor pollicis tendon and fascia at the thumb proximal phalanx.

Symptoms

The thenar region and first webspace are characteristically swollen and exquisitely tender to palpation. Thumb motion, both passive and active, induces severe pain. The swelling often results in thumb abduction as the volume of the thenar space increases due to the expanding purulence or swelling. Because of the higher compliance of the dorsal skin, the swelling and purulence may be more noticeable dorsally.

Treatment

Surgical drainage is performed through a combination of volar and dorsal incisions (Fig. 4). A dorsal incision alone is not recommended because it offers incomplete access to the thenar plate deep to the radial finger flexor tendons. The volar incision can be approached through a transverse or longitudinal approach. The longitudinal

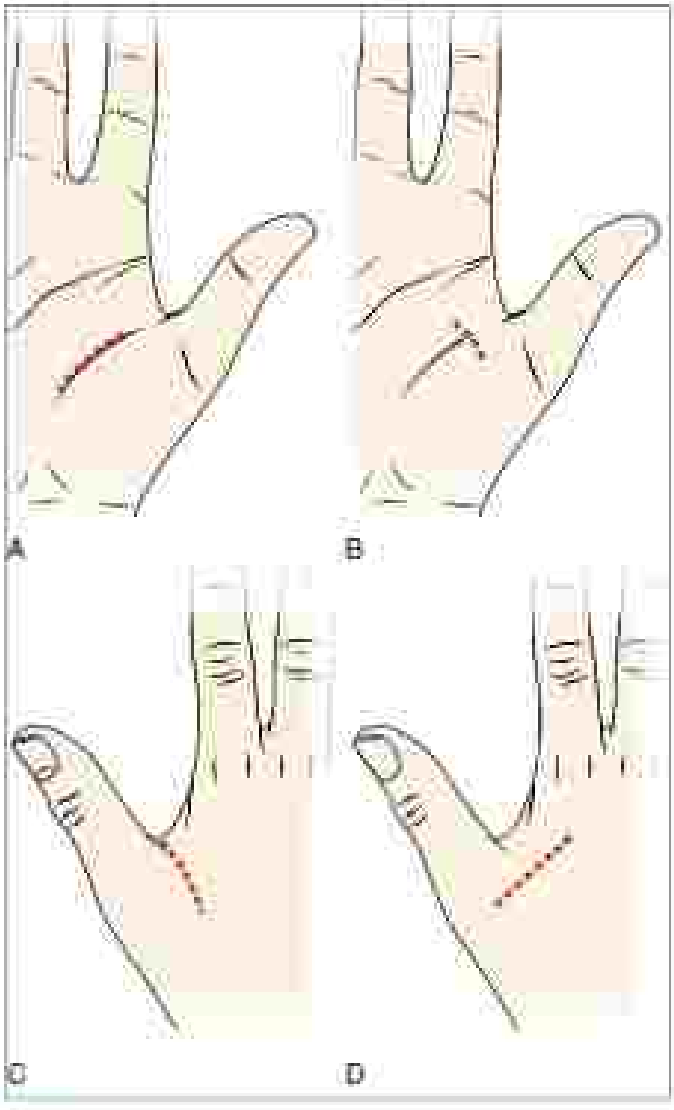

FIG. 4 Thenar space infection. (A) The palmar longitudinal incision is made parallel to or in the thenar crease. The incision is performed over the palmar transverse incision (B), dorsal and then longitudinal incision (C), and the transverse incision (D).

approach is preferred because of the decreased risk of injuring the neurovascular structures. The longitudinal incision is made parallel to or in the thenar crease. Care is taken to protect the palmar cutaneous branch of the median nerve, which lies subcutaneously in this region, as well as the recurrent branch of the median nerve, which lies deeper at the distal border of the transverse carpal ligament. The dissection is done bluntly between the first and second metacarpal entering through the palmar fascia. The dorsal compartment between the adductor and the first dorsal interosseous muscle is also decompressed.

The dorsal incision is made either longitudinally or transversely. Again, the longitudinal incision, performed by us, is placed 'in proximal to the web, centered over the dome of the dorsal extension of the infection and then extended proximally by 1 to 2 cm. To avoid a potential webspace contracture, the incision should not extend to the web edges. Care is taken to protect any sensory branches or large dorsal veins. Blunt dissection is directed deeply toward the palm, between the first dorsal interosseous and adductor pollicis muscles, to fully evacuate the space. The wound is then thoroughly debrided, irrigated, and packed.

Midpalmar Space

[illegible]

FIG. 8 Longitudinal incision for drainage of a hypothenar space is placed along the axis of the ring finger metacarpal in the proximal palm.

and the dorsal skin, and the other on the palmar surface centered on the ulnar border of the ring finger metacarpal axis above the hypothenar eminence (Fig. 8). Blunt dissection is continued until the space is reached. Neither of the two incisions should cross the wrist crease, and care is taken not to injure any neurovascular structures, particularly with the palmar approach because the ulnar nerve and artery are in close proximity to Guyon canal.

Subcutaneous (Web) Space

The triangular spaces at the base of the fingers are prone to direct penetrating trauma or irritation by insects. The roof is defined by the dorsal hand fascia and skin. The radial and ulnar borders are composed of the extensor tendon mechanism and the metacarpophalangeal joint capsular structures. The ventral septae of the palmar fascia form the distal boundary, thus limiting the extension into the palm.

Pathogenesis

Because of the limitations of the fibrous palmar fascial attachment to the palmar skin, the swelling tracks distally around the palmar fascia into the dorsal subcutaneous web space, producing a collar button abscess. Erythema, fluctuance, and sometimes cellulitis of the dorsal hand are seen. Finger abduction is seen if the pathogenesis is predominantly on the volar aspect; on the contrary, lack of abduction suggests a dorsal location of the abscess.

Treatment

Intravenous antibiotics, followed by prompt surgical drainage, are required through either the volar or the dorsal surface or both. A single longitudinal volar incision does not provide sufficient exposure, and a single transverse incision placed either dorsally or volarly may result in a web space contracture (Fig. 9). A volar zigzag incision is made first, placed between the metacarpal and beginning proximally at the level of the metacarpophalangeal joint and extending distally to the base of the involved web. Blunt dissection is done. The subcutaneous and deep tissues are divided, and the dorsal and palmar spaces are connected. Care is taken to protect the neurovascular structures as they enter either of the involved fingers. If there is a collar button abscess, a dorsal incision is made. The pus/debris is then thoroughly evacuated and the wound copiously irrigated before packing is left.

FIG. 9 Incisions for an interdigital web space infection: zigzag palmar incision (A) and dorsal longitudinal incision (B).

Deep or Subaponeurotic Space

The dorsal subaponeurotic space is a potential space located on the dorsum of the hand composed of loose areolar tissue deep to the extensor tendons and superficial to the interosseous muscle fascia and the metacarpal periosteum. Infections are usually due to a penetrating injury. Due to the overlapping presentation of cellulitis and deep space infection, advanced imaging can be helpful in establishing this diagnosis.

Symptoms

The dorsal hand is swollen and erythematous with warmth, fluctuance, and tenderness, similar to cellulitis. Finger extension is difficult and painful. The palm of the hand is usually unremarkable.

Treatment

Failure of conservative treatment, a high suspicion of a subaponeurotic space infection, or both are indications for surgical exploration. If the abscess is small and well localized, one dorsal longitudinal incision is used. A more diffuse and extensive infection, two dorsal longitudinal incisions, made over the second and fourth metacarpals, are used (Fig. 10). Care is taken not to injure the extensor tendons, and incisions are made in the fascia between the tendons to allow entry into the subaponeurotic space.

Space of Parona

The space of Parona is located in the distal forearm dorsal (deep) to the flexor digitorum profundus tendons and volar to the pronator quadratus. This space is continuous with the radial and ulnar bursae and the midpalmar space and thus is very susceptible to infections from contiguous spread. This is the most common cause of the infection. Pyogenic flexor tenosynovitis is the second most common.

FIG. 59 Location of the two dorsal incisions for draining a subperiosteal space infection.

Symptoms

Swelling, tenderness, and occasional fluctuance are noted in the distal volar forearm. Flexion of the fingers is difficult and painful. Numbness and weakness in the thumb, index, and ring finger should raise concern for acute carpal tunnel syndrome.

Treatment

A longitudinal incision is made ulnar to the palmaris longus tendon from the wrist flexion crease to the distal third of the forearm. Care is taken to protect the median nerve. The sheath and tendons are retracted radially to gain access to the space of Parona. The abscess is decompressed, and the space is thoroughly irrigated. If a subpalmar space infection is present, two separate incisions may be made to preserve the transverse carpal ligament. If there is concern for median nerve entrapment, the incision can be taken distally as a single line from the forearm across the carpal tunnel to the midpalm.

OTHER INFECTIONS

Septic Arthritis

Septic arthritis involving joints in the fingers and hand is unusual. Penetrating trauma is the most common cause. Other causes include hematogenous spread or contiguous spread from an adjacent infection. The most common organisms are [illegible] and *S. epidermidis*; a species of *Eikenella* may be present if the cause was a human bite. Signs and recognition are important because timely treatment can prevent the destruction of the articular cartilage by the infection.

Symptoms

The patient may have low-grade fever, chills, and night sweats associated with pain, erythema, and swelling to the involved joint. Because the joint space is distended with fluid, active or passive motion will result in pain.

Treatment

Aspiration of purulence from the joint confirms the diagnosis. Samples should be sent for cell counts and microscopy because crystalline arthropathy can present identically. Radiographs are usually normal but, in severe cases, may show osteomyelitis. Septic arthritis is a surgical emergence and requires immediate drainage. Arthrotomy remains the most appropriate and preferred method. In the wrist, a longitudinal incision between the third and fourth dorsal compartments is preferred. For the metacarpophalangeal joint, a dorsal midline incision is made and the joint is exposed through an incision in the extensor hood; care should be taken to preserve the sagittal bands. The joint is then thoroughly irrigated with copious saline (3–4 L). For the proximal interphalangeal (PIP) joints, a midaxial incision from the DIP joint to the subplatar is used to avoid injury to the central slip. The transverse retinacular ligament and the accessory collateral ligaments are identified and incised to expose the PIP joint. The joint is then debrided of any necrotic tissue and copiously irrigated. The wounds are closed primarily over a small Penrose drain, which is then removed on postoperative day 1. Hand motion and therapy are started on postoperative day 2 or 3, when the pain has decreased. Antibiotics should be administered intravenously for several days, followed by a course of oral antibiotics, as directed by surgical cultures.

Human and Animal Bites

As causes of penetrating injury to the hand and joints, bite injuries cause considerable morbidity and disability to the human hand. Human bites tend to be more virulent than animal bites. These bites often result after an altercation ("fight bites"), where there is a direct bite by the assailant in the finger or the hand, or the tooth penetrates the dorsal PIP or MP joints during a clenched fist punch. Human bites, regardless of where they are located, must be explored aggressively due to very high risk of joint and periosteum violation and osteolysis. The wound should be extended to allow for complete arthrotomy, liberal culturing of involved tissue, and copious irrigation. After adequate surgical drainage, the hand is immobilized and elevated. Motion is initiated as soon as feasible on postoperative day 1 or 2. Intravenous antibiotics are necessary. Recommended empiric regimens include a third-generation cephalosporin or gentamicin and penicillinase-resistant penicillin.

Of the animal bites, dog bites rarely become infected, but more than half of all cat bites become infected. Organisms tend to be mixed and include *S. aureus*, *Streptococcus viridans*, and *Pasteurella multocida*. Most dog and cat bites tend to be small but still require local wound care, including initial copious irrigation. Empiric antibiotics, usually oral amoxicillin–clavulanate or intravenous ampicillin–sulbactam (penicillin allergy: patients can benefit from a quinolone and clindamycin) are recommended. Treatment with a prophylaxis of tetanus, rabies, or both is indicated as well. Open wounds require appropriate surgical care, depending on the extent of injury and the structures damaged.

Necrotizing Infections

Necrotizing fasciitis is a true surgical emergency because infection in the hand or upper extremity can frequently lead to multisystem organ failure, amputations, and death. The typical presentation of these infections is similar to cellulitis with erythema, swelling, and pain. Concerning signs, however, include hypotension, tachycardia, soft tissue crepitus, skin sloughing or blistering, and dusky appearing skin. Any time is clinical suspicion for this infection, emergent debridement and intravenous antibiotics must happen immediately. With regard to operative treatment, involved tissue is superficial to the fascia and may appear pale gray, with a dull gray liquid discharge. This must be debrided back to bleeding tissue, with minimal regard for conventional anatomic boundaries. Repeat debridements must occur every 24 to 48 hours as needed. Amputation is a useful adjunct for severe infections but does not provide a mortality benefit.

initial empiric antibiotic therapy must cover the most likely causative organisms—group A *Streptococcus*, *Staphylococcus* species, and anaerobes. Multidrug regimens are usually required and can include vancomycin, piperacillin/tazobactam, and clindamycin or ampicillin/sulbactam, ciprofloxacin, and clindamycin. Intraoperative cultures can then be used to narrow therapy.

SUMMARY

Hand infections can have devastating effects leading to significant compromise and morbidity in the affected individual. As present this, hand infections need to be accurately diagnosed and treated appropriately and aggressively to avoid devastating and permanent [illegible].

NERVE INJURY AND REPAIR

Christopher Frost, MD, and Gudjon D. Ronson, MD

During the past [illegible] years, and mainly due to the development of microsurgical technique, surgeons have been routinely repairing severed peripheral nerves. This has paralleled the advances in macrovascular reconstruction and digital replantation. Performance of nerve repair requires meticulous microsurgical technique and the use of both the science and art of peripheral nerve surgery. Furthermore, nerve repair is often an exercise in delayed gratification because many injuries can take months or even years to recover after repair.

BASIC ANATOMY

Nerve anatomy and physiology is fundamental to peripheral nerve surgery and guides the diagnosis of nerve injury. The basic subunit of the peripheral nerve is the axon. These axons are surrounded by endoneurium and grouped into fascicles. Each fascicle is encapsulated by a perineurium, and groups of fascicles are in turn surrounded by an interfascicular epineurium. Each peripheral nerve is comprised of a group of fascicles surrounded by an external epineurium. Finally, the nerve sheath is contained within a mesoneurium, which both allows for nerve gliding during normal range of motion and contains the segmental blood supply to the nerve (Fig. 1).

FACIAL TOPOGRAPHY

When performing peripheral nerve surgery, it is important that proximal motor and sensory axons connect to their corresponding distal fascicles. More proximally there can be significant intermingling between sensory and motor axons with plexus formation in the nerve trunks proximally. As the nerves travel more distally, motor and sensory axons more clearly develop into distinct fascicles. This can have important clinical consequences after nerve repair. For example, repairing facial nerve injuries within the temporal bone often leads to improper connections between proximal and distal nerves. This can lead to a significant amount of disabling synkinesis and dyskinesis secondary to the lack of distinct fascicular architecture to the proximal facial nerve trunk. This is opposed to injuries distal within the face because these fascicles are separated into clear branches and errant innervation less likely to occur.

PATHOPHYSIOLOGY

A clear understanding of the mechanism of injury, zone of injury and degree of nerve injury is critical for successful management. Based on the mechanism of injury, lesions can be classified as open (laceration) or closed (stretching, blast, compressive trauma). Gunshot wounds behave like closed injuries typically because nerve injury is more likely due to blast effect rather than transection. Initial zone of injury can vary widely depending on the mechanism of injury. Sharp injury such as a scalpel blade produces a small zone of injury. More blunt mechanism such as a table saw on the other hand can produce a very wide zone of injury. The zone of injury can be difficult to discern on initial exploration of there is evidence of blunt trauma, crush, or nerve avulsion.

The degree of injury can be classified using several different systems (Table 1). The Seddon classification divides injuries into neurapraxia, axonotmesis, and neurotmesis based on the anatomic nerve component that is damaged. The Sunderland classification I to V is based on the degree of injury and expected recovery. Mackinnon and Dellon added a VI degree to this system (combined nerve injury).

Focal or segmental demyelination with preservation of axon continuity is termed neurapraxia (Sunderland class I). In this case functional recovery is expected to occur spontaneously as the myelin heals. This recovery occurs over a period of hours or days up to a weeks. Iatrogenic surgical intervention is required in this case. A distal nerve compression ("Saturday night palsy") with resulting wrist drop that spontaneously recovers is one common example.

Axonal injury with preservation of the endo and epineurial sheath is known as axonotmesis (Sunderland class II–IV). In this case the axon will die back to the nearest node of Ranvier. After initial stabilization the axon will begin to form multiple "growth cones" and will regrow at a rate of 1 mm/day or 1 inch/month through the distal endoneurial tubes. The axons distal to the injury site undergo Wallerian degeneration whereby myelin and cellular debris are phagocytosed, and the axon replaced. Axonotmesis can result in a range from complete recovery to minimal or no recovery. Degree of recovery is dependent on the degree of damage to the surrounding structures (endoneurium, perineurium and epineurium) and the resulting scar tissue. If the surrounding tissues remain intact the axons will usually reach the distal endoneurial tubes and spontaneous recovery will occur (Sunderland class II–III). On the other hand, if the sprouting axons are unable to reach the distal endoneurium, then a neuroma in continuity will develop, and no spontaneous recovery will occur (Sunderland class IV).

Finally, complete transection of all neural structures is termed neurotmesis (Sunderland class V). Spontaneous recovery in this case is not expected. Surgical intervention is required in all cases of neurotmesis and in cases of axonotmesis where regenerating axons are unable to regenerate successfully through the distal endoneurium.

Importantly, the distal axons in all cases of nerve injury will have viable axons that can transmit electrical signals for between 72 and [illegible] hours after injury. After this time period the distal axons will irreversibly degrade and undergo Wallerian degeneration. In cases where it is critical to stimulate distal motor branches during repair such as in facial nerve injury, patients should be brought to the operating room within 72 hours of initial injury. Nerve repair between

initial empiric antibiotic therapy must cover the most likely causative organisms—group A *Streptococcus*, *Staphylococcus* species, and anaerobes. Multidrug regimens are usually required and can include vancomycin, piperacillin/sulbactam, and clindamycin or ampicillin/sulbactam, ciprofloxacin, and clindamycin. Intraoperative cultures can then be used to narrow therapy.

SUMMARY

Hand infections can have devastating effects leading to significant compromise and morbidity in the affected individual. To prevent this, hand infections need to be accurately diagnosed and treated appropriately and aggressively to avoid devastating and permanent effects.

NERVE INJURY AND REPAIR

Christopher Frost, MD, and Gudjon D. Runnon, MD

During the past 50 years, and mainly due to the development of microsurgical technique, surgeons have been routinely repairing severed peripheral nerves. This has paralleled the advances in macrovascular reconstruction and digital replantation. Performance of nerve repair requires meticulous microsurgical technique and the use of both the science and art of peripheral nerve surgery. Furthermore, nerve repair is often an exercise in delayed gratification because many injuries can take months or even years to recover after repair.

BASIC ANATOMY

Nerve anatomy and physiology is fundamental to peripheral nerve surgery and guides the diagnosis of nerve injury. The basic subunit of the peripheral nerve is the axon. These axons are surrounded by endoneurium and grouped into fascicles. Each fascicle is encapsulated by a perineurium, and groups of fascicles are in turn surrounded by an interfascicular epineurium. Each peripheral nerve is comprised of a group of fascicles surrounded by an external epineurium. Finally, the nerve sheath is contained within a mesoneurium, which both allows for nerve gliding during normal range of motion and contains the segmental blood supply to the nerve (Fig. 1).

FASCICULAR TOPOGRAPHY

When performing peripheral nerve surgery, it is important that proximal motor and sensory axons connect to their corresponding distal fascicles. More proximally there can be significant intermingling between sensory and motor axons with plexus formation in the nerve trunks proximally. As the nerves travel more distally, motor and sensory axons more clearly develop into distinct fascicles. This can have important clinical consequences after nerve repair. For example, repairing facial nerve injuries within the temporal bone often leads to improper connections between proximal and distal nerves. This can lead to a significant amount of disabling synkinesis and dyskinesis secondary to the lack of distinct fascicular architecture to the proximal facial nerve trunk. This is opposed to injuries distal within the face because these fascicles are separated into clear branches and errant innervation less likely to occur.

PATHOPHYSIOLOGY

A clear understanding of the mechanism of injury, zone of injury and degree of nerve injury is critical for successful management. Based on the mechanism of injury, lesions can be classified as open (laceration) or closed (stretching, blast, compressive trauma). Gunshot wounds behave like closed injuries typically because nerve injury is more likely due to blast effect rather than transection. Initial zone of injury can vary widely depending on the mechanism of injury. Sharp injury such as a scalpel blade produces a small zone of injury. More blunt mechanism such as a table saw on the other hand can produce a very wide zone of injury. The zone of injury can be difficult to detect since an initial explosion of there is evidence of blunt trauma, crush, or nerve avulsion.

The degree of injury can be classified using several different systems (Table 1). The Seddon classification divides injuries into neuropraxia, axonotmesis, and neurotmesis based on the anatomic nerve component that is damaged. The Sunderland classification I to V is based on the degree of injury and expected recovery. Mackinnon and Dellon added a VI degree to this system (combined nerve injury).

Focal or segmental demyelination with preservation of axon continuity is termed neuropraxia (Sunderland class I). In this case functional recovery is expected to occur spontaneously as the myelin heals. This recovery occurs over a period of hours or days up to 6 weeks. No surgical intervention is required in this case. Radial nerve compression ("Saturday night palsy") with resulting wrist drop that spontaneously recovers is one common example.

Axonal injury with preservation of the endo and perineurial sheath is known as axonotmesis (Sunderland class II–IV). In this case the axon will die back to the nearest node of Ranvier. After initial stabilization the axon will begin to form multiple "growth cones" and will regrow at a rate of 1 mm/day or 1 inch/month through the distal endoneurial tubes. The axons distal to the injury site undergo Wallerian degeneration whereby myelin and cellular debris are phagocytosed, and the axon replaced. Axonotmesis can result in a range from complete recovery to minimal or no recovery. Degree of recovery is dependent on the degree of damage to the surrounding structures (endoneurium, perineurium and epineurium) and the resulting scar tissue. If the surrounding tissues remain intact the axons will usually reach the distal endoneurial tubes and spontaneous recovery will occur (Sunderland class II–III). On the other hand, if the sprouting axons are unable to reach the distal endoneurium, then a neuroma in continuity will develop, and no spontaneous recovery will occur (Sunderland class IV).

Finally, complete transection of all neural structures is termed neurotmesis (Sunderland class V). Spontaneous recovery in this case is not expected. Surgical intervention is required in all cases of neurotmesis and in cases of axonotmesis where regenerating axons are unable to regenerate successfully through the distal endoneurium.

Importantly, the distal axons in all cases of nerve injury will have viable axons that can transmit electrical signals for between 72 and 96 hours after injury. After this time period the distal axons will irreversibly degrade and undergo Wallerian degeneration. In cases where it is critical to stimulate distal motor branches during repair such as in facial nerve injury, patients should be brought to the operating room within 72 hours of initial injury. Nerve repair between

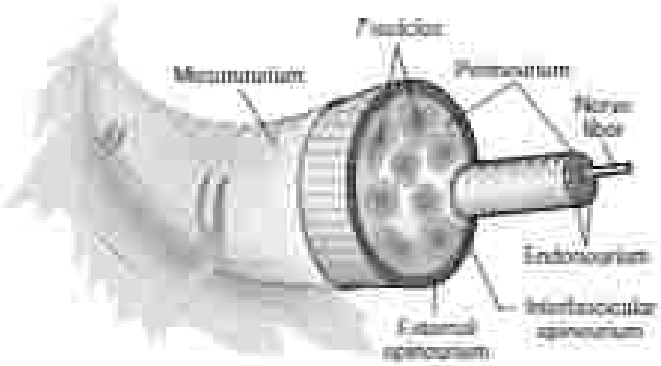

FIG. 1 Anatomy of a peripheral nerve.

inappropriate proximal and distal motor muscles can lead to weakness and dysfunction.

After muscles lose innervation they begin to degenerate from both chronic atrophy and denervation atrophy. Motor endplates within the muscle will irreversibly degenerate after 12 months and will be gone by 18 to 24 months. After this point, the muscle cannot be reinnervated, creating a relative deadline for recovery of motor function at 1 year after injury. On the other hand, sensory end organs do not undergo degeneration and reports have been made of successful sensory reinnervation many years after initial injury (Table 2).

TIMING

Optimal surgical timing is essential for successful nerve repair. Closed injuries should be approached differently from open injuries. Early recognition and treatment of nerves unlikely to recover

TABLE 1 Classification and Expected Recovery of Nerve Injuries

Classifications		Nerve Components Injured					Expected Recovery		
Seddon	Sunderland Degree of Axonotmesis	Myelin	Axon	Endoneurium	Perineurium	Epineurium	Extent	Rate	Surgery Indicated
Neurapraxia	First	+					Complete	Fast	No
Axonotmesis	Second	+	+				Good	Slow	Not usually
	Third	+	+	+			Variable	Slow	Variable
	Fourth	+	+	+	+		None	None	Yes
Neurotmesis	Fifth	+	+	+	+	+	None	None	Yes

+, Injury.

TABLE 2 Treatment Options and Indications for Repair of Nerve Injuries

Options	Indications
Observation	Recovering nerve injury Partial nerve injury
Neurapraxia	Nerve in continuity, but with NAP
Axonotmesis	Axonotmesis Some preservation of axons in nerve, but with poor NAP
Neurotmesis	Axonotmesis (i.e., disruption of endoneurium, perineurium, and epineurium) Nerve in which stimulation distal to the injury does not produce a muscle contraction
Nerve repair (end-to-end neurorrhaphy)	Sharp nerve transection in which the nerve ends can be approximated without tension
Nerve graft	Nerve gap in which tension would be excessive if the nerve ends were sutured directly together Nerve injury in which end-to-end repair would result in a poor functional outcome (e.g., proximal nerve grafting in the upper arm)
Nerve transfer (neurotization)	Nerve injury proximal to the target muscle, with the donor nerve innervating a muscle that is less important than the target muscle
Nerve transplantation	Nerve injury proximal to the target muscle
Functional muscle transfer	Irreparable nerve injury, with no donor nerve available
Free muscle transplantation	Irreparable nerve injury, with no donor nerve available
Amputation	Irreparable nerve injury, with no donor nerve available, and the patient desires amputation

NAP, Nerve action potential.

TABLE 3 3+1 Rule for Timing of Nerve Repair

Timing	Time	Injury Type	Injury Classification
Early	3 days	Sharp laceration or transection Acute nerve compression resulting from vascular (e.g., hematoma, pseudoaneurysm) or bony injuries Acute neurologic worsening under close observation	Neurotmesis
Subacute	3 weeks	Blunt transection Ragged transection	Neurotmesis
Delayed	3 months	Lesions in continuity (nonpenetrating injuries such as stretch injuries, contusive injuries, gunshot wounds)	Axonotmesis
Late	>1 year	Salvage procedures	Neurotmesis or axonotmesis

spontaneously to key and "time to muscle" remains a fundamental concept. Surgical timing can be summarized by the 3+1 rule (Table 3), with early repair occurring within 3 days, subacute repair at 3 weeks, delayed repair at 3 to 6 months, and late repair after 1 year.

Early repair, occurring within 3 days after the injury or at presentation if evaluated after 3 days, is indicated in cases of suspected transection with sharp injuries. In this case, any neural deficits are likely to represent nerve transection (neurotmesis or Sunderland class V) and will require surgical intervention. It is also indicated in situations with vascular (e.g., hematoma, pseudoaneurysm) or bony injuries causing acute nerve compression, especially if they occur in the vicinity of a closed compartment. If a neurologic examination worsens acutely under close observation, the nerve damage potentially can be reversed or reduced by immediate surgical intervention.

Subacute repair, occurring around 3 weeks after injury, is advocated by some for blunt or ragged transections (e.g., by projectiles, blades or chainsaws), but others still treat these injuries acutely. These injuries clearly represent neurotmesis and surgical intervention is required. Such injury can cause a large and unpredictable zone of injury; however. Delaying repair for a few weeks allows Wallerian degeneration to begin occurring, better defining the zone of injury. At the time of repair, the nerve endings can be resected back to healthy tissue. This could be difficult to evaluate if the injured nerves were explored immediately after the injury.

In contrast, advocates for earlier surgery feel that surgery is easier and more practical at an earlier time, especially if done at the same time that surgical intervention is performed by another team, such as a general, vascular, or orthopedic surgical team. Furthermore, the additional technical challenges of dealing with scarring can be avoided. For example, if a patient with a fracture and associated nerve palsy is being examined by an orthopedist, it would be reasonable to explore the nerve at the same time. If the nerve is found to be in continuity but nonfunctional, observation for several months is indicated. Note that because Wallerian degeneration does not occur until 2 to 3 hours after injury, intraoperative electrophysiologic testing would not be reliable or helpful in predicting recovery or acutely determining the grade of injury. If the nerve is found to be ruptured, some would repair it at the same time. Others would perform the surgery at a second stage, when the zone of injury can be better defined; nerve ends are tacked down under tension as they do not retract, using radiopaque clips or sutures so that they can be identified easily. At a later time, a subacute nerve repair can be done.

Delayed repair, occurring approximately 3 months but up to 6 months after injury, is indicated for lesions in continuity, such as the majority of stretch injuries, contusive injuries, and gunshot wounds. In these cases, it is difficult to predict with certainty which path the nerve injury will follow from those described previously and whether the injury will recover spontaneously or require surgical repair. Nonoperative treatment can be continued in patients with early signs of spontaneous recovery or in partial lesions. Note that 90% of nerves that recover do so within 6 months. Surgery is indicated when there has been no evidence of clinical or electrical recovery after this period of observation. In these cases, the delay also will allow lesions in continuity to be evaluated during surgery with nerve action potential (NAP) testing to distinguish between recovering lesions (Sunderland class II–III) and nonrecovering (Sunderland class IV) lesions that require repair.

Late repair, occurring more than 1 year after injury, may be considered a salvage procedure in patients who are seen for a delayed fashion or in those who either have not recovered or have recovered incompletely after spontaneous recovery or previous nerve surgery. Nerve repair and reconstruction typically does not work well after this period, which can be considered as short as 9 months by some surgeons because of permanent changes at the muscular level. The one exception might be distal nerve transfers (those performed close to the end organ), which can be performed in select cases even up to 18 months after injury. However, reconstructive options addressing muscles, tendons, bones, and joints may be useful.

TREATMENT FOR NERVE INJURY

The management and surgical treatment of nerve injury involves the application of general principles that are relevant to all nerve surgeries and of specific nerve repair techniques particular to each situation.

GENERAL PRINCIPLES

Preoperative Assessment

The optimal approach to nerve injury assessment includes a detailed history of the mechanism of injury and the onset of the deficit, a physical examination (neurologic, vascular, and musculoskeletal examination), and electrodiagnostic studies, such as electromyography and nerve conduction studies. These three pillars (history, physical examination, and electrodiagnostic studies) help the clinician to determine the extent and severity of the nerve injury. Additionally, imaging studies (radiography, ultrasonography, computed tomography, magnetic resonance imaging, and neurography, or myelography) can further enlighten the clinical scenario and the operative planning. Specifically, high resolution (3 Tesla) magnetic resonance neurography (MRN) has been increasingly used to better define the anatomy of injured nerves. MRN provides a substantial benefit for the evaluation of large proximal nerve elements such as the brachial plexus, the lumbosacral plexus, the sciatic nerve in the pelvis, and other nerves that follow deep or complex courses, where electrodiagnostic studies are difficult to use. The clinician must also remember to use sensory and motor function grading scales, which will facilitate follow-up and assessment of the results of interventions (including observation).

Key Operative Principles

At surgery, the steps taken to expose the injured nerve before the nerve repair itself are important. Knowledge of the anatomy is crucial, especially when scarring from the injury is expected and likely will distort the anatomy. Adequate exposure should be planned, including the possibility of harvesting nerve grafts. Dissection usually is done between two muscle groups parallel to the long axis of the nerve. Ideally, a normal segment of the nerve is identified first, both proximally and distally, before dissection is carried toward the injured segment. If the injured segment is near a compression site, such as the median nerve near the carpal tunnel, then the site of compression should be released at this time. For practical purposes, there are two possibilities: the identification of a neuroma in continuity or nerve stumps.

If there is a neuroma in continuity, intraoperative NAP recordings can be performed to assess the degree of injury (recovery or no recovery) (Fig. 2). These are helpful because gross inspection or palpation of a neuroma in continuity does not predict histology, recovery, or outcomes. Furthermore, NAP can determine recovery across a short segment of nerve (i.e., proximal and distal to an injury) before recovery can be seen by physical examination or conventional electromyogram. When a NAP is present across a lesion, the lesion should not be resected because the outcome generally will be better with neurolysis alone. If a NAP is absent across a lesion, the outcomes are generally poor if the lesion is left intact, therefore surgical repair is indicated.

If two nerve ends suggestive of a rupture or transection are identified or if a nerve end suspicious for an avulsion is found, a nerve repair or reconstruction is indicated. The use of NAP recordings still can be helpful in these situations and can allow identification of the proximal location at which nerve grafting can be performed. Some use NAP to brachial plexus avulsion injuries to define preganglionic responses. Others use other techniques, including somatosensory evoked potential and motor evoked potential, to assess whether the proximal nerve stump is intact and can be used for reinnervation.

For the nerve repair, microsurgical techniques, which involve the use of micro instruments and of a microscope or magnifying loupes, should be used. The nerve ends on both sides should be prepared by removing sharply the neuroma and scar tissue, until normal fascicular structures are obtained. The nerve stumps should be sliced proximally and distally (like slicing a loaf of bread) until a healthy fascicular pattern is visualized. This is called the nerve divergent (snail's eyes). This pattern of healthy fascicles protruding from the cut nerve endings is due to the pressure within the endoneurium. The fascicles that protrude past the cut nerve ending should be divided further until all of the fascicles fit "flush" with the epineurial sheath. This is critical so that the fascicles do not overlap once the epineurium is sutured. Optimal microsurgical technique will cause minimal surgical trauma and permit an end to end repair or interfascicular grafting. It is further recommended that 8-, 9-, or 10-0 sutures be used, and using the fewest number of sutures to approximate the nerve accurately is preferred. The repair must be without tension to obtain good results. Fibrin glue may be used to reinforce the suture line, but other methods involve the use of fibrin glue alone or with a variety of nerve conduits (conduitation).

If repair of a motor nerve is planned (and it is within 72 hours of the original injury), it is crucial to remember that a tourniquet applied longer than 30 minutes can cause ischemia of the distal nerve, and intraoperative nerve stimulation will no longer be possible. Thus the initial dissection must be well planned, focused, and directed to ensure there is enough time to dissect the injured distal nerve and apply stimulation for 5- minutes afterward.

FIG. 2 Intraoperative photograph showing [illegible] nerve [illegible] the upper trunk [illegible] the UT [illegible] the [illegible] nerve [illegible] the [illegible] nerve [illegible] the [illegible] nerve [illegible] proximal [illegible] distal to it.

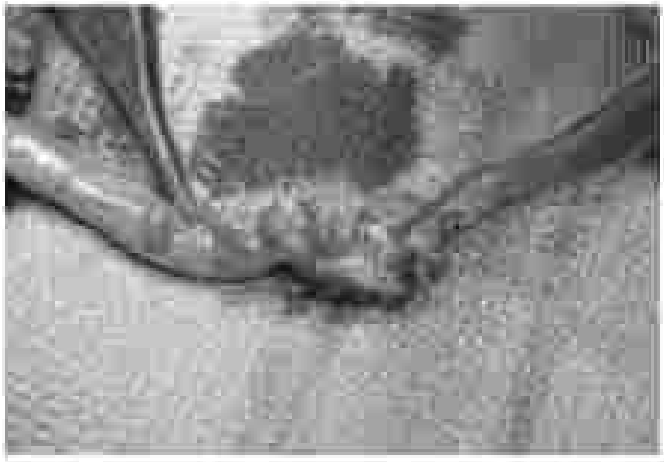

FIG. 3 Nerve ruptured [illegible] with healthy fascicles are uncovered in a sagittal manner to the end a neuroma is resected from the proximal nerve end.

TECHNIQUES FOR NERVE SURGERY

Neurolysis

Neurolysis, defined as releasing scar tissue surrounding the injured nerve, is indicated when a neuroma in continuity with intact NAP conduction is found. In general, external neurolysis, which is completed during the nerve exposition, is sufficient. In select instances, some advocate limited internal neurolysis or removal of the scar tissue between the various nerve fascicles.

Direct Repair

Direct nerve repair is the end to end suture of nerve stumps. It is indicated when a short nerve gap exists, either from a sharply transected nerve (such as a cut from glass, a knife, or a razor) or after removing a focal neuroma in continuity that did not conduct a NAP. Direct repair is the preferred method of nerve repair whenever possible, assuming that the damaged segment of the nerve has been resected and that the sutures are without tension. This method allows direct delivery of proximal axons to the distal stump via a single suture line. It also usually permits fascicular alignment, which increases matching between motor and sensory axons and their targets.

For primary nerve repair, an epineurial repair is usually the most predictable (Figs. 3, 4, and 5). The external epineurial vessels can be arranged to ensure that the fascicles are appropriately aligned.

FIG. 8 Patient with a partial laceration of the radial nerve trunk at presentation 1 week after injury. (A) The open knife injury wound is seen in the right arm slightly proximal to the elbow near the interval between the brachioradialis and triceps. The knife blade had penetrated the arm to a depth of approximately 5 cm (2 inches). The patient had no motor, sensation, partial weakness of the finger extensors and wrist extension, and decreased sensation in the domain of the radial nerve. (B) At exploration the radial nerve was found to be partially lacerated at its bifurcation into the deep and superficial radial nerve. The complete laceration of the superficial (sensory) radial nerve is seen, as is the partial injury to multiple fascicles of the deep (motor) branch of the radial nerve. (C) Direct repair of the superficial sensory radial nerve and the fascicles of the deep branch of the radial nerve are shown. A nerve graft was used to perform a side repair. (D) After 6 months, the patient had already regained good finger and wrist extension (medical research council [MRC] grade 4). Thumb extension (the most distal motor target) improved to MRC grade 3, although the patient still had sensory abnormality in the domain of the hand.

Additionally, to facilitate maximization of fascicular orientation, it is important to be familiar with the serial cross sectional fascicular topography, fascicular stimulation, histochemical stains, and gross fascicular matching. Often, only two or three interrupted sutures are necessary to align and coapt the nerve endings. It is critical at this stage to ensure there is no overlapping of the fascicles (Fig. 6). The fascicles should just be gently coapted within the epineurium. It is also important to make sure the needle passes only through the epineurium and does not catch a portion of one of the fascicles because this can lead to a small intraneural neuroma and the fascicle will not heal properly.

Occasionally, it is appropriate to perform fascicular or grouped fascicular repairs. In a large nerve where the fascicles are easily identifiable, it may be possible to suture the internal epineurium between the fascicles with a few small, interrupted nylon sutures and then perform the epineurial repair. Some researchers have reported that grouped fascicular repair results in more intraneural scarring, so most peripheral nerve surgeons continue to use the epineurial repair. When performing nerve repairs, it is important to understand the difference between the fascicular topography in the proximal nerve trunk and the fascicular topography in the distal nerve (Fig. 7). Most nerves have a significant intermingling of sensory and motor fibers with plexus formation proximally, whereas more distally they usually become groups of sensory or motor fibers. This partially explains why more distal nerve repairs have better long-term functional outcomes.

If a small nerve gap is present, several methods can be used to reduce the gap and achieve a direct repair. Commonly used methods include nerve mobilization, nerve transposition, as with the ulnar and radial nerves, and joint positioning, such as repair and immobilization of a joint in some degree of extension with gradual postoperative extension beginning at about 3 weeks. In some cases, bone shortening, as with comminuted fracture, may offer an opportunity for decreasing a nerve gap.

Nerve Graft

Nerve graft repair is performed when nerve stumps on either side of a gap cannot be opposed for a direct end to end repair without tension. Often this technique is necessary for recurrent or continuity of moderate or longer lengths with unrecordable (negative) NAP or for transected nerves with retracted stumps, which occurs when the initial surgery is delayed.

The most frequent source of nerve graft is the sural nerve (Fig. 8). However, the medial or lateral antebrachial cutaneous nerves, superficial sensory radial nerve, superficial peroneal nerve, distal posterior interosseous nerve, great auricular nerve, and cervical plexus nerves are alternatives. The nerve graft should be sutured into place in a reversed fashion from its usual anatomic course (i.e., the more distal end of the nerve graft should be sutured to the proximal end of the

FIG. 5 Patient with a spinal accessory nerve injury after a right retrosigmoid craniotomy for removal of a vestibular schwannoma. (A) Surgical incision used for the resection of the right vestibular schwannoma. After surgery, the patient developed prominent scapular winging, atrophy of the right trapezius muscle, and significant difficulty in abducting the right arm. Electromyography 1 months after surgery confirmed a right spinal accessory neuropathy affecting the motor branch to the trapezius (normal sternocleidomastoid) without evidence of reinnervation. (B) At exploration, soon thereafter, the great auricular nerve (at the right of the nerve stump) and the greater occipital nerve (blue vessel loop) were identified. The proximal and distal stumps (stapled to a green background) of the spinal accessory nerve were found within the area of the prior surgical exposure. (C) To achieve a direct repair the two nerve stumps were mobilized proximally and distally. (D) A direct end-to-end repair was performed using an 8-0 suture. (E) The patient regained excellent function, scapular stability, and range of motion, shown here at 15 months after the repair.

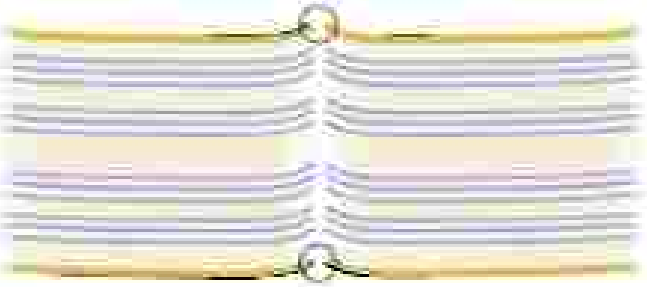

FIG. 6 Nerve ends should be trimmed to remove scarred tissue and ma [illegible] healthy-appearing fascicles in a way that will allow fascicles (about the) to be trimmed, both with the epineurium. Fiber sutures a the spine should be placed with 8-0, 9-0, or 10-0 suture and should be done carefully to prevent twisting of the ends. A tradivercular suturing through a fascicle. Coronal topography can a aligned by counting of cut vessels along the epineurium.

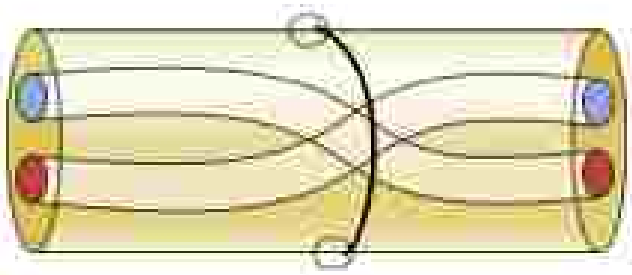

FIG. 7 Proximal nerve fascicles should be aligned to their corresponding distal fascicles. Mismatch between proximal and distal axonal can lead to errant innervation o inappropriate distal targets and lead to painful or dysfunctional.

FIG. 8 The distal nerve A the most common source of nerve graft. A purely sensory nerve, it supplies sensation to a small area of the dorsolateral aspect of the foot. The distal nerve is up to ~8 cm long in each leg; nerve grafts may be harvested bilaterally and distal nerve segments are used to bridge the nerve gap.

nerve gap being repaired, and the proximal end of the nerve graft should be sutured to the distal end of the nerve gap). This ensures that axons will not be lost through small side branches in the nerve graft as the axons grow through the graft. When the diameter of the nerve at the site of repair is much larger than the diameter of the nerve graft, grouped fascicular repair may be used (Fig. 9). The disadvantage of nerve grafting is related to the donor sequelae associated with donor morbidity from the nerve harvest, such as expected permanent sensory loss and small chance of neuropathic pain.

The graft length is calculated by measuring the nerve gap and adding 10% to account for some elongation of the graft and to avoid tension. One graft or several "cable" grafts are placed to maximize the surface area at the repair sites and to prevent mismatch. Interfascicular grafts may be sutured individually at both ends or may be placed together and then sutured as a single unit.

Vascularized nerve grafts have been advocated by some to improve the speed and quality of regeneration compared with standard, non-vascularized nerve grafts; however, this practice is controversial. Autogenous or synthetic conduits may be used for short gaps (<3 cm) of small diameter, usually sensory nerves (e.g., digital nerves). Using a nerve conduit requires an coaptation technique. The nerve conduit must be the correct diameter to accommodate the nerve and should be approximately 10 mm longer than the nerve gap. The coaptation technique involves placing the proximal nerve ending 5 mm within

FIG. 9 Intraoperative image of three sural nerve segments bridging a radial nerve gap in the distal arm after a humeral fracture.

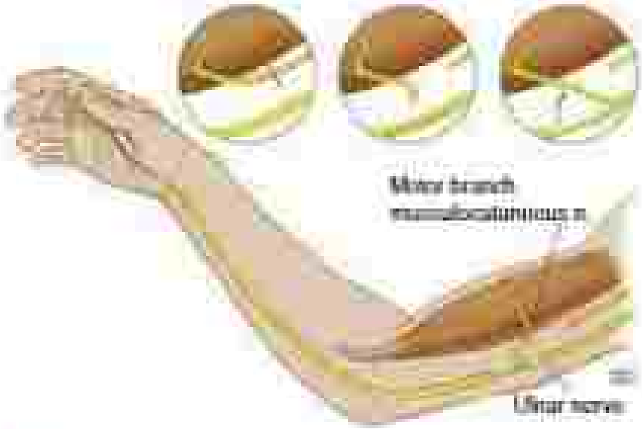

FIG. 1[illegible] Oberlin nerve transfer technique (Oberlin procedure) used for the repair of injury to the brachial plexus or musculocutaneous nerve leading to loss of biceps motor function. To perform this transfer the ulnar nerve function must be preserved. At the level of the middle or proximal third of the arm, a functioning ulnar nerve fascicle is used to reinnervate the biceps motor branch originating from the musculocutaneous nerve. In general, ulnar motor function is preserved [illegible], but the patient may experience transient sensory changes in the distribution of the ulnar nerve. [illegible] series using this technique reports that [illegible] of patients recovered good elbow flexion after surgery.

one end of the nerve tube and the distal nerve [illegible] 5 mm within [illegible] end [illegible] the [illegible] with [illegible] sutures [illegible] on [illegible] nerve conduit.

Nerve Allografts

[illegible]

Nerve Transfers

[illegible]

distal nerve [illegible] closer to the end organ as opposed to proximal nerve grafting farther from the end organ (Table [illegible]).

Muscle and Tendon Transfer and Bone and Joint Procedures

These various procedures usually are performed in a delayed fashion, sometimes more than a year after the injury. Muscle or tendon transfer is the transfer of a muscle or tendon that is working and is expendable to achieve a new function. This technique, similar to nerve transfer, requires a functional expendable innervated muscle in the vicinity. Examples of reliable tendon transfers include opponensplasty, anticlaw procedure, thumb adductorplasty, flexor to extensor transfers, elbow flexorplasty, transfers for shoulder external rotation, antiwing (scapular) transfers, transfers for pronation, and extensor to flexor transfers. An alternative is the transfer of a free functioning muscle, such as the gracilis muscle from the lower extremity, which can be transferred at a late stage for elbow flexion or finger flexion. This requires the presence of an arterial and venous supply, as well as a functioning nerve to reinnervate the muscle. Bone and joint procedures, such as osteotomies and arthrodeses, also may improve function. Shoulder fusion may be an option for patients with brachial plexus palsy and refractory instability with pain.

EXPECTED OUTCOMES FROM REPAIR AND RECONSTRUCTION

Outcomes after nerve injury and repair are variable owing to a multitude of underlying factors. The best outcomes are achieved when spontaneous neural recovery occurs (i.e., when surgery is not indicated). Other factors influencing the recovery of nerve repair and reconstruction include the following:

1. Patient age. The younger the patient, the better the recovery because of inherent physiologic factors related to regeneration, limb length, and capacity for cortical reorganization and reeducation.
2. Level of injury. Distal injuries fare better because of the shorter distance to the end organ.

TABLE 4 Common Motor Nerve Transfers of Upper Extremity

Motor Deficit	Recipient Nerve(s)	Donor Nerve(s)
Elbow flexion	Biceps, brachialis branches of MCN	Ulnar nerve fascicle to FCU Median nerve fascicle to FDS/PL/FCR
Elbow flexion	MCN	Medial pectoral nerve branches
Elbow flexion	MCN	Thoracodorsal nerve
Elbow flexion	MCN	Distal accessory nerve
Elbow flexion	MCN	Intercostal nerves
Shoulder abduction, external rotation	Suprascapular nerve	Accessory nerve (distal end-to-end or end-to-side with neurotomy and proximal crush injury) Pectoral fascicle of C7, middle trunk
Shoulder abduction	Axillary nerve	Medial triceps branch
Shoulder abduction	Axillary nerve	Medial pectoral nerve
Shoulder abduction	Axillary nerve	Thoracodorsal nerve
Shoulder abduction	Axillary nerve	Intercostal nerves
Scapular winging, instability	Long thoracic nerve	Thoracodorsal nerve[a]
Scapular winging, instability	Long thoracic nerve	Pectoral fascicle of C7, middle trunk[b]
Scapular winging, instability	Long thoracic nerve	Intercostal nerves
Intrinsic hand	Deep motor branch/fascicle of ulnar nerve	Distal AIN
Pronation	Pronator teres branches of median nerve	ECRB branch of radial nerve FDS or ECRB/palmaris longus branch of median nerve
Wrist, finger extension	ECRB, PIN branches of radial nerve	FDS, FCR/PL branches of median nerve
Finger flexion	AIN branch of median nerve	Brachialis branch of MCN ECRB, supinator branches of radial nerve
Elbow extension	Triceps branch of radial nerve	FCU fascicle of ulnar nerve ECRL fascicle of radial nerve
Elbow extension	Triceps branch of radial nerve	Intercostal nerves

[illegible]

1. Type of nerve injured: Pure nerves fare better than mixed nerves because there is less chance of fascicular mismatch.
4. Specific nerve involved: Radial nerve recovers better than median nerve, which recovers better than ulnar nerve; nerves C5 and C6 and those of the upper trunk recover better than nerves C8 and T1 and those of the lower trunk; and tibial nerve recovers better than peroneal nerve.
5. Mechanism of injury: Lacerations have better outcomes than low-velocity gunshot injuries, which in turn have better outcomes than high-velocity gunshot injuries; transections have better outcomes than crush or avulsion injuries; and stretch injuries generally have better outcomes than ruptures, which fare better than avulsions. These variations in outcomes are related to the zone of injury and associated soft tissue and vascular damage.
6. Timing of repair and reconstruction: The earlier the better; outcomes are typically best before 6 months, but they depend on the size of the gap, the status of the end plate, and the status of the alpha motor neurons.
7. Type of repair or reconstruction: Patients in whom exploratory surgery is indicated, but in whom only neurolysis is performed because of a positive NAP, generally have favorable outcomes. Patients in whom direct end-to-end nerve repair can be performed generally have better outcomes than patients who undergo conventional interpositional nerve grafting. Improved techniques with nerve transfers, especially distal nerve transfers, have improved outcomes in peripheral nerve surgery in recent years. Direct nerve transfers have better outcomes than nerve transfers with interpositional grafts.

WHO SHOULD OPERATE

By extrapolation based on data related to other surgical techniques, it seems reasonable to expect improved outcomes in centers performing high-volume practice. Timely referral to centers specializing in evaluation and management of nerve injuries is important and should be considered.

SUMMARY

The treatment and management of nerve injuries require thorough knowledge of anatomy, of the nerve injury process, and of the available repair and reconstructive options. It also requires specific microsurgical skills in the context of a multidisciplinary team able to address the peripheral nerves and associated muscles, tendons, and joint problems, as well as concomitant injuries in the central nervous system (spinal cord and brain) and other systems.

GAS GANGRENE OF THE EXTREMITY

Sharon Henry, MD, FACS, and Christine Cole, MD

Gas gangrene is a term generally reserved for a devastating infection caused by Clostridium species. Its occurrence is a medical and surgical emergency. Gas gangrene rapidly affects muscle and results in necrosis. Once a dreaded complication of battlefield wounds, in civilian populations it most commonly follows traumatic injury, particularly those occurring during natural disasters such as earthquakes, after operative procedures, or in association with drug injection, either medical or recreational, or spontaneously in the immunosuppressed or those with occult malignancy. Contaminated wounds can progress rapidly to gas gangrene when they are inappropriately closed or inadequately debrided. C. perfringens is the organism most commonly involved, but several other species are pathogenic. Clostridia produce exotoxins that lead to systemic phenomena, derangements and all its ability to invade locally. Early detection and treatment limit mortality and morbidity.

EPIDEMIOLOGY

Gas gangrene is rare, an estimated 0.1 to 1.5 cases occur per 1 million people. In the United States, 1000 cases are estimated to occur annually. Before the twentieth century, gas gangrene was a common cause of limb loss and death in wartime. The introduction of gunpowder increased the complexity of extremity wounds on the battlefield. Large, rubble lead ammunition of the Civil War produced compound fractures with tissue injury that favored the development of gas gangrene. The mortality rate from gas gangrene during the Civil War was 45%. Fleming, in a description of the bacteriology of wounds during World War I, identified C. perfringens (then w...ani) to be present in 41% of wounds in the first 7 days after injury. Five percent of the wounded developed gas gangrene. During World War II, early debridement, delayed closure, antitetanus, and penicillin administration combined to decrease the mortality rate of gas gangrene from 5... in 1 80 to 1902 to 22% by 1.36 to 1.45. Subsequent wars have seen a further decline in the incidence of gas gangrene in wounds. During the Vietnam War, the incidence declined to 0.02%. Rapid evacuation of the injured soldier with prompt wound debridement is responsible for the improvement. Civilian disasters continue to be a source of potential outbreaks of gas gangrene. The Wenchuan earthqua... e of 200... in China saw a 2.4% incidence of gas gangrene among hospitalized patients.

Gas gangrene occurs in three clinical settings: traumatic, postoperative/cultural, and spontaneous. A shift in the epidemiology of gas gangrene has occurred in recent decades, from traumatic injuries to postoperative wounds and sites of intravenous drug administration (Box 1). Traumatic causes include penetrating wounds from gunshots and stab injuries, crush injuries, and fractures, especially those injuries contaminated by soil. Nontraumatic cases are seen in postoperative wounds and among intravenous drug users. Central are colonization of the gut is a potential source of nontraumatic cases of spontaneous clostridial myonecrosis. These patients often have a hematologic or occult malignancy as their underlying predisposition to seeding from a gastrointestinal source, leading to "bland" myonecrosis. Mortality rates have decreased considerably in recent decades, but case fatality rates remain as high as 2...%.

PATHOGENESIS

George Nuttall and William Welch discovered C. perfringens in 1892. This gram-positive bacillus was initially called C. welchii but was renamed C. perfringens. This species is part of the normal flora of the human gastrointestinal, biliary, and genitourinary tracts. Soil, especially of farms or ranches, can be heavily contaminated with Clostridium species. It logically follows that traumatic open wounds that are heavily contaminated with soil are at risk from these organisms. C. perfringens is anaerobic but is somewhat aerotolerant. It forms spores that are heat resistant. The spores are capable of surviving in harsh environments and so can be difficult to eradicate. Under the proper conditions, this organism is capable of rapid multiplication and can have a generation time as short as 8 to 10 minutes with the production of a significant amount of gas.

Predisposing factors to the development of gas gangrene are lacerations, punctures, or crush wounds contaminated with soil that contain the spores. Immunocompromise is implicated in nontraumatic cases.

Initial growth of the organism begins within the area of devitalized tissue in an anaerobic environment. The infection advances through healthy living tissue, producing destruction and necrosis. It can advance at alarmingly rapid rates. Gas gangrene proceeds in four stages. Contamination and proliferation is the first stage. The degree and type of tissue injury and hypoxia and the amount of contamination are essential at this stage. A low pH favors the growth of clostridia. Muscle hypoxia leads to the release of amino acids and glycogen supporting survival and replication of the bacteria. Phagocytes are ineffective in the hypoxic environment. The bacteria elaborate toxins in stage 2. Muscle destruction provides nutrients such as

SUMMARY

The treatment and management of nerve injuries require thorough knowledge of anatomy, of the nerve injury process, and of the available repair and reconstructive options. It also requires specific microsurgical skills in the context of a multidisciplinary team able to address the peripheral nerves and associated muscles, tendons, and joint problems, as well as concomitant injuries in the central nervous system (spinal cord and brain) and other systems.

GAS GANGRENE OF THE EXTREMITY

Sharon Henry, MD, FACS, and Christian Cain, MD

Gas gangrene is a term generally reserved for a devastating infection caused by *Clostridium* species. Its occurrence is a medical and surgical emergency. Gas gangrene rapidly affects muscle and results in necrosis. Once a dreaded complication of battlefield wounds, in civilian populations it most commonly follows traumatic injury, particularly those occurring during natural disasters such as earthquakes, after operative procedures, or in association with drug injection, either medical or recreational, or spontaneously in the immunosuppressed or those with occult malignancy. Contaminated wounds can progress rapidly to gas gangrene when they are inappropriately closed or inadequately debrided. *Clostridium perfringens* is the organism most commonly involved, but several other species are pathogenic. *Clostridia* produce exotoxins that lead to systemic physiologic derangements and aid its ability to invade locally. Early detection and treatment limit mortality and morbidity.

EPIDEMIOLOGY

Gas gangrene is rare; an estimated 0.1 to 1.5 cases occur per 1 million people. In the United States, 1000 cases are estimated to occur annually. Before the twentieth century, gas gangrene was a common cause of limb loss and death in wartime. The introduction of gunpowder increased the complexity of extremity wounds on the battlefield. Large, rubble-lead ammunition of the Civil War produced compound fractures with tissue injury that favored the development of gas gangrene. The mortality rate from gas gangrene during the Civil War was 42%. Fleming, in a description of the bacteriology of wounds during World War I, identified *C. perfringens* (then welchii) to be present in 81% of wounds in the first 4 days after injury. Five percent of the wounded developed gas gangrene. During World War II, early debridement, delayed closure, antitetanus, and penicillin administration combined to decrease the mortality rate of gas gangrene from 50% in 1940 to 1942 to 22% in 1944 to 1945. Subsequent wars have seen a further decline in the incidence of gas gangrene in wounds. During the Vietnam War, the incidence declined to 0.02%. Rapid evacuation of the injured soldier with prompt wound debridement is responsible for the improvement. Civilian disasters continue to be a source of potential outbreaks of gas gangrene. The Wenchuan earthquake of 2008 in China saw a 2.4% incidence of gas gangrene among hospitalized patients.

Gas gangrene occurs in three clinical settings: traumatic, postprocedural, and spontaneous. A shift in the epidemiology of gas gangrene has occurred in recent decades, from traumatic injuries to postoperative wounds and sites of intravenous drug administration (Box 1). Traumatic causes include penetrating wounds from gunshots and stab injuries, crush injuries, and fractures, especially those injuries contaminated by soil. Nontraumatic cases are seen in postoperative wounds and among intravenous drug users. *Clostridium colonization* of the gut is a potential source of nontraumatic cases of spontaneous clostridial myonecrosis. These patients often have a hematologic or occult malignancy as their underlying predisposition to seeding from a gastrointestinal source, leading to distant myonecrosis. Mortality rates have decreased considerably in recent decades, but case fatality rates remain as high as 25%.

PATHOGENESIS

George Nuttall and William Welch discovered *C. perfringens* in 1892. This gram-positive bacillus was initially called *C. welchii* but renamed *perfringens*. This species is part of the normal flora of the human gastrointestinal, biliary, and genitourinary tracts. Soil, especially of farms or ranches, can be heavily contaminated with *Clostridium* spores. It logically follows that traumatic open wounds that are heavily contaminated with soil are at risk from these organisms. *C. perfringens* is anaerobic but is somewhat aerotolerant. It forms spores that are heat resistant. The spores are capable of surviving in harsh environments and so can be difficult to eradicate. Under the proper conditions, this organism is capable of rapid multiplication and can have a generation time as short as 8 to 10 minutes with the production of a significant amount of gas.

Predisposing factors to the development of gas gangrene are lacerations, punctures, or crush wounds contaminated with soil that contain the spores. Immunocompromise is implicated in nontraumatic cases.

Initial growth of the organism begins within the area of devitalized tissue in an anaerobic environment. The infection advances through healthy living tissue, producing destruction and necrosis. It can advance at alarmingly rapid rates. Gas gangrene proceeds in four stages. Contamination and proliferation is the first stage. The degree and type of tissue injury and hypoxia and the amount of contamination are essential at this stage. A low pH favors the growth of clostridia. Muscle hypoxia leads to the release of amino acids and glycogen supporting survival and replication of the bacteria. Phagocytes are ineffective in the hypoxic environment. The bacteria elaborate toxins in stage 2. Muscle destruction provides nutrients such as

branched chain amino acids and carbohydrates. An acidic environment with higher sodium to potassium ratio is ideal for continued bacterial growth and toxin production. Stage 3 is tissue destruction. The toxins create their effect systemically and locally. A hallmark of clostridial infection is the lack of inflammatory response. The α toxin produced increases the adherence of platelets and neutrophils causing vascular occlusion. This occlusion results in tissue ischemia and death and accounts for the pain noted clinically. The last stage is systemic toxicity. θ- and ι1 toxins combine to interact with macrophages, platelets, and endothelial cells to induce cytokine production. Tumor necrosis factor-α and interleukin 1 and 6 contribute to the development of shock and multiple organ dysfunction. The toxins also have direct effects on phagocyte and macrophage function, as well as on endothelial integrity. Toxins induce hemolysis and directly affect cardiac output, heart rate, and systemic vascular resistance.

C. perfringens is the organism most commonly cultured from traumatic wounds that have developed gas gangrene. *C. perfringens* is the causative organism in 80% to 95% of cases (Table 1). Other clostridial species cultured include *Clostridium novyi* (8%), *Clostridium septicum* (6%), and *Clostridium histolyticum*, *Clostridium fallax*, and *Clostridium sordellii* (1%). *C. septicum* infections frequently spread from a hematogenous or gastrointestinal source. Patients who survive an episode of gas gangrene with this organism should be evaluated for occult gastrointestinal malignancy. Nearly three-quarters of patients with *C. septicum* gas gangrene have a malignancy. A gastrointestinal malignancy was noted in about one-half of those patients, and another one-third will have a hematologic malignancy. *C. novyi* and *C. sordellii* have been associated with outbreaks among injection drug users. Table 1 shows the clostridial species most commonly seen in gas gangrene infections.

PRESENTATION

It can take as little as 6 to 8 hours for a clostridial infection to become well established, and muscle destruction can progress rapidly. It generally occurs within 2 to 5 days of the injury, although cases with longer incubation times have also been reported.

Pain is the first symptom noted. It is described as out of proportion to the degree of injury and is "sometimes so sudden as to suggest a vascular catastrophe." The pain may progress to anesthesia. Tissue changes develop rapidly and include swelling, blistering, purple skin discoloration, and then fluid drainage. Fig. 1 shows classic advanced skin changes. A musty or sweet odor may be present. Patients frequently display mental status changes, hypotension, anemia, thrombocytopenia, and acute kidney injury. A profound leukemoid reaction with a white blood cell count (WBC) of greater than 30 × 10⁹/L or leukopenia can be seen with gas gangrene. Pyrexia is usually absent, and the patient is instead hypothermic.

Tissue cultures with gram stains are vitally important to support the clinical diagnosis. Blood cultures are typically negative in gas gangrene but should be obtained in any case. In the case of post-traumatic or postoperative causes, the diagnosis may be clearly evident. In the case of nontraumatic gas gangrene, the earliest signs are nonspecific and include pain and mental confusion. In this case, imaging can be

FIG. 2 The right leg of a patient who presented with rapidly progressive pain in the leg. On transfer to a tertiary center extensive skin changes were apparent, as was proximal limb involvement. This patient died despite undergoing a hip disarticulation. Notice the necrosis to the tumor.

essential to help localize the site of infection before the advanced or classic physical findings are evident. Whenever there is clinical doubt, operative exploration is warranted to exclude the diagnosis. Figs. 1 and 2 show the classic skin changes with subcutaneous discoloration and blistering.

DIAGNOSTIC TESTS

Ancillary diagnostic imaging may not be of value in evaluating for gas gangrene. Frequently clinical symptoms are advanced enough to require no further imaging. Plain radiography or ultrasound scanning can identify air in the tissues and is probably more sensitive than physical examination; however, in cases not due to trauma or related to a procedure computed tomography scan can be useful for identifying an occult site (Fig. 3). Some describe magnetic resonance imaging as useful. Operative exploration for diagnosis may be necessary in case of clinical uncertainty. Exploration is unlikely to worsen the clinical condition.

TREATMENT

Resuscitation occurs simultaneously with evaluation. Broad-spectrum antibiotics should be given at the outset (Table 2). *C. perfringens* is very penicillin sensitive; however, it may be present alone or in combination with gram-positive, gram-negative, or other anaerobes. *C. septicum* has some penicillin resistance. Protein synthesis inhibitors are added to penicillin to limit toxin production. Standard blood work includes complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, and creatine phosphokinase, liver function tests, and possibly erythrocyte sedimentation rate and C-reactive protein. Anemia, thrombocytopenia, and coagulation abnormalities may be present and require correction with the resuscitation. Tetanus immunization should be updated and tetanus immune globulin administered to those patients not vaccinated previously.

OPERATIVE TREATMENT

Definitive treatment is surgery. Although those patients present with severe physiologic derangement and some attempt at correction must occur before surgery, it is important to recognize that the physiology will not be restored with medical therapy alone and proceeding to the operating room even with persistent physiologic abnormalities is a risk that must be taken. The resuscitation can continue into the operative phase of treatment.

The extremity must be circumferentially prepped and draped, extending to the joint above and below the involvement. When the diagnosis is in question, exploration of the extremity can be diagnostic. Historically amputation has been the only procedure recommended to treat gas gangrene. Amputation is often quick and definitive. The goal is to get ahead of the infection. The limb is removed above the level of gross involvement of infection. If amputation is planned, through joint amputation should be considered because it is frequently less time consuming and results in lower blood loss. It also spares tissue for reconstruction or closure. A tourniquet used during surgery can diminish blood loss. Tourniquet use is generally discouraged in the patient with vascular disease or diabetes undergoing an amputation. However, with a patient in an unstable condition due to coagulopathy or thrombocytopenia, use of this device may prevent further debilitation from blood loss.

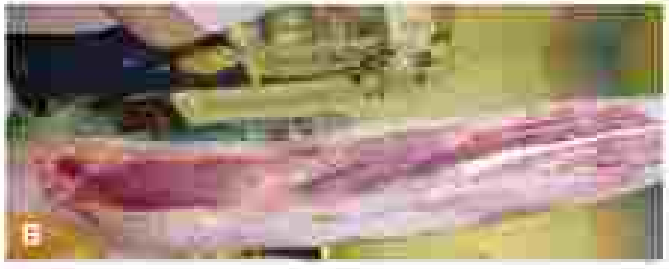

FIG. 3 (A) Computed tomography scan scout film demonstrating military appearance of air in the muscle. Also note calcified femoral artery (*arrow*). (B) Note abnormal appearance of the muscle: splendor of arm muscle with dark maroon and pale light areas with no bleeding note vertical incision that allows proximal and distal extension.

Unfortunately, gas gangrene often involves the proximal extremities, making forequarter or hindquarter amputation necessary. When hip or forequarter amputation is necessary, tourniquets are not an option (Fig. 2). There is a balance between aggressive debridement to remove compromised tissue and arrest bacterial growth with tissue preservation for further reconstruction and the possibility of recurrence of infection.

The patient's physiology usually drives decision making regarding amputation or limb salvage. In less dire cases exploration of the compartments with resection of the involved muscles is an option. When debridement is the chosen option, a vertical skin incision is made over the area of maximal skin abnormality because the skin with evidence of purpura or necrosis will be removed with the debridement. Because this infection strikes the muscle, it is therefore vital to ensure

TABLE 2 Antibiotic Choices

Clinical Circumstance	Antibiotics
Empiric antibiotics	Piperacillin-tazobactam
Gram negative	Imipenem-cilastatin
Gram positive	Meropenem
Anaerobes	Cefoxitin/ceftriaxone/cefotaxime/ceftazidime + clindamycin

Targeted to *Clostridium* species	High-dose penicillin (*Clostridium septicum* can be resistant) Clindamycin (inhibits toxin production)

MRSA, Methicillin-resistant *Staphylococcus aureus*.

FIG. 4 Patient from Figure 1 after subsequent amputation and extensive chest wall debridement. Negative pressure wound therapy is used to manage the wound after the active infection is controlled.

exploration of the muscle compartments because the more superficial tissue may appear unaffected. The dissection must continue through the deep fascia for thorough muscle inspection. Debridement must extend to viable muscle. It is imperative that all devitalized muscle be removed. Evaluate the muscle for color, consistency, contractility, and perfusion. Nonviable muscle is friable and pulls away easily, offering little resistance to removal. Involved muscle has a characteristic dark, maroon, or pale appearance, does not contract when stimulated with the cautery, and does not bleed when cut. (Fig. 3B shows abnormal muscle appearance.) Knowledge of the distribution of the neurovascular bundles in the muscle compartment is essential because the functional outcome can be impaired through inadvertent or unnecessary transection of blood vessels or nerves. When multiple muscle groups are involved, or the patient is hemodynamically compromised, amputation may be the best treatment option. Cultures of fluid and tissue from the wound should be obtained in the operating room. Gut gram stains can indicate the types of bacteria present and influence antibiotic choice. Pathologic evaluation can be requested as well if there is a question regarding the diagnosis.

Wound care with simple gauze dressing is the best option for immediate wound management. Gauze is inexpensive and can frequently be changed to allow the evaluation of the wound at the bedside to assess for advancing infection. Planned reevaluation of the wound in the operating room is imperative. Return is planned for 12- to 24-hour intervals until the infection is entirely controlled. Advanced wound care using negative pressure wound therapy (Fig. 4), alginates, foam, and antimicrobial impregnated dressings can be considered once the infection is controlled. These infections result in large wounds that are disfiguring and require multiple operative procedures. Caring for these patients is resource intense. Hospital and intensive care unit stays are extensive. Sepsis and the large surface area of the wound continue to increase the basal metabolic rate and increase nutritional requirements. Wound coverage ultimately requires skin grafts and or skin flaps (Fig. 5).

HYPERBARIC OXYGEN THERAPY

The use of hyperbaric oxygen for the treatment of gas gangrene is controversial. The controversy lies mostly in the lack of randomized controlled trial data supporting its routine use as an adjunct to management in the infection. Theoretically, enhanced delivery of oxygen through the tissue can be lethal to the clostridial bacteria. Because clostridia lack superoxide dismutase, they cannot survive in an oxygen-rich environment. High oxygen tensions stop α-toxin production. However, dormant spores of *Clostridium* species are unaffected by the high arterial Po_2 of 800 to 1000 mm Hg. Although

FIG. 5 Patient from Figure 4 after skin graft. Patient grew *Clostridium septicum* and was subsequently diagnosed with advanced colon cancer.

in vitro studies demonstrated hyperbaric oxygen therapy (HBOT) to be effective, clinical findings have been mixed. Small retrospective studies using a variety of protocols have yielded both positive and negative effects on outcome measures. HBOT should not delay resuscitation, antibiotic administration, or surgical debridement.

OUTCOMES

Clostridial gas gangrene infections are life changing for patients. They often affect previously healthy people, rapidly progress, and may result in sepsis and death. In a retrospective review, Ellis and colleagues identified death correlating with the presence of organ failure at admission and delay in the first debridement. Aniya and

associates found death to occur more commonly in patients who had a WBC higher than 30 × 10⁹/L, serum creatinine greater than 2 mg/dL, or preexisting heart disease. Others have found that mortality increased with the presence of premorbid conditions. The mortality rate was more than 50% in patients who had three or more of the following risk factors: age older than 50 years, malnutrition or obesity, diabetes, injection drug use, and hypertension. In short, clostridial gas gangrene infections are rapidly progressing infections that necessitate equally rapid and early diagnosis and treatment. Although novel therapies are currently under investigation as adjuncts to the treatment, surgical debridement remains the cornerstone of treatment.

Necrotizing Skin and Soft Tissue Infections

Patrick B. O'Neal, MD, and Carl P.E. Hart, MD

OVERVIEW

Necrotizing skin and soft tissue infections (NSTIs) represent a range of infectious conditions causing deep tissue necrosis, with nomenclature based on location of infection, pathogen, and depth of necrosis. The most frequently used names include necrotizing fasciitis, Fournier's gangrene, clostridial myonecrosis, synergistic necrotizing cellulitis, and gas gangrene. Necrotizing fasciitis represents infection extending through the deep fascia below the subcutaneous layers. Fournier's gangrene is a similar condition that originates in the perineum, whereas clostridial myonecrosis and synergistic necrotizing cellulitis extend into the deep muscle compartments, causing muscular necrosis. These diseases have received extensive media attention and have been lumped under the catchy rubric of "flesh-eating" bacterial disease. Hippocrates (400 BC) acknowledged necrotizing fasciitis as "diffuse erysipelas caused by trivial accidents, where flesh, sinews, and bones fall away in large quantities, leading to death in many cases." The elaborate categorization of these conditions has caused confusion regarding this disease. Put simply, the pathophysiology of these infections in all categories is the same and is the result of bacterial penetration of skin defenses, causing widespread necrosis and leading to rapid systemic deterioration and death. Any patient who presents with signs or symptoms concerning for NSTI should raise a sense of urgency for the clinician to achieve rapid diagnosis and deliver early treatment. Unfortunately, the diagnosis of NSTI can be difficult, tempting the clinician to postpone his eating treatment while obtaining time consuming diagnostic studies. This should be absolutely avoided in favor of urgent operative management.

PATHOPHYSIOLOGY

NSTI occurs when bacteria gain entry into the subcutaneous layers of the body where areas of relatively poor blood flow and relative hypoxia exist. Such conditions allow for poor immune response to infection and rapid overgrowth and spread of bacteria. Often, these microorganisms elaborate toxins that lead to both direct necrosis and indirect necrosis through thrombosis of perforating vessels and vasoconstriction increasing tissue hypoxia. Furthermore, these bacteria elaborate exotoxins that can lead to shock and multiorgan dysfunction.

DIAGNOSIS

Necrotizing fasciitis is a rare disease with an incidence estimated at 0.4 cases per 100,000 individuals by the United States Centers for Disease Control and Prevention. Because delay in adequate treatment can have tremendous deleterious effects on outcome with increased morbidity and mortality, early diagnosis is paramount in dealing with necrotizing soft tissue infections. Surgical consultation should be immediate, and surgeon judgment should dictate management when diagnostic ambiguity exists. A thorough history and physical examination should be performed because this diagnosis relies more on clinical judgment rather than diagnostic testing. Certain comorbidities may predispose patients to this disease. Such conditions include advanced age, obesity, diabetes mellitus, alcoholism, cirrhosis, chronic debilitation, encephalopathy, intravenous drug use, immunosuppression, malignancy, chemotherapy, hypertension, chronic obstructive pulmonary disease, congestive heart failure (conditions that impair oxygen delivery), end stage renal disease, peripheral ulcers, perforated viscus, and recent surgery. A thorough history to assess patient comorbidities and risk factors may help raise suspicion of this problem. Despite this extensive list of predisposing conditions, as many as 20% of NSTIs occur in patients with no apparent predisposing factor. Although NSTI may seem to occur spontaneously without any clear injury or portal of entry, NSTI often originates in the perineum, diabetic foot ulcers, decubitus ulcers, necrotic ulcers, puncture and traumatic wounds, and as a result of perforated viscus with subsequent soiling of soft tissues.

Initial physical examination findings may range from minimal to quite dramatic (Table 1). Some of the findings can include swelling, induration, mild to exquisite tenderness, crescendo pain, mild to violaceous erythema, tenderness beyond areas of erythema, cutaneous anesthesia, necrotic tissue in skin with a blue or purplish hue, and wounds exuding purulent, gray, or foul smelling drainage (Fig. 1). The skin may blister or slough, and crepitus may be present, indicating gas formation in the tissues. Crepitus, however, is present in only a fraction of patients and should not be relied on for diagnosis. One must keep in mind that obvious signs of NSTI may be subtle. Any patient with soft tissue exhibiting pain out of proportion to examination findings should be considered to be potentially harboring an elusive deep NSTI that has yet to make itself obvious because early skin changes may be minimal despite extensive subcutaneous fat, fascia, or muscle destruction. Tenderness beyond areas of erythema may be particularly ominous because it is indicative of rapidly progressive infection in the deep layers beneath the skin.

The hallmark of NSTI is its rapidly virulent and destructive behavior. Tracking within the fascial planes beneath the skin, a place with

associates found death to occur more commonly in patients who had a WBC higher than 30 × 10⁹/L, serum creatinine greater than 2 mg/dL, or preexisting heart disease. Others have found that mortality increased with the presence of premorbid conditions. The mortality rate was more than 50% in patients who had three or more of the following risk factors: age older than 50 years, malnutrition or obesity, diabetes, injection drug use, and hypertension. In short, clostridial gas gangrene infections are rapidly progressing infections that necessitate equally rapid and early diagnosis and treatment. Although novel therapies are currently under investigation as adjuncts to the treatment, surgical debridement remains the cornerstone of treatment.

FIG. 1 Black discoloration of penile, scrotal, and perineal skin in a patient with necrotizing infection of the perineum. There is also erythema, edema, and serous exudation over the lower abdomen. (From Quiñones D, Kuo AMK. Necrotizing soft tissue infections. In: Stevens D, Bisno A, eds. *2009 IDSA Clinical Practice Guidelines for Clinical Diagnosis and Management of Infectious Diseases*. London: Future Medicine Ltd; 2009:49–67.)

poor vascularity and thin host defenses, allows for the rapid spread of bacteria and overwhelming infection. Most patients quickly develop signs of systemic toxicity, including high fever, nausea, vomiting, malaise, tachycardia, hypotension, shock, mental status changes, and oliguric renal failure.

Laboratory values are nonspecific. White blood cell counts may reveal extreme leukocytosis, leukopenia, and high bandemia. Other common laboratory abnormalities include those indicating dehydration/fluid sequestration, such as low bicarbonate levels, elevated blood urea nitrogen, creatinine, and lactate levels. Additionally, patients may present with hyponatremia, elevated creatine phosphokinase, hyperamylasemia, and coagulopathy. The Laboratory Risk Indicator for Necrotizing Fasciitis Score System (Table 2) can be used as an adjunct to assess the probability of necrotizing fasciitis. It is important to remember, however, that this scoring system is meant to assist in risk stratification but is not meant to supersede sound surgical judgment. Those patients with low risk scores may still have NSTI, whereas those with high risk scores may not have NSTI. Thus this scoring system should not discourage operative debridement when clinical suspicion is high.

TABLE 2 LRINEC Score System

LRINEC Variable	Values	Score Points
C-reactive protein (mg/L)	<150	0
	≥150	4
WBC (cells/mm³)	<15	0
	15–25	1
	>25	2
Hemoglobin (g/dL)	>13.5	0
	11–13.5	1
	<11	2
Sodium (mmol/L)	≥135	0
	<135	2
Creatinine (mg/dL)	≤1.6	0
	>1.6	2
Glucose (mg/dL)	≤180	0
	>180	1
Sum of Points	**Risk Category**	**Necrotizing Fasciitis Probability**
≤5	Low	<50%
6–7	Intermediate	50%–75%
≥8	High	>75%

For intermediate and high risk patients, the model has positive predictive value of 92.3 and negative predictive value of 96.

LRINEC, Laboratory risk indicator for necrotizing fasciitis; WBC, white blood cells.

From Wong CH, Khin LW, Heng KS, et al. The LRINEC (laboratory risk indicator for necrotizing fasciitis) score: a tool for distinguishing necrotizing fasciitis from other soft tissue infections. *Crit Care Med*. 2004;32:1535–1541.

Because of the rapid lethality of necrotizing soft tissue infection, one should be cautious about obtaining advanced radiographic evidence of disease because this can delay lifesaving operative treatment. If obtained quickly in relatively stable patients, plain films may reveal air tracking in the soft tissues. Computed tomography and magnetic resonance imaging may show air tracking in soft tissues, fascial separation, and abscess formation, but often these studies do not add much because they may only reveal edema and nonspecific fat stranding. In unstable patients, these studies should be avoided in favor of rapid transfer to the operating room.

Biopsy of involved tissue typically reveals liquefaction necrosis of subcutaneous tissues and fascial layers with polymorphonuclear infiltrates and thrombosis of the perforating vessels to the skin. The fascial planes may weep a dishwater appearing or hemorrhagic fluid; fixation of soft tissues and digital probing may reveal separation of subcutaneous tissue from underlying fascia with minimal effort.

MICROBIOLOGY

Necrotizing fasciitis is well suited to a classification system based on the pathogen of origin. Type I represents polymicrobial infections, type II represents monomicrobial infections, type III represents

TABLE 3 Organisms Recovered From 198 Consecutive Patients With Necrotizing Soft Tissue Infections

Organism	No. of Cultures	No. of Isolates (% of Cultures)
Aerobic:		
Streptococci	182	83 (45.6)
Enterococci	182	61 (33.5)
Staphylococci	182	64 (35.2)
Escherichia coli	182	57 (31.3)
Proteus spp.	182	38 (20.9)
Other gram-negative bacilli*	182	76 (41.8)
Anaerobic:		
Peptostreptococci	151	45 (30.4)
Bacteroides spp.	128	29 (56.7)
Clostridium perfringens	129	13 (10.3)
Other clostridia	128	17 (13.3)
Other anaerobic species	128	27 (21.1)
Fungal species	171	9 (5.3)

*No information provided: Klebsiella spp., Enterobacter spp., Pseudomonas, Acinetobacter spp., Hemophilus influenzae, Citrobacter freundii.

From Elliott DC, Kufera JA, Myers RA. Necrotizing soft tissue infections. Risk factors for mortality and strategies for management. Ann Surg. 1996;224:672–683.

marine organisms, and type IV represents fungal organisms. In all classifications, the organisms gain entry to the subcutaneous space multiplying in areas of relative hypoxia and low blood flow, allowing for rapid proliferation.

As many as 75% of necrotizing soft tissue infections are polymicrobial, with an average of four organisms in a single infection (Table 3). For this reason, initial antibiotic treatment should be broad in spectrum. Polymicrobial infections often cause extensive local damage but on the whole are less lethal than other highly virulent monomicrobial infections. The most commonly isolated gram-positive organisms in polymicrobial infections include *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Enterococcus* species. *Escherichia coli* is the most common gram-negative organism isolated, whereas *Bacteroides* species and *Peptostreptococcus* species are the most common anaerobes isolated from polymicrobial infections.

The patient's history and physical examination may provide clues regarding which organisms may be the culprit of the soft tissue infection. Soft tissue infections located in the perineum, those secondary to perforated viscus, and those secondary to decubitus ulcers in diabetics, foot ulcerations tend to be polymicrobial in nature. These infections may contain all three, gram positive, gram negative, and anaerobic organisms.

Monomicrobial infections tend to be more aggressive, commonly presenting with acute onset and rapid progression to fulminant infection. Highly virulent pathogens include *Streptococcus pyogenes* (group A, β-hemolytic *Streptococci*), *Clostridium* species, community-acquired methicillin resistant *Staphylococcus aureus* (MRSA), *Vibrio vulnificus*, and *Pseudomonas aeruginosa*.

Group A, β-hemolytic *Streptococci*, by far the most common monomicrobial isolate, can result in a rapidly progressive NSTI with systemic toxicity and high mortality rates. These bacteria produce exotoxins that independently cause systemic toxicity resulting in multisystem organ failure. Additionally, exotoxins released include powerful proteolytic enzymes such as hemolysins, fibrinolysins, hyaluronidases, streptokinases, M proteins, leukocidins, and streptolysin O and S. These allow for rapid tracking through otherwise healthy tissue.

Clostridium species such as *Clostridium perfringens* are of particular concern in puncture and traumatic wounds, as well as in intravenous drug users. *Clostridium* also produces exotoxins that are responsible for its rapid destructive spread, systemic toxicity, and high mortality rate. *Clostridium* reproduces every 8 minutes and produces a toxin (phospholipase C) and 8 toxin (perfringolysin). These toxins cause direct tissue injury, kill neutrophils, as well as impede migration, and lead to hemolysis, microvascular thrombosis, and increase vascular permeability leading to rapid destruction of soft tissues including muscle tissue. Additionally, α toxin directly inhibits myocardial contractility resulting in shock.

NSTI resulting from community-acquired MRSA is on the rise. Community-acquired MRSA is able to produce exotoxins that lead to direct tissue invasion and necrosis. In addition, this bacterium has the ability to produce Panton Valentine leukocidin, which is a potent white blood cell and dermonecrotic toxin. Common populations affected with this disease include contact sports teams, prisoners, military recruits, injection drug users, institutionalized residents, and those who attend child and adult day care centers.

Bite wounds and water borne infections are unique subdivisions of polymicrobial infections that, in addition to the more common bacteria species, tend to harbor unusual organisms including *Pasteurella multocida* in cat and dog bites and *Capnocytophaga canimorsus* from dog bites. In human bite wounds, *Eikenella corrodens* is common. Water borne infections often contain *Vibrio* and *Aeromonas* species.

TREATMENT

Support

On identifying patients with necrotizing soft tissue infection, rapid operative management should be made top priority and not be delayed for any other therapeutic or monitoring interventions so as not to increase risk of morbidity and mortality. Nonetheless, supportive measures should be initiated as soon as possible in an intensive care unit. Appropriate antibiotic therapy should be immediately delivered. Invasive monitoring should be implemented including arterial lines for blood pressure monitoring and central venous lines for the delivery of medications and central venous pressure monitoring. Patients should receive aggressive fluid resuscitation as well as vasopressor and inotropic support when needed. Aggressive glycemic control can improve outcomes; thus an insulin drip may be appropriate. Serial laboratory values should be obtained because these patients can have rapid fluid and electrolyte shifts. Foley catheter placement and lactic acid measurements can be used to direct fluid resuscitation. Urine myoglobin and creatine kinase levels should be obtained when rhabdomyolysis is suspected. Blood products should be made available because it is not unusual for these patients to develop coagulopathy or have excessive operative blood loss. Early parenteral or enteral support should be initiated on a patient dependent basis. These patients exhibit high protein and caloric requirements due to their highly catabolic state.

ANTIBIOTIC THERAPY

Antibiotic therapy should be initiated immediately on presentation and continued until there is no further evidence of infection in the involved tissues or signs of systemic toxicity. Antibiotic choice should initially be broad spectrum and then tailored to microbiologic obtained from specimens retrieved at the time of surgery (Table 3). One should acknowledge the likely origin of infection in choosing antibiotics. For example, infections from perineal and intraabdominal sources or from diabetic foot ulcers and pressure sores are more

TABLE 4 Suggested Antimicrobial Therapy for Necrotizing Infections Based on Suspected Causative Organisms

Agent	Dose	Comment
EMPIRIC THERAPY		
Vancomycin*	15 mg/kg IV q12h	
Plus one of the Following		
Piperacillin/tazobactam (Zosyn)	3.375 g IV q6h	Use aminoglycoside or fluoroquinolone with anaerobic coverage, i.e., metronidazole in patients with penicillin allergy
Ertapenem (Invanz)	1 g IV q24h	
Meropenem (Merrem IV)	1 g IV q8h	
Imipenem/cilastatin (Primaxin)	1 g IV q6–8h	
Ciprofloxacin (Cipro)	400 mg IV q12h	Require added anaerobic coverage, i.e. metronidazole
Cefotaxime (Claforan)	2 g IV q4h	
Or		
Cefoxitin	2 g IV q12h	Broad spectrum coverage including MRSA, requires added anaerobic coverage, i.e., metronidazole
Tigecycline (Tygacil)	100 mg IV, then 50 mg IV q12h	
Consider Adding to Any of These Regimens		
Clindamycin*	600–900 mg IV q8h	Provides anaerobic coverage and inhibits bacterial ribosomal exotoxin synthesis
When Newer Agents Are Unavailable, Consider		
Vancomycin*	15 mg/kg IV q12h	Provides broad spectrum coverage including MRSA and anaerobes, excellent streptococcal and clostridial coverage, clindamycin inhibits bacterial ribosomal exotoxin production, may be a lower cost regimen with improved availability in some areas
Plus		
Penicillin	2–4 MU IV q4–6h	
Plus		
Gentamicin (Gram negative coverage)	2–2.5 mg/kg IV q24h	
Plus		
Clindamycin*	600–900 mg IV q8h	
INFECTIONS DUE TO STREPTOCOCCI		
Penicillin	2–4 MU IV q4–6h	Use vancomycin, linezolid (Zyvox), or daptomycin (Cubicin) in patients with severe penicillin allergy
Plus		
Clindamycin	600–900 mg IV q8h	Inhibits bacterial exotoxin production by streptococci
INFECTIONS DUE TO MRSA		
Vancomycin	15 mg/kg IV q12h	Does not inhibit toxin production
Linezolid	600 mg IV q12h	Bacteriostatic, inhibits toxin production
Daptomycin	6 mg/kg IV q24h	Bactericidal, excellent tissue penetration, risk myopathy
Ceftaroline	600 mg IV q12h	Bactericidal
Quinupristin/Dalfopristin (Synercid)	7.5 mg/kg IV q8h	Bactericidal, inhibits toxin production
INFECTIONS DUE TO CLOSTRIDIUM SPECIES		
Penicillin	2–4 MU IV q4–6h	
Plus		
Clindamycin	600–900 mg IV q8h	
INFECTIONS DUE TO ANIMAL AND HUMAN BITES		
Ampicillin/sulbactam	1.5–3 g IV q6–8h	Good activity against *Pasteurella multocida* and *Eikenella corrodens*
Cefuroxime (Ceftin, Zinacef)	1 g IV q24h	
Cefoxitin	1 g IV q6–8h	
Ciprofloxacin	400 mg IV q12h

IV, Intravenously; MRSA, methicillin-resistant *Staphylococcus aureus*; mU, million units; q, every; qid, four times daily; tid, three times daily.
*The combination of vancomycin and clindamycin can be substituted with linezolid alone in patients requiring >2 weeks of MRSA coverage and who are receiving an serotonin reuptake inhibitors.

likely to be polymicrobial, whereas necrotizing infections are more likely to be monomicrobial. Extremity infections, infections related to intravenous drug use, and infections in patients from certain backgrounds including prison inmates, Alaska natives, institutionalized individuals, and athletes are more likely to harbor community-acquired MRSA.

Infections that are likely polymicrobial can be treated empirically with broad-spectrum agents such as piperacillin-tazobactam, imipenem-cilastatin, meropenem, ticarcillin-clavulanate, and tigecycline. Vancomycin and metronidazole should be included as part of empiric therapy if MRSA and anaerobes are not covered by other agents. Evidence suggests that clindamycin's ribosomal inhibitory properties may reduce toxin production responsible for widespread organ dysfunction. As such clindamycin should be considered as an adjunct to other antimicrobial regimens. Like clindamycin, linezolid also has ribosomal blocking properties that may reduce toxin production. Combination therapy with both vancomycin and clindamycin can be substituted with linezolid alone, which covers MRSA and has ribosomal inhibitory activities. The combination of vancomycin, penicillin, and clindamycin along with a gram-negative agent such as an aminoglycoside can be used for empiric therapy if newer antimicrobials are unavailable. This combination exhibits broad-spectrum coverage including MRSA and anaerobes with a strong effectiveness against *Streptococcus* and *Clostridium*, has excellent tissue penetration, provides reduction of bacterial toxin production by clindamycin, tends to be readily available, and may have a lower cost. This combination will, however, not cover for penicillinase-producing organisms in areas where these organisms are prevalent. Antimicrobials should be de-escalated as soon as culture results and sensitivities are available. Antibiotics should be continued until the patient's clinical condition has stabilized, fever has subsided, and white blood cell count is normal.

SURGERY

Surgery should focus on rapid identification of affected tissue, with complete excision of all devitalized skin and soft tissue (Fig. 2). Reports show a seven- to nine-fold increased risk of death with inadequate or delayed initial debridement. Incision should be made with dissection through all soft tissue layers until the deep muscle

FIG. 2 Extensive debridement of the scrotum, penis, perineum, and lower abdomen was performed. A sigmoid loop colostomy was also created. (From Daigle CJ, Kuru AM: Necrotizing infection of the perineum. *Emerg Physician*. 2008;6:37.e5.)

layers are encountered. A thorough probing of all tissue and fascial planes to assess for tracking should be made to direct further dissection. Typical findings indicating devitalized tissue include murky dishwater appearing fluid in the subcutaneous fat and fascial layers, tissue that dissects from deeper tissue with minimal resistance, nonbleeding tissue, and vascular thrombosis. Non-contractile muscle indicates devitalized muscle tissue. All tissue overlying involved fascial planes should be immediately debrided along with the affected fascia. Easy separation of fascia from underlying tissue using the "finger test" indicates active infection and indicates tissue that should be debrided. All fluid collections should be drained. Debridement should extend back to viable soft tissue and muscle that exhibit brisk bleeding. Tissue (including fascia) should be sent to microbiology for Gram stain and culture for aerobic, anaerobic, fungal organisms to help tailor antibiotic usage.

In certain patient populations and NSTI presentations, operative management should be further tailored. Amputation may be necessary for infections rapidly progressing toward the trunk, involving major joints, or if extensive myonecrosis has occurred. Guillotine amputations of lower extremities should be considered, especially in patients with peripheral vascular disease for rapid containment of infection. In patients suffering from Fournier's gangrene, all affected perineal soft tissue including the scrotum and penile skin should be debrided and colonic diversion considered. Colonic diversion may need to be delayed until a second operation, depending on patient stability. Testicles can usually be preserved because they have an independent blood supply, although removal should not be delayed if they are involved. Patients with perforated viscus will require the intraperitoneal injury to be addressed, likely with diversion if caused by perforated colon.

Return to the operating room within 24 hours or earlier for a second look should strongly be considered and debridement of any retained devitalized tissues performed. Patients may require multiple trips to the operating room before the infection is eradicated completely, with a median number of returns around four.

Wounds should be treated with serial wet-to-dry dressing changes until all infection has been cleared. Some authors prefer Dakin's or iodine soaked gauze dressings and some authors recommend the use of topical antibiotics such as silver sulfadiazine. Vacuum assisted closure of wounds can send once the infection is cleared either as a primary therapy or until reconstruction is done. *No tissue grafting* should be attempted until infection is fully treated and the patient's condition has stabilized.

Adjunct Treatments

Although urgent surgical debridement is the most important therapeutic maneuver for NSTI and should never be postponed in favor of other treatment modalities, it is worth mentioning a number of mostly theoretical adjunct treatments. These include hyperbaric oxygen therapy, intravenous immunoglobulin, and plasmapheresis. Hyperbaric oxygen therapy works on the premise that it increases oxygen supply to infected tissues thus inhibiting bacterial growth and improving host response to infection. Evidence supporting hyperbaric oxygen therapy is limited, and many authors refute effectiveness. Furthermore, as urgent surgical debridement is the most lifesaving therapy, no patient should be transferred to a facility housing a hyperbaric oxygen chamber without first performing adequate surgical debridement. Intravenous immunoglobulin works by binding exotoxins and potentially decreasing systemic toxicity. Plasmapheresis filters bacterial exotoxins that result in shock and multiorgan dysfunction. By reducing circulating toxin, intravenous immunoglobulin and plasmapheresis may hasten recovery from systemic shock. Again, evidence for these treatment modalities is controversial.

RECONSTRUCTION

Reconstruction should be initiated as soon as possible once all infection has been eradicated and systemic toxicity has subsided. This will aid in ensuring hemostasis, speed healing, decrease fluid losses, and improve final cosmetic outcome. Split thickness skin grafts are favored. Staging reconstructions are used for complex reconstructions. The assistance of a plastic surgeon or urologist may be beneficial for difficult areas such as the hands, face, and perineum particularly if flaps are needed or pockets need to be made for uncovered testicles.

COMPLICATIONS

Multiple complications can occur with NSTI. Despite attempts at improving recognition and speed in surgical management of necrotizing fasciitis, improvement in mortality has been plagued with death rates remaining around 25%. Obviously, with the extent of debridement necessary, disfigurement and disability are considerable. Contractures can occur in involved limbs. Secondary infections in the critically ill are common including line infections, pneumonias, urinary tract infections, and secondary soft tissue infections. For those with Fournier's gangrene, impotence and decreased sperm count or motility are common. In addition, debridement of the perineal muscles may result in fecal incontinence and the need for a permanent colostomy.

CONCLUSION

Necrotizing soft tissue infections should be promptly recognized to expedite surgical treatment and minimize morbidity, long-term disability, and death. Diagnosis can be difficult, and there are no firm diagnostic criteria. The clinician must recognize the clues and have a low threshold for exploring areas of concern.

P[illegible]

[illegible]

[illegible]

[illegible] by physical exam. Contrast enhanced magnetic resonance imaging is an essential tool for the evaluation of soft tissue masses and will additionally offer improved appreciation of nerve involvement and degree of bony invasion for analytic lesions. There are some general imaging findings that may be useful in assessing malignant versus benign lesions. For soft tissue masses, increased size is associated with a higher risk of malignancy, while superficially located tumors are more likely to be benign. Concerning bony abnormalities, benign lesions are usually smaller and with concrete well defined borders, while bony destruction is more characteristic of malignancies. [illegible] emission tomography (PET) scanning is appropriate for evaluating distant spread, but given the potential for benign disease, it may be prudent to wait for biopsy results before proceeding (Fig. 1).

The intention of biopsy depends on several factors, most prominently the size of the tumor and its location. Classically, tumors smaller than 5 cm in size should undergo excisional biopsy, but in practice, location and anatomic position must be considered. When an excisional biopsy is performed, the surgeon and patient should both be aware that re-resection for margins may be necessary if the diagnosis reveals malignancy. If an excisional biopsy is not feasible, an incisional biopsy offers superior diagnostic accuracy over a core needle biopsy. Some tumor types may be inconclusively identified after a core needle biopsy, as the possibility of diagnostic confusion exists with a small sample. Repeat biopsy is indicated for inconclusive samples. Once the pathologic diagnosis is obtained, a surgical plan can be appropriately and accurately devised (Box 1).

BENIGN SOFT TISSUE

Lipoma

Lipomas remain the most common soft tissue tumor in adults and are more prevalent in obese patients. On imaging, they possess attenuation common with fatty deposits, with mild enhancement of their septations. Lipomas do not enhance with contrast. Deep chest wall lesions are generally less well circumscribed than superficial lesions and may be difficult to differentiate from surrounding fat. Preoperative tagging is sometimes necessary. The principles of surgical excision involve complete removal of the capsule to prevent recurrence. Surgical removal is usually limited to symptomatic lesions, to those that are cosmetically troublesome, or where the etiology is uncertain.

Desmoid Tumor

Desmoid tumors, aggressive fibromatosis, or desmoid type fibromatosis, are soft tissue tumors that develop from deep tendons and connective tissue. While officially benign without metastatic potential, they behave clinically like low grade sarcomas with high rates of local recurrence. The tumors are slow growing and usually diagnosed incidentally but may be a source of pain or compressive symptoms. Desmoid tumors are associated with subtypes of familial adenomatous

pathogens such as Gardner's syndrome, in which case patients present with multiple lesions. Desmoids are more common in younger adults.

Desmoid tumors can be difficult to assess radiographically. On computed tomographic (CT) scan, they will appear as soft tissue masses of variable appearance, usually without distinct markings or calcifications. Low enhancement may be more common with chest wall lesions, but this is not a reliable feature. These lesions are usually well vascularized. Magnetic resonance imaging (MRI) is clearer than CT scanning, with the desmoids most commonly appearing as isointense lesions with a rim of fat. These lesions may also travel along fascial planes some distance from the main body of the tumor, and MRI is most effective at evaluating the extent of this spread. On pathology, these tumors have a solid scar-like appearance, which may be tough enough to make needle biopsy very challenging.[14] While the biologic mechanism of tumor development may vary, a central theme is β-catenin overexpression throughout the lesion, which can be immunohistochemically stained for diagnosis. These lesions appear on microscopy as poorly organized mesenchymal myofibroblasts without classic signs of malignancy.

The treatment of symptomatic desmoid tumors is primarily surgical resection. Without intervention, they usually continue to grow and become more severely symptomatic. While they are benign lesions that almost never metastasize, local recurrence is common and can be as high as 50%. Great care should be taken to obtain microscopically negative operative margins. Desmoid tumors are infiltrative and may involve themselves in critical structures, especially blood vessels, which can complicate resection. Especially complex presentations may benefit from referral to a tertiary care center, as the challenges of these resections should not be underestimated. There is still some debate on adjuvant approaches after obtaining microscopically positive margins, but re-resection should be attempted if feasible.

As an alternative to surgery, observation or systemic therapy is sometimes pursued. Observation is appropriate for lesions that are asymptomatic or multifocal, as these lesions are slow growing. For systemic therapy, tyrosine kinase inhibitors, nonsteroidal anti-inflammatory drugs and hormonal therapy have all shown efficacy in disease control and treatment usually begins with these agents. Cytotoxic chemotherapy is reserved for those patients that fail this management or present with severe disease. Due to slow response times, neoadjuvant therapy is not typically offered. The role of radiotherapy in management is currently unclear. Due to the rates of local recurrence and slow growth of the tumor, extended follow-up is recommended. When recurrence occurs, re-resection remains the treatment of choice.

MALIGNANT SOFT TISSUE

Rhabdomyosarcoma

Rhabdomyosarcoma is known for being the most common pediatric soft tissue tumor but can also present in adults with severe consequences. They uncommonly arise in the chest wall, but the course is usually a fast growing lesion with the patient seeking medical care due to pain at the site or compression of other structures. The tumor originates in skeletal muscle but can quickly invade nearby tissue.

Lesion imaging begins with CT, which will usually describe the location of the tumor, but MRI is superior for diagnosis and determining degree of involvement of other structures. The tumor usually presents with ring-like regions of contrast enhancement on MRI, which correlate with areas of vascularity versus necrosis. Biopsy is often required to obtain a diagnosis and an open biopsy is usually superior for providing an adequate sample. Rhabdomyosarcoma has several named subtypes, correlating to different macroscopic and histologic appearances, although they all develop from skeletal muscle. Adults with this disease are more likely to present with less favorable subtypes than pediatric patients.

Surgical resection represents the best chance for durable cure, but even with negative margins, the chance of recurrence remains high. Radiation and chemotherapy are routinely used, with regimens inspired by pediatric therapies, as there is a paucity of data in adult patients. Chemotherapy is typically vincristine, actinomycin

and cyclophosphamide, interposed with ifosfamide and etoposide. Median radiation dose is roughly 45 Gy. If resection compromises the chest wall or breathing mechanics, reconstruction should be done immediately. Follow up should be frequent after surgery given the likelihood of recurrence.

Malignant Fibrous Histiocytoma/Undifferentiated Pleomorphic Sarcoma

Malignant fibrous histiocytoma or undifferentiated pleomorphic sarcoma (UPS) is a sarcoma of uncertain etiology. It can arise from either soft tissue or bone and represents one of the most common soft tissue sarcomas. It often presents in the extremities but can be found in the retroperitoneum and in the chest wall. Pain is usually the presenting complaint, though asymptomatic swelling and incidentally found lesions are not uncommon. The rate of diagnosis has been decreasing over recent decades as improved diagnostic techniques label fewer tumors as UPS. As diagnostic criteria narrow, the disease is trending toward being more common in older males. Additionally, like many sarcomas, there may be risk to prior radiation.

UPS is difficult to characterize radiographically, as it has myriad appearances. Centrally, these lesions are indeterminate heterogeneous masses, with the heterogeneity more pronounced as the lesions grow. There is no imaging modality that is explicitly more advantageous, as most suspicious lesions may require imaging with CT, PET and MRI. Pathologic results are similarly varied; however, $T^{53}C$ expression and deletion mutations of $p16^{INK4A}$ have been implicated in this disease. Pleomorphic spindle cells are usually seen as infiltrative tumor on histology.

Management is surgical resection. Outcomes are poor, underscoring the importance of negative margins. When this tumor is present on the extremities, 2 cm resection margins are usually required, but this may be challenging to accomplish in the chest wall. Chemotherapy is exploratory, with new treatments seeking to explore treating this previously diverse tumor group by targeting conserved mutations. Currently, cytotoxic chemotherapy is reserved for disseminated disease for which the prognosis is extremely poor. Radiation has some efficacy and merits consideration, especially for patients for whom wide margins are not feasible. Close follow up is warranted as rates of recurrence are quite high.

Liposarcoma

Liposarcomas are responsible for a minority of chest wall soft tissue sarcomas. As understanding of their biology has progressed, the tumor is now divided into three main subtypes, well differentiated liposarcoma, myxoid round cell liposarcoma and pleomorphic liposarcoma. Well differentiated liposarcoma (referred to as atypical lipomatous tumor when localized to the extremities) is the most common subtype of liposarcoma and lacks metastatic potential. However, it can degenerate into dedifferentiated liposarcoma, which is clinically similar to high grade disease and may metastasize. Myxoid round cell liposarcoma is a mid grade tumor, while pleomorphic liposarcoma reflects high grade disease.

The diagnostic value of imaging varies by tumor subtype. For well differentiated liposarcomas, it is difficult to differentiate them from benign lesions. Myxoid round cell usually appears as multilobular lesions within muscle and with a high water content that is visible on MRI. CT scans of pleomorphic liposarcoma reveal a well circumscribed lesion, notable for the absence of fat. Necrosis, infarction and hemorrhage may all be visible on MRI.

Surgical resection affords the best opportunity for durable cure. Multiple studies have demonstrated the therapeutic benefit of appropriate surgical margins and the standard of care for malignant liposarcoma is a 2 cm margin. Liposarcomas are difficult to detect early and often present where obtaining 2 cm margins is technically demanding or infeasible. In these cases, resection even with limited margins provides a survival benefit and should be pursued, with the understanding that the goals of primary resection must be balanced against surgical feasibility on a patient to patient basis.

The role of radiotherapy in treatment of liposarcoma varies depending on tumor subtype. Well differentiated liposarcoma has no malignant potential by itself, so radiotherapy only reduces the risk of local recurrence. Myxoid round cell liposarcomas is usually highly radiosensitive, and radiation is both effective at preventing local recurrence and for shrinking the tumor preoperatively. Chemotherapy remains exploratory and patients should be considered for clinical trials if they present with disseminated disease. Neoadjuvant chemotherapy is similarly limited, and is attempted for patients who present with initially unresectable disease.

Close follow up is critical for expectant management as recurrence rates can be high. Of particular note, the myxoid round cell variant appears to have a metastatic preference for high fat locations.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a rare tumor derived from uncontrolled proliferation and subsequent migration of Langerhans cells. The etiology of this disease is unclear, but a viral vector has been suggested. This disease develops as a single site approximately 75% of the time, with the remainder representing as a more diffuse process. Patients may present with a growing mass or with a variety of systemic symptoms including chills, weight loss, lymphadenopathy, or bone pain. In chest wall cases, LCH predominantly affects the ribs.

Chest radiographs may be useful for identifying lytic lesions. Chest CT is more sensitive and may demonstrate a beveled edge along areas of lytic destruction, due to variable destruction of inner and outer bone cortex. MRI will show contrast enhancement and any soft tissue component of this tumor should appear hyperintense on T2 imaging. Biopsy is usually needed for diagnosis and microscopic evaluation should reveal round cells with a "coffee bean" nucleus. This tumor should be clonal, expressing CD1a, CD207, S100 and potentially BRAF^{V600E}.

While surgical excision is occasionally necessary for diagnosis or for impingement on other structures, the mainstay of treatment for diffuse disease is chemotherapy, traditionally with vinblastine and prednisone. There is also a role for curettage and irrigation of bone lesions, which has demonstrated success with small solitary lesions, but should only be attempted by experienced surgeons. Microscopically negative margins should be sufficient if formal resection is required.

Primary Pleuropulmonary Synovial Sarcoma

Primary pleuropulmonary synovial sarcoma is a synovial sarcoma that affects the chest wall, pleural, lung, heart or mediastinum and is a subtype of spindle cell sarcoma. It is alternatively referred to as primary mediastinal synovial sarcoma if affecting the heart or the mediastinum. The most common clinical presentation is consistent with obstructive symptoms, cough, dyspnea, hemoptysis or chest pain. Incidental discovery on routine imaging is also common.

CT is usually the initial diagnostic choice; the lesion is typically well defined, with areas of fluid heterogeneously present within. The CT image alone may be sufficient, depending on the tumor's size and location. A "triple sign" representing tumor, hemorrhage and necrosis is sometimes noted. Ipsilateral pleural effusion may be present as well as pleural thickening. MRI may also assist in delineation when this disease spreads into adjacent structures. Pulmonary and mediastinal lymphadenopathy is less common than with traditional lung cancer.

The vast majority of primary pleuropulmonary synovial sarcomas occur as a result of a gene translocation mutation between chromosome "X and chromosome X, leading to the common

fusion gene *SYT-SSX*. Microscopically, the spindle cells classically possess elongated nuclei and irregular borders, while the cytoplasm may stain basophilic. The extracellular membranes can be variable. Well differentiated tumor is associated with improved prognosis.

Although most tumors are diagnosed late, complete resection is the factor most associated with favorable long term outcomes. Negative margins should be pursued whenever possible. If the tumor is confined to the lung, lobectomy is appropriate. Since the diagnosis is usually made postoperatively, experience with neoadjuvant therapy is limited but could be pursued in select patients. Radiotherapy may be used for positive margins, though its efficacy is unclear. Chemotherapy agents used most often are ifosfamide and doxorubicin, which can be efficacious in up to 50% of patients. Close follow up is indicated due to the likelihood of recurrence.

BENIGN BONE AND CARTILAGE

Fibrous Dysplasia

Fibrous dysplasia is the most common benign lesion in the rib. It is characterized by progressive replacement of calcified bone and marrow with fibrous tissue due to abnormal proliferation of bone marrow stromal cells. Patients are most commonly identified either incidentally on imaging, due to chest wall swelling or complaints of bone pain at the lesion site.

Chest radiographs should classically demonstrate a well circumscribed ground glass lesion in the bone. Chest CT provides the most diagnostic value and the lesion should enhance with contrast due to its high vascularity. MRI may incrementally provide additional detail about the size and depth of the tumor, but it is difficult by MRI scan to differentiate between other bony lesions and fibrous dysplasia. A bone scan is useful for detecting multifocal disease. If radiographic diagnosis is inconclusive, biopsy may be performed for histologic evaluation.

Management of this condition is guided by the presence of symptoms. Pain may be refractory to medical management or the lesion may mechanically obstruct movement or compress structures. Rarely, the lesion may be growing sufficiently quickly to merit resection prior to the onset of probable complications.

Osteochondroma

Osteochondroma is a benign tumor that presents as an exostotic growth with a cartilaginous cap on the affected bone. While it is perhaps the most common benign bone lesion, it is relatively rare in the chest wall, responsible for fewer than 10% of bony chest wall abnormalities. These lesions are usually diagnosed either incidentally on imaging, due to a pathologic fracture or chronic pain.

Osteochondromas can extend cartilaginously, which may be appreciated on routine chest radiographs. The growth of the lesion is often complex, and CT scans better appreciate the depth of the cartilaginous cap. An MRI may have additional utility in evaluating how deeply the lesion involves the affected bone.

Malignant transformation to sure and surgical resection is typically reserved for chronic pain, impingement, or cosmesis. The one notable exception to the use of surgery for rapidly growing tumors, since these are highly suspicious for malignancy. During the procedure, the entire cartilaginous cap should be removed to prevent recurrence. The presence of more than one osteochondroma suggests a hereditary cause.

Chondroma

Chondroma is a classically benign cartilaginous cyst that can arise completely within or on the surface of bone. These hyaline cartilage producing tumors are the second most frequent cause of a benign rib lesion after fibrous dysplasia. Like most other benign bony lesions, this is usually an incidental finding as patients usually lack symptoms.

When symptoms are present, pathologic fracture or physical deformity from growth are the most common presentations. Pain may also be a referring symptom, which is classically worrisome for malignancy though retrospective studies have failed to find this link. A subset of patients will present with multiple lesions, which is often the sign of a genetic condition. Having multiple lesions also increases the risk of malignant degeneration.

Chest radiographs should show lytic lesions, while a CT scan will allow for visualization of endosteal scalloping of the tumor, which helps to differentiate chondromas from other lesions. An MRI may be useful for observation, as it is more sensitive for detecting malignant degeneration.

Resection is typically reserved for pathologic fractures or a concern for secondary chondrosarcoma. Resection of the entire cyst will minimize the risk of recurrence and eliminate the possibility of malignant degeneration. If the lesion is easily accessible and solitary, empirical resection can be considered to eliminate the possibility of any future malignancy.

Aneurysmal Bone Cyst

An aneurysmal bone cyst (A, C), despite the name, is not truly a cyst, but a benign skeletal tumor. It most commonly presents with pain, but when localized to the chest, may present with a palpable mass or atelectasis and pneumonitis from pulmonary compression. The majority of these tumors are small in size, but if undiagnosed or untreated can grow in excess of 10 cm in diameter.

This tumor appears classically on a radiograph as a "blow out" appearance in bone. CT affords better visualization, as the cortical thinning of the involved bone may lead to a soap bubble like appearance. An MRI often reveals multiple bony cysts with a thin septum, containing blood products. A biopsy usually results in blood products and most often is inconclusive. Despite this, radiographic and biopsy results can be very suggestive of this disease process even if a formal diagnosis is elusive.

Curative treatment is resection of the lesion, with complete removal of the aneurysmal bone cyst. There is no unusual urgency for resection, but if left untreated, the cyst can compromise the structure of the bone, and may cause secondary symptoms as it continues to grow.

MALIGNANT BONE AND CARTILAGE

Chondrosarcoma

Chondrosarcoma is the most common primary malignancy of the sternum, although primary chest wall malignancies represent a heterogeneous group of tumors. Pain and swelling are the most common symptoms leading to the diagnosis of chondrosarcoma, though incidental diagnosis is not unusual. Chondrosarcoma can present throughout adulthood and about 1 % of cases occur from degeneration of benign lesions, most commonly osteochondromas.

CT is the initial imaging tool of choice both for its convenience and because of its sensitivity to distinguishing the pattern of mineralization that is classic for chondrosarcoma. MRI may also be necessary to determine the degree of invasion throughout the affected bone. Histologically, these tumors have a multinodular architecture found in the myxoid stroma that is usually distinct enough to provide an accurate diagnosis after biopsy or resection. It is not unheard of, however, for additional cells or debris to be present that can cloud the diagnosis. An excisional biopsy is sometimes necessary to obtain sufficient tissue for accurate diagnosis.

Complete surgical resection is deemed for initial therapy as there are limited adjuvant treatments available. Appropriate margins vary depending on grade, but at least 1 cm margins should be obtained whenever possible. Small tumors in the chest wall should be completely resected. Limitations due to chest stability may influence totality of resection with larger lesions, but this worsens prognosis. There is some indication for curettage and cryosurgery for grade

chondrosarcoma, but this had been historically used in the long bones for limb salvage. These techniques are also associated with an increased rate of local recurrence.

Efficacy of chemotherapy depends on histologic subtype, but offers only limited benefit. Chondrosarcomas are usually also radiation resistant and require doses above 60 Gy for local control. Local recurrence may be treated with re-resection, while treatment of the unresected disease is essentially palliative.

Osteosarcoma

Osteosarcoma is most commonly thought of as a tumor of the long bones in children and adolescents. Its presentation in the chest wall is uncommon, but when it occurs, it most commonly affects adults. It usually presents as an intramuscular tumor but may extend extraskeletally. In adults, pain and swelling with a growing mass are the most common symptoms. Classically, this pain is substantial enough to wake a patient from sleep. There is some evidence of increased risk of osteosarcoma of the chest wall with prior radiation exposure to the region.

Radiographic diagnosis is made primarily through CT scanning, which allows both tumor identification and evaluation of distant spread. Radiographs are more beneficial in identifying peripheral osteosarcoma and have limited utility in the chest. MRI scanning helps delineate degree of local invasion. Core needle biopsy should be used with caution, as it may provide insufficient sample for accurate diagnosis. Pathologically, the origin of osteosarcoma is mesenchymal and the tumor classically appears as spindle cells within an immature osteoid matrix. Biopsy methods that disrupt this organization may hinder the ability to make a diagnosis. The grade of the tumor is usually high and this is unfortunately associated with worse clinical outcomes.

While local resection is the mainstay of treatment and the resection is usually straightforward, if the tumor is located in the sternum ideally some of the sternum should be salvaged to use as an anchoring point for prosthetic support. Reconstruction can safely be undertaken immediately.

Unlike many other common cancers, neoadjuvant chemotherapy has been shown to be effective, both at preventing recurrence and at limiting the scope of initial resection. Standard chemotherapy is methotrexate, Adriamycin, and cisplatin, but experimental studies are exploring tailoring this further for specific subtypes. Complete resection of affected tissue is necessary for optimal outcomes following therapy. Depending on the adequacy of response, chemotherapy may continue after resection. Radiation is typically reserved for cases that are unresectable or failed resection.

Recurrence can be either local or metastatic, and thorough physical exam as well as high clinical suspicion are essential when monitoring during follow up.

Ewing's Sarcoma

Ewing's sarcoma represents one of the most common chest wall tumors in young adults, and it is the most common chest wall tumor in the pediatric population. Ewing's sarcoma of the chest wall may present with pathologic fracture, pain, swelling or fever and systemic complaints. Pathologic fracture associated with chest wall tumors is less common than with the extremities, but there is more incidental diagnosis due to the increased frequency of routine chest imaging.

Characteristically, Ewing's sarcoma presents on radiograph as a mass with bony destruction. CT imaging affords greater visualization of the extent of disease process and can identify those instances where the bony involvement of the tumor is rather small. As the tumor grows, appearance on CT should mature from homogeneous to heterogeneous. Classically, the tumor also has an onion skin appearance, though the absence of this does not rule out Ewing's sarcoma as a diagnosis. MRI may help with evaluating for further local spread or identifying small metastasis.

Ewing's sarcoma is a result of a chromosome 22 translocation. Histologically, the small round cells of this tumor will stain for cytoplasmic glycogen, which can be used to differentiate this appearance from other tumors. Open biopsy provides superior results to core needle, but imaging may be descriptive enough to proceed with resection without a formal diagnosis if the lesion is easily accessible.

Margin-free resection is critical for favorable clinical outcomes. Chemotherapy is usually indicated after surgery, with a typical drug regimen of vincristine, actinomycin and cyclophosphamide, interspersed with ifosfamide and etoposide. Radiation is usually offered if surgical resection is not feasible or to irradiate residual tumor. Resection should be reconsidered if nonsurgical therapy shrinks a tumor to the extent it is resectable, assuming there is no growth of the disease epidemically. Reconstruction, if required, should be conducted at time of resection. Even with adequate resection and adjuvant therapy, recurrences are not unusual, so close follow up is required.

OTHER TISSUES OF ORIGIN

Benign Localized Solitary Fibrous Tumor

Solitary fibrous tumors are rare, usually benign tumors that arise from the mesenchymal layer of the parietal pleural. These localized tumors derive from the submesothelial layer. They differ from diffuse pleural neoplasms (mesothelioma), which originate from the mesothelial layer and are associated with asbestos exposure. The majority of patients with solitary fibrous tumors are asymptomatic and diagnosed incidentally on pulmonary imaging. Patients may rarely present with a paraneoplastic syndrome, most commonly hypoglycemia from tumor production of insulin-like growth factor II.

Radiologically guided biopsy may be inaccurate, as the tumor is poorly organized with spindle cells of indistinct borders interminglely situated throughout collagen and extracellular matrix, with mixed hypo- and hypercellular regions. Necrosis is most common in larger tumors and increasing tumor size is associated with the rare malignancy. An MRI may provide additional information about invasion into surrounding structures but will not usually aid with diagnosis. There are several promising diagnostic biomarkers, and presence of CD34 on staining is the most widely accepted.

Complete surgical resection is the mainstay of treatment. Lobectomy should be performed for pulmonary involvement since preoperative determination of malignancy may be imprecise. Adequate surgical resection is the most important prognostic factor, and all involved surrounding tissues should be removed. If complete resection is impossible, partial resection may be indicated for symptom management. Nonsurgical approaches should be reserved only for patients who cannot tolerate resection.

Schwannoma

Chest wall schwannomas typically arise from intercostal nerves and are most prevalent in the mediastinum. Specifically, schwannomas originate in Schwann cells, perineural cells, important for peripheral nerve support. This benign lesion is rarely encountered but can easily be misconstrued for a malignant lesion. Patients are usually asymptomatic but may develop paresthesia or other compressive symptoms as the lesion grows.

Schwannomas can be appreciated on CT imaging, but evaluating the tumor on CT images alone can be quite challenging. MRI affords superior diagnostic accuracy and can show heterogeneity, with a multicolor hyperintense appearance as the nerve tissue stands out from surrounding muscle, bone, and soft tissue. Ultrasound also has a role in diagnosis as sonographic characteristics can be used to differentiate between nerve sheath tumors. Grossly, these tumors are encapsulated and present as lobular growths along the nerve. On histology, schwannomas are divided into type 1 and type 2, with type 1 presenting with typical high cellularity and abutting Verocay bodies, while type 2 represents a degeneration of these typical features.

Surgical resection is indicated for all symptomatic lesions, but degeneration into malignant disease is exceedingly rare. If resection is complete, local recurrence is unusual, but follow up is warranted for those with underlying genetic disorder like neurofibromatosis.

Cavernous Hemangioma

Cavernous hemangiomas are benign lesions that rarely present in the chest wall. These congenital vascular malformations develop over the first decades of life and are sometimes confused as malignancies. The location of cavernous hemangiomas may vary from superficial to deep and some may invade muscles or bony structures of the chest wall, presenting as lytic lesions.

The radiographic test of choice for evaluating these lesions is an MRI scan. Characteristically there are internal T1 foci of hyperintensity with T2 shortening around the periphery with a heterogeneous appearance. The lesion should be without mass effect, unless there is surrounding hemorrhage. CT scans may help identify the presence of a lesion, but it is inferior to MRI when assessing the lesion's impact on surrounding structures. Excisional biopsy is superior as incisional or needle biopsy can carry the risk of severe bleeding due to the vascular nature of the lesion.

Surgical excision is usually performed when the diagnosis is unclear or the lesion is invading into adjacent structures. Total resection is indicated to eliminate recurrence and prevent bleeding.

Alternatives to surgical excision include observation and vascular embolization. Growth of the vascular malformation can occur after embolization, close follow up is required if this modality is used, especially if the cavernous hemangioma presents with osteolytic damage as this process can progress.

Lymphoma

Primary lymphoma of the chest wall is relatively rare. However, there is an increased incidence in patients with chronic pyothorax, resulting in pyothorax associated lymphoma (PAL). When PAL presents, they are most commonly Hodgkin's or large B cell lymphoma.

Diagnosis is preferably accomplished with a tissue biopsy as complete excision is usually unnecessary. The rare instances where resection would be indicated are in cases where a mass effect of the tumor caused a life threatening complication.

Chemotherapy is the first line therapy for lymphoma regardless of whether they are chest wall primary or metastatic. CyCOP (cyclophosphamide, doxorubicin, vincristine, prednisone) is the most common regimen, though targeted immunotherapies are increasingly being used. Radiation may be indicated depending on tumor histology of the primary lymphoma.

Solitary Myeloma (Plasmacytoma)

Solitary plasmacytoma is a rare presentation of myeloma accounting for approximately 5% of malignant plasma cell tumors. Plasmacytomas of the bone preferentially occur in the vertebrae, while soft tissue plasmacytomas are most commonly localized to the head or neck. The hallmark of this disease is that unlike multiple myeloma, which may present with multiple lytic lesions, there is an absence of disseminated disease. Resection should be considered, as conversion to multiple myeloma can occur in up to 70% of cases. Plasma cytomas of the bone are more likely to progress than plasmacytomas of soft tissue and should be treated more aggressively.

SURGICAL APPROACH

There is great variety in the pathology and treatment of chest wall tumors, which makes summarizing an operative approach challenging (Box 2). However, there remain some universal guidelines that can be used to approach these patients in a safe and systematic manner.

BOX 2 Operative Chest Wall Localization Techniques

Preoperative Techniques

Correct patient positioning
Interventional radiology guided coil or wire
Methylene blue
Radiolabeled marker

Intraoperative Techniques

Manual rib counting
Angiocath placement and intraoperative imaging
Thoracoscopic entry and chest wall evaluation

Like all operative candidates, the patient must be able to safely tolerate the surgery. This threshold is understandably lower for malignant tumors, but in many cases, there is sufficient time to optimize a patient prior to surgery and a delay of even several months can be clinically appropriate.

Preoperative planning is the key to success. Complex patients or rare presentations should be ideally discussed at a multidisciplinary board and images should be reviewed with a radiologist if the surgeon does not frequently read chest wall masses. Preoperative interventional radiology guided tumor marking should be strongly considered, and while there are no specific guidelines, coils, wire localization, methylene blue, and radiographic marking with fiducial markers are all appropriate modalities to use. If a physical marker like coils or wire is used, care should be taken to position the patient identically to how they will be positioned in the operating room, as there are reports of wires moving after placement due to patient positioning.

Operative approach is most appropriately done following the experience of the surgeon, as there is no empirically superior method. The primary challenge operatively is usually identification of the lesion. Some lesions are pathologically easily identifiable, while others closely mimic surrounding tissue or are not palpable, such as lytic bone lesions. Preoperative imaging should be easily available in the operating room for reference. If any doubt exists to the location of the lesion, positioning should be reviewed. Manual counting of the ribs is the simplest means of approaching this problem, but surgeons interested in a more thorough approach may wish to place an angiocatheter needle in the suspected lesion and perform an intraoperative radiograph to confirm that the operative site matches the site on preoperative imaging. Additionally, a thoracoscopic approach may be used to verify the location of resection, either through rib counting or direct visualization. The key point is despite the apparent simplicity of removing the correct rib, medical errors do occur. A wise surgeon will be vigilant against this possibility (Box 2; Fig. 1).

The degree of resection can vary dramatically by tumor type. In some cases, diagnosis is unclear at the time of surgery, so an overly wide resection would be inappropriate. In these cases, marking the location of the lesion is important so it may be necessary to return to obtain appropriate margins or guide adjuvant treatment.

Complex or recurrent disease should be referred to a specialist if possible. While chemotherapy and radiation are usually of secondary importance when compared to primary surgical resection, for recurrent disease additional modalities need to be considered. Metastatic disease will obviously require systemic therapy, but even locally recurrent disease merits the consideration of additional therapies. Given the limitations of available data on primary chest wall tumors, these treatments may be experimental in nature and should be considered with the help of a specialist or tertiary care center.

If a large resection is required, reconstruction may be required with either tissue flap, prosthetic or both. If the complexity of the

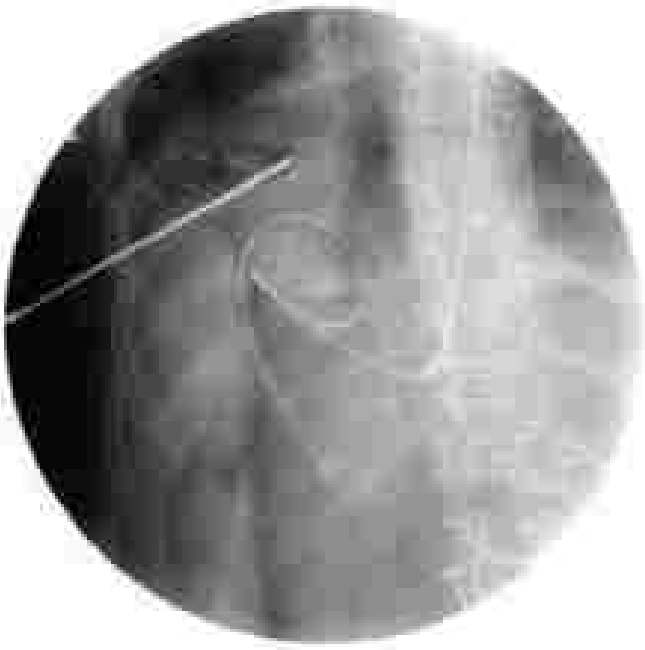

FIG. 2 Intraoperative imaging can reduce the risk of wrong site and other surgical errors. Imaging with a radiopaque overlay such as a *star* ripe or sophisticated can confirm that the suspicious lesion is located in the correct anatomic position based on preoperative imaging and exam. This is especially relevant for tumors with similar appearance to the surrounding tissue.

reconstruction is significant, a co-operative case with a reconstructive specialist is advisable. Given the nature of the chest wall as mechanically essential for respiration, immediate reconstruction is warranted even in the face of malignancy. Fortunately, the safety of this approach has also been demonstrated, as tumor seeding of these reconstructions is relatively rare. While an in-depth discussion of reconstruction goes beyond this chapter, commonly used muscle flaps are pectoralis major, latissimus dorsi, serratus anterior, rectus abdominis, and the external oblique. Choice depends on degree and location of resection, as all flaps are limited to the anatomic area they can safely cover. Prosthetics are usually mesh or titanium overlays, with some supporting that titanium may afford better chest wall mechanics for larger defects.

CONCLUSION

Primary chest wall tumors owe much of their clinical challenge to their rarity and heterogeneous nature. Despite this, with appropriate resection and use of adjuvant therapies, outcomes can be favorable. This chapter provides guidance to the general approach to these patients and how to safely manage their care. A surgeon treating these tumors will need to be familiar with both diagnosis and therapy to navigate this complex and evolving field.

MEDIASTINAL MASSES

Hugh G. Auchincloss, MD, MPH, and Elon Jan J. Mathisen, MD

The mediastinum refers to the compartment bounded by the thoracic inlet superiorly, the diaphragm inferiorly, the paravertebral sulci posteriorly, and the pleura laterally. Historically it has been subdivided into an anterior, middle or visceral, and posterior compartment. These divisions remain useful for surgeons. The differential diagnosis for a mass arising within the mediastinum is largely a function of its location. The anterior compartment—located between the pericardium and the sternum and below the innominate vessels—contains thymic, lymphoid, and residual embryonic tissue and is a common site for an ectopic parathyroid or hyperplastic thyroid gland. Primary tumors may arise from any of these structures. The visceral compartment includes all the structures of the pericardium, heart, great vessels, airway, and esophagus. Masses in this compartment are often lymphoid in origin or may represent a cyst arising from one of the native structures. The paravertebral sulci makes up the posterior compartment and includes the sympathetic chain and roots of the intercostal nerves. Neurogenic tumors dominate the differential diagnosis within this compartment.

Mediastinal masses are uncommon. They make up only 3% of thoracic tumors. The age distribution is bimodal; however, the differential diagnosis differs between the adult and pediatric populations. Over 50% of masses arising in adults are thymic or lymphatic in origin, whereas most masses in children are neurogenic. Accordingly, three-quarters of tumors in adults are in the anterior mediastinum, whereas more than half of masses in children are in the posterior mediastinum. The origin of a mediastinal mass may therefore be suspected on the basis of its location and the age of the patient. Imaging characteristics alone are often diagnostic, and serologic study is helpful for certain tumors. Tissue biopsy remains the gold standard. Most masses are treated with surgical resection or chemotherapy.

DIAGNOSIS

Clinical Presentation

Most mediastinal masses grow slowly and are asymptomatic. They appear as incidental findings on imaging studies. Over 30% or so of masses that cause symptoms do so by compression or invasion of surrounding structures. Rarely, they present with a paraneoplastic phenomenon such as myasthenia gravis, Cushing syndrome, multiphasic hypercalcemia, or hypercalcitriolism. The most common symptoms are respiratory: nonproductive cough, dyspnea, and pleuritic pain. Compression of the superior vena cava (SVC) may result in the classic syndrome of facial edema and orthopnea (Fig. 1). Compression of

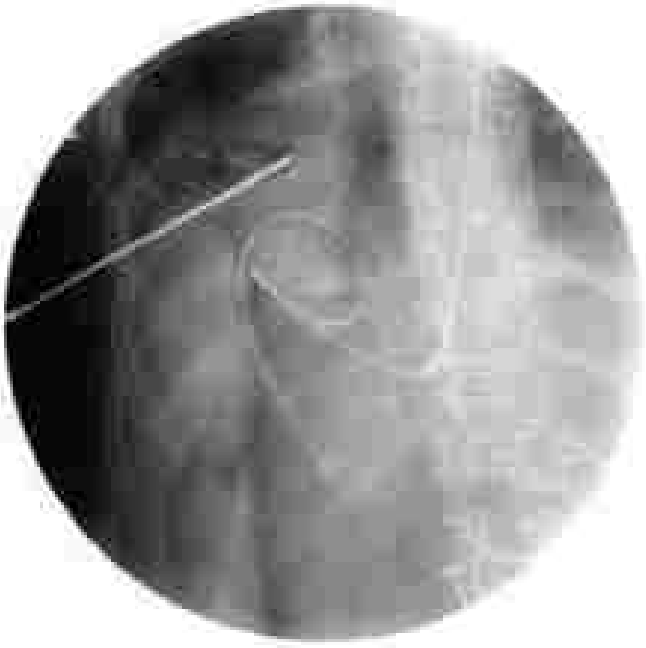

FIG. 2 Intraoperative imaging can reduce the risk of wrong site and other surgical errors. Imaging with a radiopaque overlay such as a forceps or sigmoidoscope can confirm that the suspicious lesion is located in the correct anatomic position based on preoperative imaging and exam. This is especially relevant for tumors with similar appearance to the surrounding tissue.

reconstruction is significant, a co-operative case with a reconstructive specialist is advisable. Given the nature of the chest wall as mechanically essential for respiration, immediate reconstruction is warranted even in the face of malignancy. Fortunately, the safety of this approach has also been demonstrated, as tumor seeding of these reconstructions is relatively rare. While an in-depth discussion of reconstruction goes beyond this chapter, commonly used muscle flaps are pectoralis major, latissimus dorsi, serratus anterior, rectus abdominis, and the external oblique. Choice depends on degree and location of resection, as all flaps are limited to the anatomic area they can safely cover. Prosthetics are usually mesh or titanium overlays, with some supporting that titanium may afford better chest wall mechanics for larger defects.

CONCLUSION

Primary chest wall tumors owe much of their clinical challenge to their rarity and heterogeneous nature. Despite this, with appropriate resection and use of adjuvant therapies, outcomes can be favorable. This chapter provides guidance to the general approach to these patients and how to safely manage their care. A surgeon treating these tumors will need to be familiar with both diagnosis and therapy to navigate the complex and evolving field.

MEDIASTINAL MASSES

Hugh G. Auchincloss, MD, MPH, and Douglas J. Mathisen, MD

The mediastinum refers to the compartment bounded by the thoracic inlet superiorly, the diaphragm inferiorly, the paravertebral sulci posteriorly, and the pleura laterally. Historically it has been subdivided into an anterior, middle or visceral, and posterior compartment. These divisions remain useful for surgeons. The differential diagnosis for a mass arising within the mediastinum is largely a function of its location. The anterior compartment—located between the pericardium and the sternum and below the innominate vessels—contains thymic, lymphoid, and residual embryonic tissue and is a common site for an ectopic parathyroid or hyperplastic thyroid gland. Primary tumors may arise from any of these structures. The visceral compartment includes all the structures of the pericardium, heart, great vessels, airway, and esophagus. Masses in this compartment are often lymphoid in origin or may represent a cyst arising from one of the native structures. The paravertebral sulci makes up the posterior compartment and includes the sympathetic chain and roots of the intercostal nerves. Neurogenic tumors dominate the differential diagnosis within this compartment.

Mediastinal masses are uncommon. They make up only 3% of thoracic tumors. The age distribution is bimodal; however, the differential diagnosis differs between the adult and pediatric populations. Over 20% of masses arising in adults are thymic or lymphatic in origin, whereas most masses in children are neurogenic. Accordingly, three-quarters of tumors in adults are in the anterior mediastinum, whereas more than half of masses in children are in the posterior mediastinum. The origin of a mediastinal mass may therefore be suspected on the basis of its location and the age of the patient. Imaging characteristics alone are often diagnostic, and serologic study is helpful for certain tumors. Tissue biopsy remains the gold standard. Most masses are treated with surgical resection or chemotherapy.

DIAGNOSIS

Clinical Presentation

Most mediastinal masses grow slowly and are asymptomatic. They appear as incidental findings on imaging studies. Over 30% or so of masses that cause symptoms do so by compression or invasion of surrounding structures. Rarely, they present with a paraneoplastic phenomenon such as myasthenia gravis, Cushing syndrome, multiphasic hypertension, or hypercalcitriolism. The most common symptoms are respiratory: nonproductive cough, dyspnea, and pleuritic pain. Compression of the superior vena cava (SVC) may result in the classic syndrome of facial edema and orthopnea (Fig. 1). Compression of

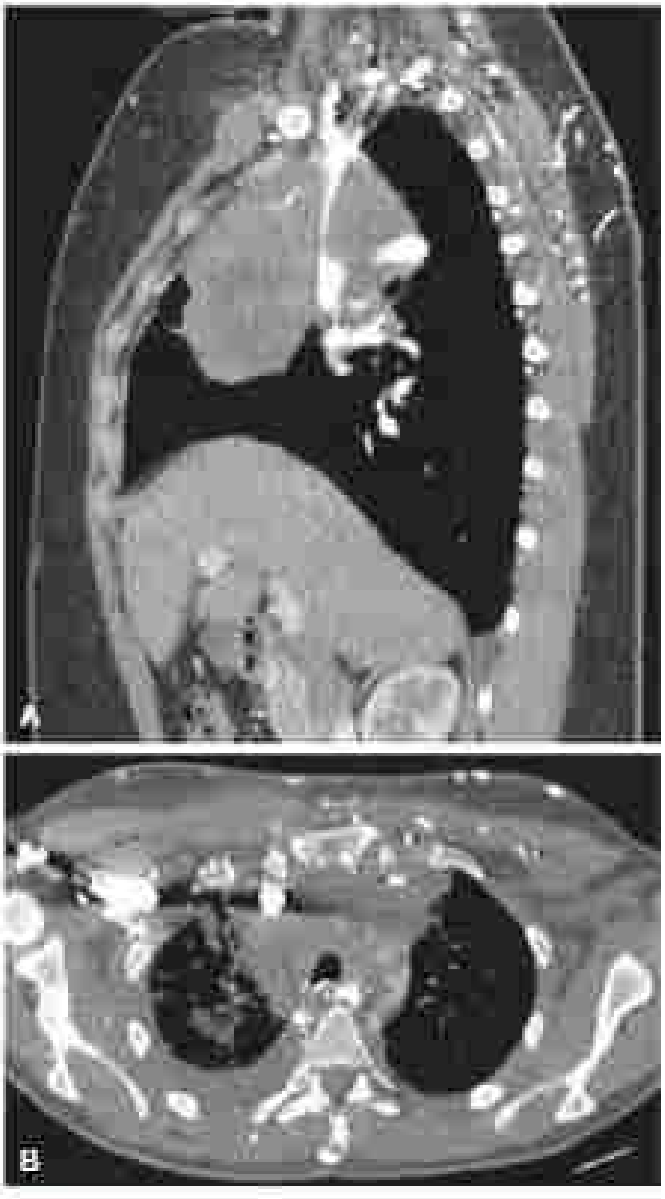

FIG. 1 Two patients with mediastinal lymphoma and superior vena cava syndrome. There are extensive venous collateral vessels in the chest wall.

the cardiac chambers is unusual, but a sympathetic pericardial effusion may produce tamponade physiology. Direct invasion of critical thoracic nerves such as the phrenic nerve, recurrent laryngeal nerve, or sympathetic trunk may result in diaphragm paralysis, hoarseness, or Horner syndrome, respectively. Duplication cysts can become superinfected and cause the patient to present with fever and malaise. Rarely these infections may present with systemic sepsis.

Imaging

Most mediastinal masses have a characteristic radiographic appearance that strongly suggests the diagnosis. Computed tomography (CT) is the primary modality for evaluating a mediastinal mass. CT demonstrates the location, size, density, and architecture of the mass. The addition of intravenous contrast helps determine the relationship between a mass and surrounding structures. Masses with neovascularity such as Castleman disease, paragangliomas, or thyroid neoplasms may demonstrate enhancement on contrast CT. Magnetic resonance imaging (MRI) is an essential adjunct to CT and has become a standard part of the workup for a mediastinal mass. MRI excels at differentiating soft tissue subtypes. A well-protocolled MRI should be able to determine whether a mass is cystic or solid and whether it invades rather than displaces surrounding soft tissue. MRI is also critical in determining whether a posterior neurogenic mass involves the spinal foramen.

Additional radiologic studies are indicated when a specific type of tumor is suspected. Positron emission tomography (PET) should be performed when thymic carcinoma is on the differential (Fig. 2). PET is also valuable when the mass is believed to be lymphoma or other lymph node disease, because it provides the best assessment of extrathoracic involvement. Other nuclear imaging studies can help localize specific tumors, including gallium citrate for neuroendocrine tumors and technetium sestamibi for parathyroid adenomas. Endobronchial ultrasonography (EBUS) and endoesophageal ultrasonography (EUS) are typically thought of in terms of their role in guiding biopsy; however, the ultrasound images from these studies may be thereafter for diagnostic, as with mediastinal cysts.

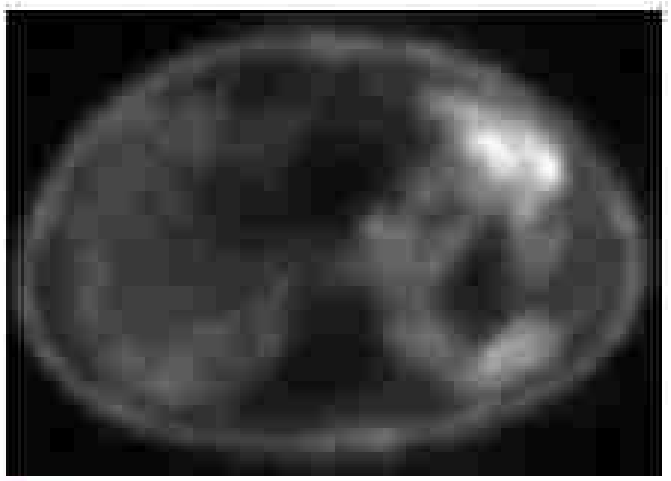

FIG. 2 A positron emission tomography scan of a patient with thymic carcinoma and extensive involvement of the left pleural space.

Serology

Certain laboratory findings provide essential diagnostic and prognostic information about a mediastinal mass, but an unfocused barrage of tests is costly and unnecessary. α-fetoprotein (AFP) and β-human chorionic gonadotropin (β-HCG) are critical to the diagnosis and management of suspected germ cell tumors. Lactate dehydrogenase (LDH), uric acid, and phosphate should be checked in patients with probable lymphoma, because treatment may induce tumor lysis syndrome. Catecholamine metabolites, adrenocorticotropic hormone levels, vasoactive intestinal polypeptide, and countless other tests are indicated only when concordant symptoms are present.

Biopsy

The role of tissue biopsy for mediastinal masses is controversial. Because many masses can be diagnosed on the basis of imaging alone and treatment is typically surgical extirpation, older thinking held that a biopsy—and the concomitant risk of seeding other structures—ought to be avoided. This is still true for small, encapsulated anterior mediastinal masses that have the classic appearance of thymoma or mature teratoma. However, a growing awareness of the benefits of induction therapy for invasive thymoma, coupled with the expanded repertoire of biopsy techniques and improved pathologic

assessment has led many surgeons to reconsider the role of biopsy for otherwise resectable mediastinal masses. At minimum, biopsy should always be performed when thymic carcinoma or lymphoma are suspected. Biopsy should be avoided for mediastinal duplication cysts, where the risk of superinfection is high. All biopsies should be undertaken with the future surgical approach in mind, especially for suspected thymoma and sarcoma where seeding is a real and costly possibility.

If a biopsy is needed, the choice is between fine needle aspiration (FNA), core needle biopsy, and surgical biopsy. The first two options can be performed via a transthoracic image guided fashion or via EBUS or EUS. FNA is sensitive for carcinoma but provides no information about the architecture of a lesion. For diagnoses where architecture is important—thymoma and lymphoma in particular—a core needle biopsy may provide that information; alternatively, a surgical biopsy may be necessary.

The choice of surgical biopsy approach depends on the location of the lesion. Cervical mediastinoscopy provides excellent access to middle mediastinal nodes and structures. For masses in the anterior mediastinum, an anterior mediastinotomy—or Chamberlain procedure—may be performed. The original description of an anterior mediastinotomy assumed the indication of staging ipsilateral pulmonary window lymph nodes for lung cancer and therefore watched sided. In practice the approach—which involves accessing the second intercostal space lateral to the sternal border while sparing the internal mammary structures, sometimes removing the third costal cartilage—can be performed on either side. It is particularly useful for patients with bulky anterior mediastinal masses and SVC syndrome who may present an anesthetic challenge. Finally, a video assisted thoracoscopic surgery (VATS) approach can be undertaken from either side and provides access to all parts of the mediastinum.

SURGICAL APPROACHES

The treatment of many mediastinal masses is complete surgical resection. The choice of surgical approach is determined by location, size, and malignant potential of the mass, and by surgeon preference.

Transcervical

A minority of anterior mediastinal masses can be approached through a transcervical approach. These include parathyroid adenomas, thyroid goiters, and benign thymic lesions like thymic hyperplasia. A collar incision is used. The platysma is divided and the strap muscles separated in the midline. A specially designed retractor is placed under the sternal notch and used to elevate the sternum. A plane is then developed above the great vessels, and the mass is removed with a combination of blunt dissection and occasional cautery. This technique spares the morbidity of a thoracic incision but has generally fallen out of favor, given the difficulty in clearing all of the anterior mediastinal contents. It has been described as an adjunct to the thoracoscopic approach to thymic tumors because of its efficacy in clearing the superior pole of the thymus.

Median Sternotomy

A median sternotomy provides access to all the structures in the anterior mediastinum and is the gold standard for resection of large or invasive anterior mediastinal tumors. An upper sternal split can be used instead of a complete sternotomy if access to only the superior anterior mediastinum is needed; alternatively, a complete sternotomy may be supplemented with an anterior thoracotomy to provide enhanced exposure to one of the pleural spaces. The chief advantage of a median sternotomy is that all of the critical structures typically involved with invasive anterior mediastinal tumors are accessible for resection and reconstruction. This includes the anterior pericardium, arch vessels, phrenic and recurrent laryngeal nerves, and SVC. Many approaches to resection and reconstruction of the SVC for mediastinal tumors have been described, including reconstruction using cardiopulmonary bypass with or without deep hypothermic circulatory arrest, placement of an extramediastinal graft of reinforced synthetic material followed by resection of the native SVC, and venoplasty with or without a shunting procedure (Fig. 2). If such a procedure is anticipated, the patient should have intravenous access established in the lower extremities, the blood pressure should be elevated, and the head of the bed should remain elevated during SVC clamping to minimize cerebral edema.

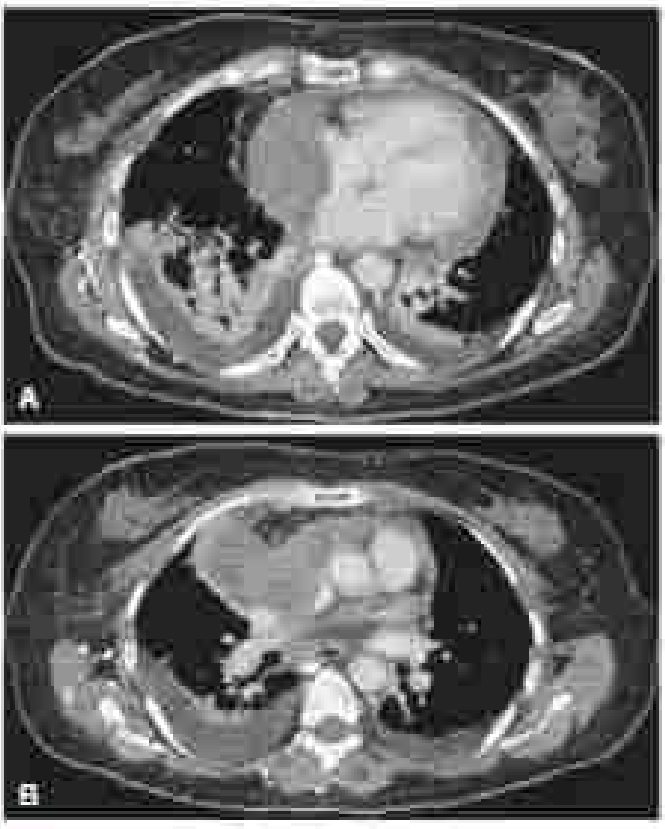

FIG. 2 A mediastinal liposarcoma with invasion into the (A) superior vena cava and (B) right atrium requiring resection and reconstruction under deep hypothermic circulatory arrest.

Thoracotomy

Mass in the middle and posterior mediastinum are amenable to a transthoracic approach. A posterolateral thoracotomy offers exposure to all the relevant hilar and posterior structures. Occasionally a partial anterior thoracosternotomy is chosen when an anterior mediastinal mass extends into the hilum. A full bilateral thoracosternotomy—clamshell incision—is required only for bulky mediastinal tumors with extension into both pleural spaces.

Minimally Invasive Approaches

Selected mediastinal tumors lend themselves well to minimally invasive surgical approaches, including transthoracic or subxiphoid VATS and robot assisted surgery. Resection of small thymomas, mediastinal cysts, and benign posterior mediastinal tumors can be performed with less morbidity than with an open approach. In many cases the improved visualization that these modalities offer leads to a more satisfying technical operation. Large, invasive, and highly malignant tumors should not be approached with these techniques because a risks compromising the oncologic outcome of the operation.

FIG. 4 Aggressive World Health Organization type B2 thymoma with involvement of the left pleural space, requiring left extrapleural pneumonectomy.

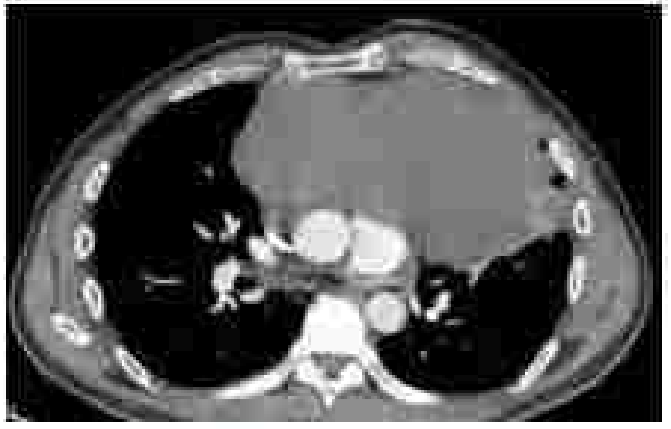

FIG. 5 Mediastinal seminoma.

ANTERIOR MEDIASTINAL MASSES

Primary Thymic Tumors

Primary tumors of the thymus include the full spectrum of thymomas, as well as neuroendocrine tumors of the thymus (sometimes called thymic carcinoids). Together these are the most common masses of the anterior mediastinum. Thymomas are classified according to either their histology using the World Health Organization (WHO) designations, or by their locoregional behavior using the Masaoka-Koga staging system. In 2016 a traditional TNM staging system was introduced that borrows heavily from Masaoka-Koga but indirectly incorporates the WHO classification system because only histologically aggressive thymomas have the propensity for nodal metastases.

Half of thymomas present with a paraneoplastic syndrome, of which myasthenia gravis is by far the most common. Red cell aplasia and hypogammaglobulinemia are also seen. The remainder present with cough or other local compressive symptoms or are discovered incidentally during routine imaging. The appearance on CT of well-defined solid or cystic soft tissue mass within the anterior mediastinum is highly suggestive of thymoma and may obviate the need for a biopsy. MRI adds clarity to the diagnosis and assesses for invasion of surrounding structures. An invasive mass should invite consideration of thymic carcinoma—WHO type C thymoma—which in turn should prompt additional workup, including PET scan, biopsy, and neoadjuvant chemoradiotherapy.

Complete surgical resection is the mainstay of treatment for thymoma and is associated with excellent long-term outcomes. Ninety percent of patients with a thymoma resected completely at an early stage are alive at 10 years. Thymic carcinomas are more aggressive and follow a course that is similar to invasive lung cancer. Complete surgical resection for thymoma may entail extensive resection of the pericardium, great vessels, and thoracic nerves, or thymoma with extensive pleural or pulmonary involvement, extrapleural pneumonectomy is sometimes performed (Fig. 4). Surgery has a role in recurrent thymoma as well. Pleural metastases are frequently managed with a combination of surgical resection and radiation.

Germ-Cell Tumors

Extragonadal germ cell tumors are comprised of three entities: mature teratomas, primary mediastinal nonseminomatous germ cell tumors (PMNSGCT) and primary mediastinal seminomatous germ cell tumors (PMSGCT). PMNSGCTs are commonly called teratomas. All arise from embryonic cells. Seminomas and PMNSGCT occur only in young men, whereas mature teratomas are seen in men and women of varying ages. Imaging and serologic studies provide initial diagnostic and prognostic information, but biopsy is usually obtained as well.

Mature teratomas are the most common germ cell tumor. They contain tissue from mesodermal, ectodermal, and endodermal cell lines. The radiographic appearance is of a heterogeneous mass often containing fluid, fat, and calcifications. AFP and β-HCG are normal. Mature teratomas are resected to prevent local compression and because there is a small incidence of immature, malignant elements being contained within otherwise mature tumors. Once resected, these tumors seldom recur.

Seminomas are slow growing tumors that rarely cause symptoms. As a result, 70% have metastasized to lymph nodes, bone, or lung at the time of presentation. Seminoma may be suspected on the basis of imaging showing a large, lobulated homogeneous lesion within the anterior mediastinum (Fig. 5). Diagnostic evaluation includes investigation for a gonadal primary, biopsy of the mediastinal lesion, and comprehensive imaging looking for other sites of disease. Laboratory studies indicate normal or mildly elevated β-HCG and normal AFP. Treatment is with systemic chemotherapy including bleomycin, etoposide, and cisplatin. Adjuvant radiation is sometimes used. Surgery has a limited role in the management of this disease. Outcomes are typically good, with survival reported to be greater than 85% at 5 years.

PMNSGCT is a more complex and varied disease than either seminoma or mature teratoma. A multimodality approach is essential to successful management. The typical presentation is of a man in the second to fourth decade life with a heterogenous anterior mediastinal mass demonstrating local invasion of surrounding structures (Fig. 6) coupled with elevation in serum β-HCG and AFP. This presentation is pathognomonic for PMNSGCT and may preclude the need for biopsy before initiation of therapy. Many patients do not have significant AFP or β-HCG elevation, though, and a biopsy is essential to differentiate seminoma from PMNSGCT. Histology shows yolk sac carcinoma, embryonal carcinoma, or choriocarcinoma. Approximately 20% of patients have metastatic disease at the time of presentation. Once the diagnosis is made, treatment begins with chemotherapy typically using bleomycin, etoposide, and cisplatin but with the availability of bleomycin sparing regimens when pulmonary toxicity is a concern. Ideally, induction chemotherapy results in normalization of serum tumor markers and decrease in the size of the mediastinal mass. Chemotherapy is followed by surgical extirpation of the residual mass. Unlike with seminoma—where a residual mass after chemotherapy is presumed to be benign—residual viable tumor is present in 60% of postinduction resected PMNSGCT. Because residual mass may not contain viable tumor, careful judgment must be used at the time of surgery to determine whether a critical mediastinal structure ought to be resected en bloc with the mass. Pericardium is frequently resected, as are lung parenchyma, phrenic nerve, and brachiocephalic vessels. Long-term outcome is determined in large part by the presence and grade of viable tumor within the resected specimen; patients with

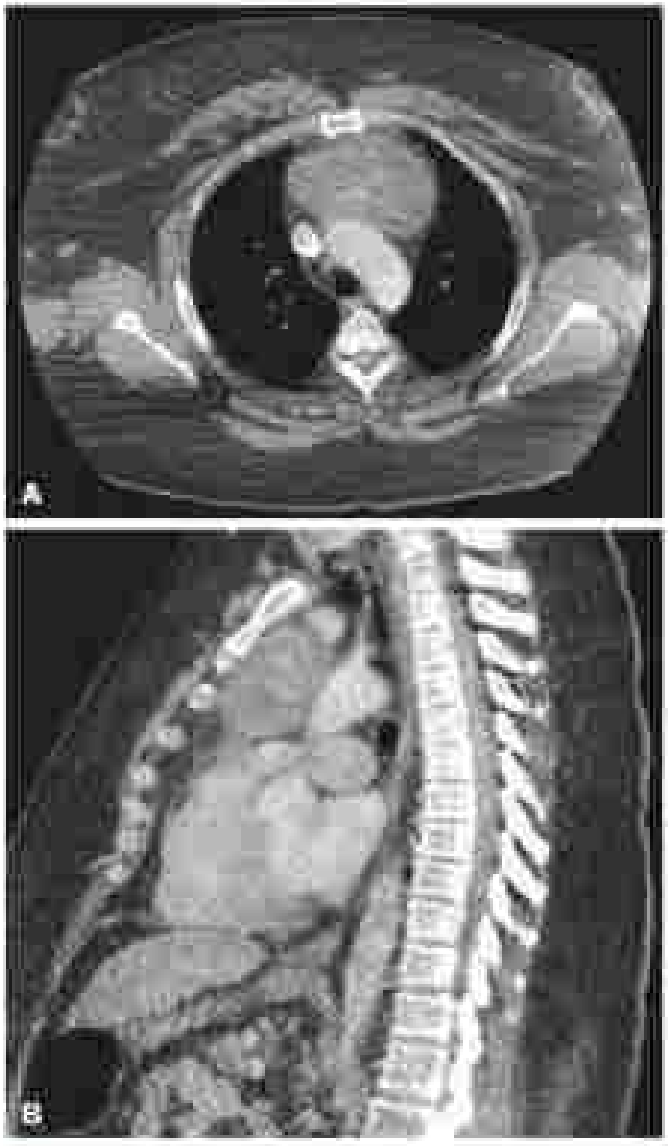

FIG. 6 Mediastinal pole tic tumor

no visible tumor can expect excellent long-term survival, whereas patients with persistent germ cell tumor elements have a poor prognosis. Patients with residual mature teratoma have intermediate outcomes. Surgery plays an important role in recurrent PMNSGCT as well. Rising serum markers and a new mass in a patient after successful resection for PMNSGCT should prompt consideration for resection.

Lymphoma

Lymphomas comprise 20% of anterior mediastinal masses and represent a heterogeneous collection of malignancies derived from lymphocytes. Broadly, they are divided into Hodgkin's and non-Hodgkin's lymphomas and staged according to degree of extranodal involvement and presence of disease on one or both sides of the diaphragm. The role of the surgeon in diagnostic surgical resection has no role in the management of lymphoma. Response to chemotherapy can initially be dramatic resulting in destruction of tumor architecture and tumor lysis syndrome. It is therefore important to obtain a biopsy before initiating treatment and to monitor uric acid, LDH, and renal function subsequently. Surgical biopsy is sometimes required when tumor architecture is crucial to a diagnosis; however, core needle biopsy targeted to PET/CT avid areas of the tumor is often sufficient.

Thyroid and Parathyroid Lesions

The thyroid and parathyroid glands coincident to the anterior cervical trachea despite distinct embryologic origins. Both can be found within the anterior mediastinum. For the thyroid gland this typically means direct extension of a thyroid goiter into the superior anterior mediastinum. Such goiters are no more likely to contain malignant cells than cervical goiters. Surgical extirpation can usually be accomplished through a low collar incision. An upper sternal split may facilitate approach to deeper lesions. A full sternotomy is unnecessary. Rarely, purely ectopic thyroid tissue can be found within the anterior mediastinum. As with a lingular thyroid, this may represent the patient's only source of thyroid function.

Parathyroid glands share an embryological origin with the thymus and therefore are frequently found in an ectopic location within the anterior mediastinum. These ectopic—or occasionally supernumerary—parathyroid glands may become hyperfunctioning adenomas resulting in symptomatic hypercalcemia. Treatment is surgical resection. Sestamibi scanning should be performed on all patients before exploration for parathyroid adenoma, given the relative frequency of a mediastinal location. Intraoperative confirmation of a 50% drop in parathyroid hormone ensures successful resection.

MIDDLE MEDIASTINAL MASSES

Mediastinal Lymphadenopathy

A mass arising in the middle mediastinum is most commonly lymphadenopathy arising from the paratracheal and subcarinal lymph nodes. The differential diagnosis for mediastinal lymphadenopathy includes infectious, inflammatory, or neoplastic lesions. Infectious lesions include bacterial, mycobacterial, and fungal diseases. The most common inflammatory lesion is sarcoidosis. Regionally advanced lung cancer, other metastatic cancer, and lymphoma may all be seen within mediastinal lymph nodes. All of these entities may demonstrate FDG uptake on PET scan. The diagnosis is made with biopsy. Cervical mediastinoscopy remains a safe and effective technique for taking large samples of mediastinal lymph nodes for culture, fungal and gram stain, flow cytometry, and pathology. EBUS or EUS with FNA or core biopsy may be sufficient to make a diagnosis—particularly when metastatic lung cancer is suspected—and is less invasive than mediastinoscopy.

Mediastinal Cysts

Cysts of bronchogenic, esophageal, or pericardial origin may arise within the mediastinum. Bronchogenic cysts are the most common—accounting for 60% of mediastinal cysts—followed by esophageal cysts. Together, these two entities may be called foregut duplication cysts. CT demonstrates a smooth-walled soft tissue density with non-enhancing—and contrast. MRI is more sensitive and specific for making the diagnosis. Increasingly, EBUS and EUS can be used to make a diagnosis. Needle biopsy is discouraged because of the risk of superinfection. These cysts are often incidental findings but may come to attention because of local compressive symptoms. Symptoms are a clear indication for surgical resection. Otherwise, the theoretical risk of malignant transformation justifies resection in patients for whom operative risk is low. Minimally invasive approaches are often used with good effect. Pericardial cysts are not believed to have any risk of malignant transformation and are resected when they are symptomatic or enlarging (Fig. 7).

Castleman's disease

Castleman's disease—or angiofollicular hyperplasia—is a rare lymphoproliferative disease that can occur anywhere in the body but favors locations adjacent to the central airways in the middle mediastinum. The classic appearance is of a solitary mass with or without associated lymphadenopathy that demonstrates intense enhancement on CT with the addition of intravenous contrast. Most patients are

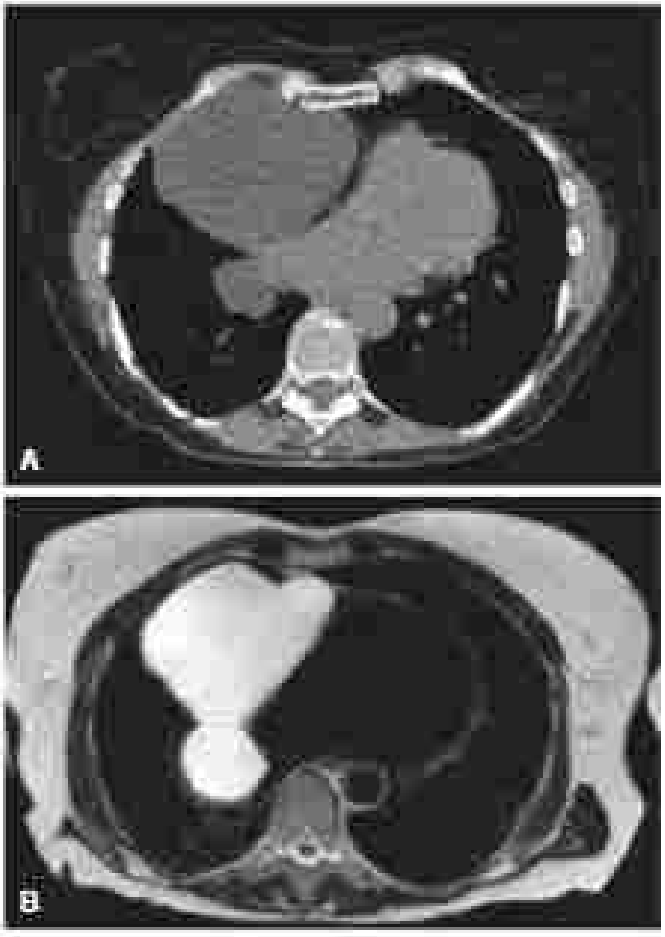

FIG. 7 Paraaortal cyst in the classic location in the right paravertebrum sulcus.

young adults and are symptom free. Immunocompromised patients are at increased risk. Treatment of unicentric disease is surgical resection. Multicentric disease is treated with a combination of B cell targeted immunotherapy and radiation.

POSTERIOR MEDIASTINAL MASSES

Most tumors in the posterior mediastinum are neurogenic in origin. This includes tumors arising from nerve sheath elements, ganglion cells, and paraganglion cells. In adults these tumors are frequently asymptomatic and benign. This is not true for children, in whom posterior mediastinal tumors are both more common and more likely to demonstrate malignant behavior. In addition to CT, MRI is indicated to determine whether the mass involves the neural foramen. In the case of dumbbell tumors, this involvement may be quite extensive and mandate the involvement of a neurosurgeon during surgical resection (Fig. 8). Biopsy is not needed before resection for most posterior masses.

Schwannomas and Neurofibromas

Tumors of nerve sheath origin make up 90% of adult neurogenic tumors. They are commonly benign, but resection is indicated to exclude malignant schwannoma or neurofibrosarcoma, both of which are highly aggressive.

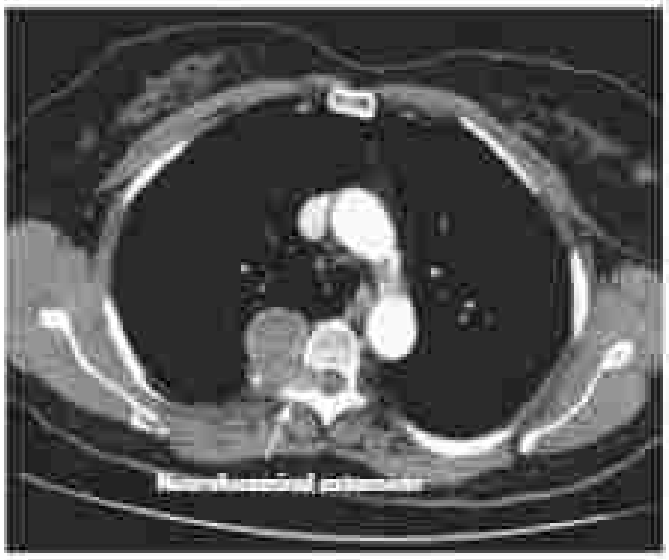

FIG. 8 Posterior mediastinal schwannoma with invasion into the neural foramen (i.e., "dumbbell" tumor).

Ganglion Cell Tumors

Ganglion cell tumors arise from the sympathetic ganglia. Ganglioneuromas are three common in adults and are benign. Ganglioneuroblastomas and neuroblastomas both arise in young children and follow an aggressive, malignant course. Any of these lesions may secrete vasoactive intestinal peptide or catecholamines. Cushing's syndrome is described. The treatment of all ganglion cell tumors is resection with adjuvant therapy reserved for those with malignant properties.

Paraganglion Cell Tumors

Mediastinal pheochromocytomas may arise from paraganglion cells and produce the classic symptoms of malignant hypertension. This symptomatology, coupled with elevated urine catecholamine metabolites and a posterior mediastinal mass that brightly enhances on contrast CT, makes the diagnosis. Biopsy should be avoided. Surgical resection is preceded by alpha and beta blockade to prevent sympathetic crisis.

Primary Tumors of the Thymus

Cameron D. Wright, MD

Thymic tumors are rare, with an estimated incidence of 0.15 cases per 100,000 person years. They are, however, the most common tumor of the anterior mediastinum seen in adults. Usually the diagnosis can be made by careful review of a contrast enhanced chest computed tomography (CT) scan. The differential diagnosis includes more importantly lymphomas, as well as germ cell tumors such as teratomas, seminomas, and nonseminomatous germ cell cancers, retrosternal goiters, thymic cysts, thymic hyperplasia, and other uncommon tumors. Most thymomas are asymptomatic. Thymomas can be associated with several autoimmune syndromes, most importantly myasthenia gravis but also red cell aplasia, hypogammaglobulinemia and other neurologic paraneoplastic syndromes. Symptoms referable to a thymoma may include substernal chest discomfort, dyspnea, cough, and the superior vena cava syndrome. If germ cell tumors are thought to be in the differential diagnosis, then an α-fetoprotein and β-human chorionic gonadotropin level should be sent. If myasthenia gravis is present, typically a myasthenia antibody panel that includes acetylcholine receptor antibodies is obtained.

IMAGING

Obtaining a CT scan with intravenous (IV) contrast is the most important step in initial decision making in assessing a possible thymic tumor. IV contrast is necessary to highlight the mediastinum and great vessels and to look for enhancement in the lesion. Thymic tumors almost always occur in the distribution of the normal thymus in the upper substernal area, but as they enlarge they often will point to one of the pleural spaces. Thymomas are typically relatively rounded masses, are often relatively homogeneous, and, although they may abut important structures, typically the edges are relatively sharp if they are not invasive (Figs. 1 and 2). Invasive thymomas or thymic carcinomas typically look different and have many characteristics, suggesting a more advanced tumor. Invasive thymic tumors typically have fuzzy edge characteristics suggesting invasion of adjacent structures such as the lung. Other features that would suggest invasion are encasement or intravascular extension into a great vessel, areas of hemorrhage or necrosis within the tumor itself, evidence of phrenic nerve invasion with an elevated hemidiaphragm, and pleural implants (Fig. 3). Although thymomas rarely metastasize to lymph nodes, thymic carcinomas not uncommonly have lymph node metastases (Fig. 4).

Thymic cysts are typically very rounded or teardrop shaped, quite homogeneous, and sharply demarcated. They have low attenuation when Hounsfield units are measured. Thymic cysts are often difficult to differentiate from small thymomas. A mediastinal magnetic resonance (MR) examination protocoled for the thymus can be very helpful to make a definitive diagnosis of a benign thymic cyst that exhibits thin walls with no internal septation and no mural nodularity.

Thymic hyperplasia is often confused by inexperienced observers as representing a possible anterior mediastinal mass, most likely a thymoma. Typically thymic hyperplasia presents as a bilobed enlargement of the normal thymus with a homogeneous appearance and sharp demarcation with normal structures (Fig. 5). Mediastinal MR examination again can be quite helpful with a thymic protocol.

Lymphomas are typically multilobular with surrounding lymphadenopathy and obvious invasive edge characteristics (Fig. 6). There are often areas of necrosis or hemorrhage within the tumor mass. There may be an associated pleural effusion or pericardial effusion. There is often encasement or primary phenomenon of the great vessels and tracheobronchial tree with lymphoma.

PATHOLOGY

A simple pathologic classification of thymic tumors defines three types of thymic tumors: thymomas that have no atypia or mitotic activity, atypical thymomas or well differentiated thymic carcinomas, which have atypical thymic epithelial cells, and thymic carcinomas with clearly malignant cytologic features and aggressive behavior. The World Health Organization classification is used by most pathology departments and is seen in Table 1. In general type A and AB tumors tend to be early stage tumors, are more commonly associated with myasthenia gravis, and generally have an excellent prognosis. Type B tumors are typically more invasive and have an intermediate prognosis. Type C tumors are locally quite aggressive, can metastasize to lymph nodes, as well as distant sites, and have a guarded prognosis. There is independent prognostic value in the World Health Organization (WHO) classification system, but the most important factors in determining prognosis are a complete resection and the stage of the tumor. Core needle biopsy is often not informative of the exact WHO type of thymoma. A rare thymic malignancy is a thymic carcinoid tumor also known as a neuroendocrine tumor of the thymus. These tend to be very locally aggressive and have a poor prognosis.

STAGING OF THYMIC TUMORS

For many years the Masaoka Koga staging system was used for thymomas (Table 2). The basis of the staging system was the degree of invasion of the tumor into adjacent structures and whether there were any metastases. The advantages of this system are that it is relatively intuitive and simple, and there is a long history with its use. More recently the eighth edition of the American Joint Committee on Cancer (AJCC) cancer staging manual was published and defines a tumor, node, metastasis staging system for thymomas and thymic carcinomas (Tables 3 and 4). This system at first glance is more complex, but most patients are either stage I or stage II, so it is not unduly cumbersome. Survival for early stage thymomas is excellent. The 5-year survival rate using the Masaoka staging system is as follows: stage I, 96%; stage II, 80%; stage III, 65%; stage IVa, 50%; and stage IVb, less than 50%.

TREATMENT PRINCIPLES

The optimal treatment for all thymic tumors is a complete R0 surgical resection. A complete resection is the most important independent predictor of disease free recurrence after resection, followed by stage and WHO histology. In general the entire thymus should be resected in continuity with the tumor along with attached mediastinal fat (typically from phrenic nerve to phrenic nerve and from diaphragm to just above the innominate vein). Resection of local invasion of attached structures such as the pericardium, pleura, ipsilateral phrenic nerve, innominate vein, and superior vena cava is typically performed to accomplish R0 resection. Areas where the surgeon knows there is a close margin should be identified with a metal clip to aid in postoperative adjuvant radiation therapy.

Patients who present with clearly encapsulated tumors or tumors that have apparent minimal invasion of easily resectable structures generally have immediate resection without an attempt at preoperative tissue diagnosis or any form of induction therapy. Patients with clear cut, locally advanced, difficult to resect disease are most commonly referred for CT guided core needle biopsy, to be followed by induction chemotherapy. Resection is then performed after restaging confirms the absence of progressive disease. Patients who

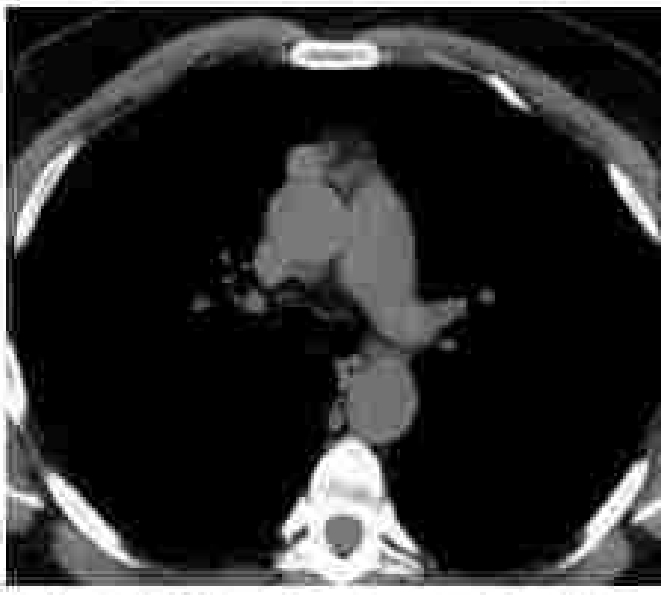

FIG. 1. Small 1.5-cm encapsulated early-stage thymoma adjacent to the aorta amenable to video-assisted thoracic surgery resection.

FIG. 2. A 10-cm thymoma, heterogeneous with murky borders and extensive lung abutment. This was removed by sternotomy and was a Masaoka stage II thymoma.

present with de novo pleural metastases are problematic, and there is no uniform approach. Upfront resection of both the tumor and pleural implants is acceptable, as well as induction chemotherapy first, followed by a resection. Lymph node dissection is unnecessary in patients with thymomas but is important and should be performed in patients with thymic carcinomas and nonmyasthenic thymic tumors. When patients have myasthenia gravis, it is important to work closely with a neurologist to optimally manage their myasthenia before proceeding to a resection. Patients should be very well controlled on their medical program and often need either plasmapheresis or intravenous immunoglobulin therapy for optimization before surgery.

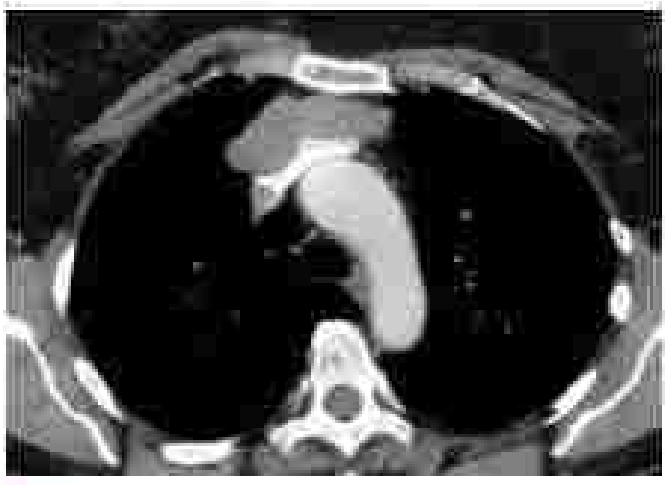

FIG. 3. Locally advanced thymoma invading the innominate vein requiring venous resection. This was a World Health Organization B3, Masaoka stage III thymoma.

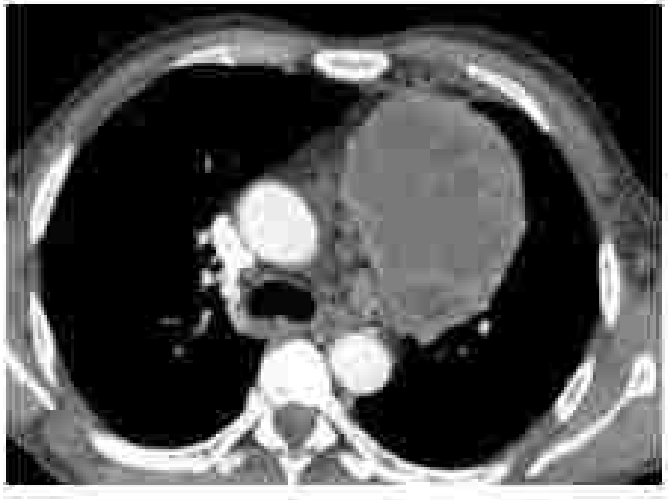

FIG. 4. Large thymic carcinoma with low-density central area (necrosis) with adjacent lymphadenopathy.

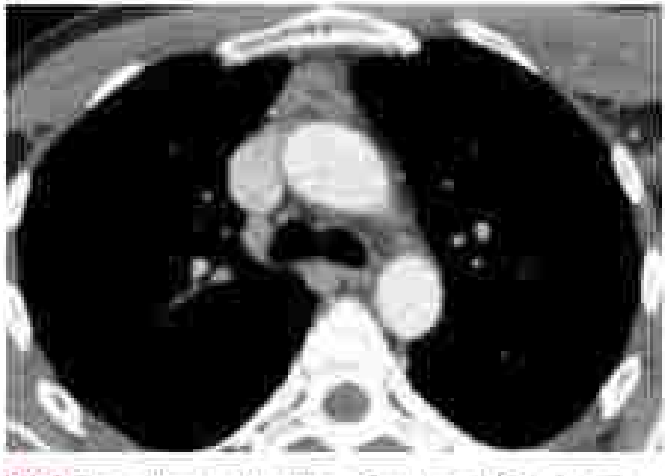

FIG. 5. Thymic hyperplasia in a symptom-free man with bilobed pleural thymus with sharp borders and no appreciable mass. The mediastinal mass mimics the normal shape of the thymus.

FIG. 1 Anterior Hodgkin's lymphoma with surrounding pathologic lymphadenopathy and encasement of the superior vena cava and brachiocephalic vein.

Table 1 Pathology of Thymic Tumors—World Health Organization Histologic Classification

Tumor Type	Diagnostic Criteria
Type A	Occurrence of bland, spindle shaped epithelial cells, paucity or absence of T cells
Type AB	Occurrence of bland, spindle shaped epithelial cells, abundance of immature T cells focally or throughout tumor
Type B	Thymus-like architecture and cytology, abundance of immature T cells, areas of medullary differentiation, paucity of polygonal or dendritic epithelial cells without clustering
Type B2	Increased numbers of single or clustered polygonal or dendritic epithelial cells intermingled with abundant immature T cells
Type B3	Sheets of polygonal slightly to moderately atypical epithelial cells; absent or rare intercellular bridges; paucity or absence of inter mingled T cells
Micronodular thymoma	Nodules of bland spindle shaped or oval epithelial cells surrounded by an epithelial cell free lymphoid stroma
Type C	Thymic carcinoma; squamous cell carcinoma, non cornified carcinoma, clear cell carcinoma, basaloid carcinoma, sarcomatoid carcinoma, anaplastic carcinoma

OPERATIVE MANAGEMENT

Thymic tumors can be removed by standard open surgery and also by minimally invasive approaches with either video assisted thoracic surgery (VATS) or robotic techniques. In general minimally invasive approaches should be reserved for small, easily removable tumors. It is very important not to violate the capsule of the thymic tumor during its removal because these tumors have a unfortunate reputation for

Table 2 Masaoka-Koga Staging System

Masaoka Stage	Diagnostic Criteria
Stage I	Macroscopically encapsulated, no microscopic invasion of the capsule
Stage II	A: Microscopic transcapsular invasion B: Macroscopic invasion into surrounding fatty tissue or grossly adherent to but not through mediastinal pleura or pericardium
Stage III	Macroscopic invasion into neighboring organs—pericardium, great vessels, lung A: Without invasion of great vessels B: With invasion of great vessels
Stage IV	A: Pleural or pericardial dissemination B: Lymphogenous or hematogenous metastases

Table 3 TNM Staging

Primary Tumor	Description
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor encapsulated or extending into the mediastinal fat, may involve the mediastinal pleura T1a: Tumor with no mediastinal pleura involvement T1b: Tumor with direct invasion of mediastinal pleura
T2	Tumor with direct invasion of the pericardium
T3	Tumor with direct invasion into any of the following: Lung, brachiocephalic vein, superior vena cava, phrenic nerve, chest wall, or extrapericardial pulmonary artery or veins
T4	Tumor with invasion into any that following: Aorta, intrapericardial pulmonary artery, myocardium, trachea, esophagus
REGIONAL LYMPH NODES	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastases to anterior lymph nodes
N2	Metastasis to deep intrathoracic or cervical lymph nodes
DISTANT METASTASIS	
M0	No pleural, pericardial, or distant metastases
M1	Pleural, pericardial, or distant metastases M1a: Separate pleural or pericardial nodule M1b: Pulmonary intraparenchymal nodule or distant organ metastases

developing pleural implants. Transcervical thymectomy is not appropriate for removal of a thymic tumor but is useful for selected patients with myasthenia gravis alone.

TRANSSTERNAL THYMECTOMY

The standard approach to most thymic tumors is by a sternotomy. Sternotomy provides excellent access to the anterior mediastinum and lower neck, and it provides reasonable access to either pleural space. Tumors that are very large and are suspected of significant involvement of lung are sometimes best approached with a hemi clamshell approach with a combination of a sternotomy and lateral thoracotomy. Except for the smallest resting thymomas, it is usually best to have the anesthesiologist place a double-lumen endotracheal tube to allow one-lung ventilation during surgery to facilitate dissection of the thymic tumor away from the pericardium, phrenic nerve, and lung. It is often helpful to use a table-mounted internal thoracic artery retractor to elevate the sternum away from the mediastinum and the thymic tumor to allow dissection away from the anterior chest wall with a safe margin. If the thymic tumor appears to involve the mediastinal pleura on preoperative imaging, opening of that pleural space is recommended both to ensure wide resection of any possible involvement of mediastinal pleura and also to inspect the pleural space for a possible drop metastasis. If pleural implants are found, they should be resected. Thymectomy should be performed in addition to resection of the thymic tumor, as well as all surrounding readily removable mediastinal fat.

The dissection can be started in the neck, with each cervical tongue being isolated, separated from the inferior portion of the thyroid, and brought down to the manubrium with level. Alternatively one may start at the diaphragm level and dissect the mediastinal fat superiorly until the area of the tumor is reached. Once the area of the tumor is isolated, it is important to ascertain to what the tumor might be adherent and plan on resecting all easily removable adherent marginal tissues. One should not hesitate to resect the underlying pericardium from the tumor to ensure that the deep margin is negative. Wedge resection of a portion of the upper lobe of the lung is frequently required. Very careful dissection around the phrenic nerve is important. If cautery must be used in this area, bipolar cautery can minimize any transmission injury to the phrenic nerve itself. Sacrifice of one phrenic nerve in an otherwise healthy person is acceptable and often necessary. Bilateral phrenic nerve resection should of course never be done. There is frequently a close margin at the phrenic nerve level, and, if there is any concern for tension to this area, it should be marked with clips to aid in postoperative adjuvant radiation therapy. Typically there are two or three veins that drain directly to the innominate vein, and these can be controlled with ties, the harmonic scalpel, or clips. If the pleural space is entered, it is typically deemed with a small suction drain. The anterior mediastinum is typically drained with a standard chest tube. The sternum is reapproximated with six parasternal wires, and then the incision is closed in layers. The specimen should be marked with sutures to orient the pathologist because these resected specimens can be quite confusing, which can lead to difficulties in making a determination about the need for postoperative radiation therapy and where any possible close margins are. Patients are extubated in the operating room and typically do not require an intensive care unit environment unless they have myasthenia gravis. Drains can usually be removed on the first postoperative day, and patients can be discharged when pain is satisfactorily controlled and the patients are independently mobile. Patients are typically followed up long term after thymoma resection with periodic contrast-enhanced CT scans, yearly for low-grade tumors and more frequently for higher-grade tumors.

MINIMALLY INVASIVE RESECTION

VATS and robotic-assisted thoracic surgery have been used for many years now for resection of thymic tumors. There are no randomized studies comparing these approaches to the open approach. Early results suggest equivalent outcomes. Retrospective studies suggest a shorter hospital stay, reduced blood loss, decreased postoperative pain, and an improved cosmetic result compared with open approaches. Although there are small series and case reports of resection of advanced thymic tumors with a minimally invasive approach, most surgeons reserve a minimally invasive approach for a clinical stage I lesion.

VATS for resection of thymic tumors can be performed on either side of the chest, and typically the laterality is chosen based on the tumor projecting into that ipsilateral pleural space. For tumors that are small and midline, most surgeons choose a right-sided approach because the confluence of the superior vena cava and innominate vein is easy to approach from the right side. A double-lumen endotracheal tube is placed, and the patient is placed in a lateral decubitus position for the typical unilateral midline thymic tumor. For larger tumors it can be helpful to place a bump underneath the operative side and prep out the contralateral side as well, which allows one to put a separate camera port on the other side to facilitate dissection on the opposite side and most importantly to avoid injury to the opposite phrenic nerve. A complete port-based approach is usually performed because that allows carbon dioxide insufflation and thus opening up the mediastinum and dissection planes for ease of dissection and resection. Typically 3 ports are placed, one for the camera and two to triangulate a grasping instrument and a harmonic scalpel superior to the camera port.

Typically the dissection is started inferiorly with dissecting the mediastinal fat and eventually the thymus off the pericardium to where the tumor is present. Dissection is then done laterally around the phrenic nerve, carefully preserving it and then skeletonizing the anterior surface of the superior vena cava, which leads one to the innominate vein. Small thymic vein branches are sealed with the energy device, and the two cervical tongues of the thymus can be easily dissected into the neck and then their attachments to the thyroid divided again with the energy device. The pericardium should be entered electively if the tumor extensively abuts the pericardium at its deep margin. The specimen should be placed in a bag and then removed through an enlarged access port to prevent spillage of any thymic tumor cells. A small silicone drain is typically left in the pleural space and removed usually the next morning. Most patients can be discharged the morning after surgery, and recovery is typically quick.

ADJUVANT RADIATION

Thymic tumors are generally radiosensitive, and radiation may help reduce local recurrence after resection of advanced thymic tumors. All patients who have incomplete resections should have adjuvant radiation therapy, and close consultation with the radiation

oncologist is important to inform them of the sites of greatest risk for recurrence. Typically all patients with thymic carcinomas are referred for postoperative radiation therapy, given their very high chance for local recurrence. Completely resected Masaoka stage I tumors do not require radiation therapy. Adjuvant radiation in Masaoka stage II or III tumors that are completely resected is controversial, and there is substantial institutional variation in referral of such patients. The recurrence pattern of thymomas is that more than 75% of all recurrences occur in the pleural space such that mediastinal radiation has a questionable role in preventing most recurrences.

Management of Tracheal Stenosis

Shahrzad Oyetunji, MD, MPH, and Douglas E. Wood, MD, FRCSEd

Disorders involving the airway are relatively uncommon, and most thoracic surgeons will see only the occasional patient with tracheal disease. However, both benign and malignant obstructions of the central airway cause significant morbidity and mortality. Successful management may correct or palliate impending suffocation, dyspnea, and obstructive pneumonitis. Tracheal resection and reconstruction may preclude the need for a lifelong tracheostomy and allow preservation of laryngeal function in patients with benign strictures and provide treatment with curative intent for airway tumors.

INDICATIONS FOR TRACHEAL RESECTION

The most common indication for tracheal resection and reconstruction is prolonged intubation or post tracheostomy stenosis. Cuff injuries occur because of prolonged pressure with resultant full-thickness necrosis of the tracheal cartilage. This produces circumferential scar contracture, with symptoms typically developing 3 to 6 weeks after extubation. Stomal stenosis after tracheostomy occurs when there is a large anterior tracheal defect from the tracheostomy stoma with subsequent anterior scar contracture when the patient is decannulated. This cause of tracheal stenosis typically results in an A frame appearance, with anterior narrowing and relatively normal posterior membranous wall.

Other causes of benign tracheal stenosis are trauma, inflammatory, or idiopathic. Neck or chest injury or operative trauma to the airway may sometimes be undetected at the time of injury but present later because of secondary tracheal narrowing. Severe tracheal infections and a number of collagen vascular diseases may result in acute and chronic inflammation with secondary tracheal stenosis. Idiopathic tracheal stenosis occurs most commonly in women from the third to sixth decade of life, most commonly located at the level of the cricoid cartilage with varying degrees of subglottic involvement.

Primary tracheal tumors are another indication for tracheal resection. Tumors of the trachea are extremely uncommon and represent only 0.2% of all malignancies of the respiratory tract. Squamous cell carcinoma and adenoid cystic carcinoma are the two most common tracheal tumors and account for more than two-thirds of all primary tumors of the upper airway. After squamous cell carcinoma and adenoid cystic carcinoma, the most common tracheal tumors are carcinoid and mucoepidermoid tumors. However, there is a wide variety of rare tumors with varying degrees of malignancy from both epithelial and mesenchymal origins. The prognosis for untreated tracheal tumors is poor even with benign tumors, because of the risk of airway obstruction. Tumors of the trachea should be considered for resection if they can be resected with less than half of the longitudinal length of the trachea and do not have unresectable local extension into surrounding structures. Although adjacent tumors with airway invasion are almost never considered for tracheal resection, one exception is locally advanced thyroid cancer. Progression of disease in the trachea can produce significant symptoms and be life limiting. These patients should be considered for tracheal resection, even in the presence of metastatic disease, because of the long natural history, and the severe impact of tracheal progression.

Tracheal reconstructive procedures are frequently regarded as complex operations with high morbidity and mortality rates. However, excellent results can be obtained in appropriately selected patients with a combination of well planned anesthetic airway management, meticulous operative technique, and careful postoperative care.

PREOPERATIVE ASSESSMENT

Symptoms of central airway obstruction can be surprisingly insidious and may often go undiagnosed for a long period of time. Dyspnea on exertion is the primary symptom in patients with a significant tracheal stenosis, but these patients may also present with wheezing, stridor, cough, difficulty clearing secretions, recurrent respiratory infections, or hemoptysis. Patients with tracheal or bronchial tumors may also present with any of the previous symptoms, but in addition may have hemoptysis. An assessment of the severity of symptoms and their time course is useful for establishing the cause and the acuity of the airway pathology. A 50% reduction in the cross-sectional area of the trachea usually results in dyspnea only with significant exertion, whereas narrowing of the lumen to less than 25% of the cross-sectional area usually produces dyspnea and stridor at rest. Patients

oncologist is important to inform them of the sites of greatest risk for recurrence. Typically all patients with thymic carcinomas are referred for postoperative radiation therapy, given their very high chance for local recurrence. Completely resected Masaoka stage I tumors do not require radiation therapy. PREOPERATIVE ASSESSMENT

Symptoms of central airway obstruction can be surprisingly insidious and may often go undiagnosed for a long period of time. Dyspnea on exertion is the primary symptom in patients with a significant tracheal stenosis, but these patients may also present with wheezing, stridor, cough, difficulty clearing secretions, recurrent respiratory infections, or hemoptysis. Patients with tracheal or bronchial tumors may also present with any of the previous symptoms, but in addition may have hemoptysis. An assessment of the severity of symptoms and their time course is useful for establishing the cause and the acuity of the airway pathology. A 50% reduction in the cross-sectional area of the trachea usually results in dyspnea only with significant exertion, whereas narrowing of the lumen to less than 25% of the cross-sectional area usually produces dyspnea and stridor at rest. Patients

may be reasonably compensated in spite of significant stenosis but can have acute life threatening deterioration with a minor amount of airway edema or secretions. A high index of suspicion in the presence of these symptoms is critical to the diagnosis of central airway pathology.

A careful history and physical examination is performed with a focus on prior trauma, respiratory illness with prolonged intubation, or prior tracheostomy. On physical examination patients will usually have wheezing or stridor if they have significant airflow obstruction. Other signs that may be present include prolonged inspiration or expiration, use of accessory muscles, or signs of retained secretions or obstructive pneumonia.

Spirometry and flow volume loops are neither sensitive nor specific when diagnosing central airway disease. They yield little in the decision making management of these patients and should not sway a practitioner to delay or proceed with treatment.

Further radiologic evaluation of the patient should be performed for patients who do not present in respiratory distress. Plain posteroanterior and lateral chest radiography often will provide evidence of proximal airway narrowing. Thin-cut computed tomography (CT) scans also provide more anatomic definition of the location, degree, and extent of airway stenosis, which is sometimes easily portrayed in a three dimensional reconstruction. CT also provides information on relation of pathology to surrounding structures that can be important for the management of both benign and malignant lesions.

Bronchoscopic evaluation is the modality for establishing the diagnosis and defining the anatomy for subsequent therapeutic decisions. Bronchoscopy should be done by the primary surgeon, and observations of others is inadequate to assess the suitability of a patient for a possible tracheal reconstruction. Although flexible bronchoscopy is generally effective for defining the airway anatomy and performing initial endoscopic palliation, surgeons evaluating tracheal stenosis should be facile with rigid bronchoscopy, and the rigid bronchoscopes should be available as needed for all bronchoscopy procedures. Rigid bronchoscopy provides the best means for airway control and emergency airway palliation and should be available as a routine management option for physicians evaluating airway obstruction. In cases of critical tracheal obstruction or bronchial obstruction, rigid bronchoscopy with dilation, core out of tumor, laser, or stenting provides effective temporary palliation, allowing completion of the medical workup and elective timing of surgical intervention. The anatomic location, proximal and distal extent, and diameter of the stenosis is carefully examined and measured to plan the surgical approach, as well as the quality of the airway and the presence of any ongoing associated inflammation.

ANESTHESIA AND AIRWAY MANAGEMENT

The surgeon should be available during induction of anesthesia to help ensure control of the airway. Postintubation tracheal stenoses are typically amenable to dilation if needed for successful passage of an endotracheal tube. This can be accomplished with a rigid bronchoscope or a balloontipped catheter, and a variety of sizes should be available in anticipation of this. Post tracheostomy stomal stenoses are not amenable to dilation because of the normal structure of the membranous wall, although the airway easily expands with the dilation, it just as readily recoils back to the preexistent diameter when the dilating force is removed. However, this also means that a symptomatic stomal stenosis can nearly always be intubated without difficulty, even with a normal size endotracheal tube.

Anesthesia for tracheal resection is best administered as mixed inhalational and intravenous anesthetic while maintaining spontaneous ventilation until the airway is established. Short acting anesthetic agents are preferred with the goal of extubating the patient in the operating room at the end of the operative procedure.

It is important to discuss the ventilation strategy and coordination of endotracheal tube exchange with the anesthesiologist in advance of the operation and again during the preoperative briefing. Before the division of the trachea, the endotracheal tube is withdrawn into the proximal trachea and once the trachea is divided, the distal trachea is intubated across the surgical field with a sterile endobronchial tube and circuit. The endobronchial tube can be safely removed intermittently for brief periods of apnea to permit precise placement of sutures during reconstruction. Once the anastomotic sutures are placed, the oral endotracheal tube is then advanced under direct vision past the incomplete anastomosis and secured. Then the anastomotic sutures are tied, and the procedure is completed.

The goal of extubating the patient in the operating room at the conclusion of the case allows for assessment of the adequacy and stability of the reconstructed airway in a controlled environment with the surgeon and anesthesiologist present thereby avoiding unnecessary prolongation of ventilation, as well as endotracheal tube trauma to the reconstructed airway. A "protective tracheostomy" should be avoided in most cases because it is rarely needed, creates a point of airway fixation that may increase tension on the anastomosis, and provides a source of wound contamination that may increase the risk of anastomotic dehiscence. For patients with a very high laryngotracheal anastomosis and postoperative vocal cord edema that threatens airway stability, a tracheostomy may be useful, placed well below the anastomosis, or an alternative is to consider a short period of oral intubation until the edema partially resolves.

SURGICAL TECHNIQUE FOR TRACHEAL RESECTION

Tracheal resection techniques have evolved over the past four decades. Initially, safe length of tracheal resection was limited to 2 cm. Pioneered by Grillo and others, tracheal resection and reconstruction was shown to be safe up to lengths of 3 to 4 cm. This is due to experience with tracheal resection technique, and development of proximal and distal tracheal mobilization to allow for tension free reconstruction. Furthermore, sulpluth- and carinal resection techniques have been developed for more proximal and distal tumors, respectively.

For benign tracheal lesions, most can be resected and primarily reconstructed if they involve less than half of the tracheal length. The primary contraindications for tracheal reconstruction include the need for continued mechanical ventilation, a lesion that cannot be completely excised and primarily reconstructed (approximately half of the trachea), active infection or inflammatory lesion, or stenosis from an uncontrolled systemic disorder such as Wegener's granulomatosis or sarcoidosis.

Despite being a major operation, tracheal resection and reconstruction are usually physiologically trivial, with minimal pain, minor fluid shifts, little blood loss, and stable hemodynamics, so that even significant comorbidities are not usually contraindications for surgery. Tracheal resection and reconstruction is a major undertaking, however, requiring experience with complex perioperative airway management, judgment regarding the extent of resection, and meticulous attention to the technical details of airway reconstruction. It is obvious that technical or judgment failures are potentially life threatening. Success with the primary attempt at reconstruction is critical because there are no prosthetic substitutes for the trachea, which limits the extent of airway resection.

Most benign stenoses are approached through a neck incision and rarely require thoracotomy. Principals of reconstruction include resection to normal airway, minimal dissection beyond the segment to be resected to avoid devascularization, and primary reconstruction without anastomotic tension, using a variety of standard and extended mobilization techniques. In some cases, proximal tracheal stenosis may extend into the subglottis, larynx, requiring resection of the anterior cricoid cartilage and laryngotracheal reconstruction. Management of tracheal stenosis by tracheal resection and

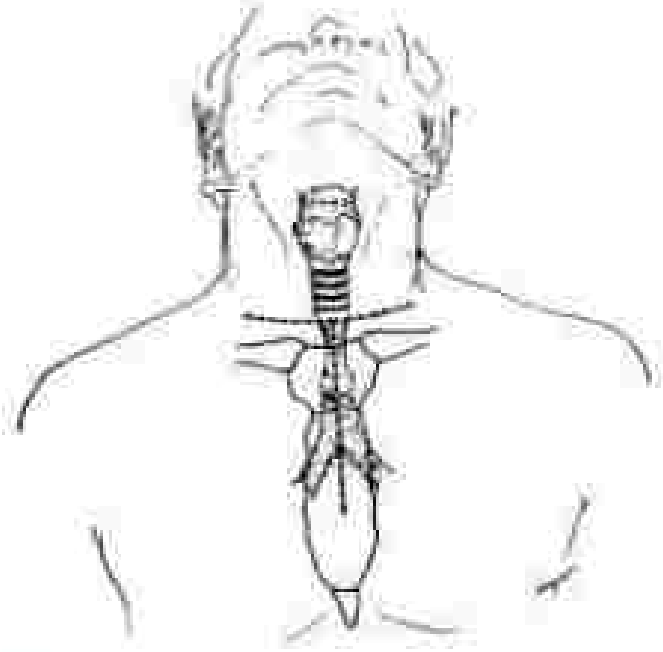

FIG. 1 Collar incision with T extension if needed for additional exposure. [This is described in] Ogura JH, Fuller DB, Calcaterra TC, Hyde GL. Management of the larynx and hypopharynx. 2nd ed. Philadelphia: WB Saunders; 1983.

reconstruction produces reliable and durable results with low morbidity and mortality rates.

For lesions in the upper two thirds of the trachea, the patient is placed supine on the operating table with a roll underneath the shoulders to extend the neck. The head is then moved to a beach chair position, with the feet flexed at the hips and the torso raised 30 degrees. A collar incision is typically used, however, for lesions that extend too caudal to be accessible through a collar incision, the exposure can be significantly increased by making a T incision in which the vertical arm extends caudal to a point 2 cm below the sternal angle (Fig. 1).

For the most common cervical approach, subplatysmal flaps are raised to the thyroid cartilage superiorly and the sternal notch inferiorly. The strap muscles are not divided but are reflected laterally to expose the anterior trachea from the cricoid to the thoracic inlet, dividing the isthmus of the thyroid gland if needed.

Tracheal reconstruction requires a clear understanding of tracheal blood supply to perform adequate airway mobilization without unnecessary devascularization of the trachea. Tracheal blood supply is segmental, and the lateral tracheal blood supply must be preserved to avoid anastomotic complications or the potential for downstream ischemic necrosis of the residual trachea. Mobilization of the trachea should be limited to the involved area and the proximal and distal tracheal margins skeletonized to the extent needed to complete the anastomosis, usually 5 to 7 mm. The lateral dissection is performed directly on the trachea wall to avoid injury to the recurrent laryngeal nerves, esophagus, and innominate artery. In general, it is safest to follow this technique rather than identifying the recurrent laryngeal nerves individually, although this may be necessary when doing more extensive radial dissections in cases of airway tumor.

To achieve a tension free anastomosis, tracheal release maneuvers are critically important. Dissection of the avascular pretracheal plane as described above and neck flexion are two tracheal release maneuvers that are simple and effective and should be performed routinely for all tracheal resections.

Dissection of the avascular pretracheal plane should be performed routinely early in the dissection because it also helps with surgical exposure. From a cervical approach, this is similar to development of the plane for mediastinoscopy; the pretracheal fascia is incised, and blunt digital dissection over the anterior surface of the trachea is performed down to the carina and mainstem bronchi. The smallest zoscope and mediastinoscope dissector can be used to ensure complete dissection of this plane and allow an extension of the dissection over each mainstem bronchi beyond what can be reached with digital dissection alone. Neck flexion up to 30 degrees is simple and effective in further decreasing anastomotic tension and is usually well tolerated by the patient. If needed, further neck flexion beyond 30 degrees may permit resection of an additional 1 to 1.5 cm of trachea, however, this degree of flexion will likely be uncomfortable for the patient to maintain in the postoperative period. These two maneuvers (pretracheal dissection and neck flexion) provide assurance of a tension-free anastomosis in nearly all short-segment tracheal resections and are the only airway release maneuvers required in more than 90% of patients.

Once the tracheal mobilization and dissection is completed, the endotracheal tube is withdrawn into the proximal trachea and the trachea is divided. The division of the trachea should be performed sharply and perpendicular to the axis of the airway. The distal trachea is then intubated across the surgical field with a sterile endobronchial tube and circuit. The endobronchial tube can be safely removed intermittently for brief periods of apnea to permit precise placement of sutures during reconstruction.

The anastomosis is performed and is end first by placing traction sutures using 2-0 absorbable braided suture in the mid-lateral portion of each airway approximately one or two tracheal rings back from the cut edge of the trachea; a total of four traction stitches are placed, two in the proximal trachea and two in the distal trachea. If the tracheal circumference is considered as a clock face, with the mid anterior trachea at 12 o'clock, these full thickness lateral traction sutures are placed at 3 and 9 o'clock, respectively. The first stitch for anastomosis is placed at the midline posteriorly (6 o'clock) using 4-0 absorbable braided interrupted stitches. The sutures are placed in a manner such that the knots will be on the outside. Subsequent sutures are placed approximately 4 mm from the cut ends, generally ignoring the tracheal rings, but ensuring a healthy, full thickness bite that incorporates the tracheal mucosa. Posteriorly, it is important to hold the placed sutures out for each subsequent suture placement to prevent suture entrapment when these are tied in reverse order. Using an open anastomotic technique, placing all sutures before pulling the anastomosis together provides several advantages. First, it allows very accurate suture placement and progressive correction of any size discrepancy. Second, it avoids tension on the anastomosis during suture placement and allows maximum exposure because the neck can stay extended during suture placement. The sutures are placed circumferentially, from posterior to anterior in four quadrants: 6 to 3 o'clock, 6 to 9 o'clock, and then 3 to 12 o'clock and 9 to 12 o'clock, respectively. Meticulous attention is necessary, and systematic approach is needed to keep all the stitches in order on the surgical field; this can be achieved by individually placing each suture on a separate clamp and lining the clamps up in order. Once all of the sutures are placed, the oral endotracheal tube is advanced through the anastomosis under direct vision. The shoulder roll is removed and the neck flexed forward by the anesthesiologist, approximating the proximal and distal tracheal ends to allow a tension free anastomosis. The head flexion is not simply an elevation of the head, as for intubation, but rather an actual rotation of the head forward, bringing the chin down toward the manubrium. The lateral traction sutures are tied, and each anastomotic suture is then tied in the reverse order of placement to avoid entanglement of the sutures (Fig. 2).

The neck is maintained in gentle flexion during the initial postoperative period to prevent tension on the anastomosis. This is achieved by use of a guardian suture placed just posterior to the tip of the chin and deep within the presternal soft tissue at the level of the sternal manubrial junction. This suture is typically left in place for 7 days after operation, and it is an effective reminder for the patient during sleep or other unconscious movement to prevent neck extension beyond the degree determined at time of surgery.

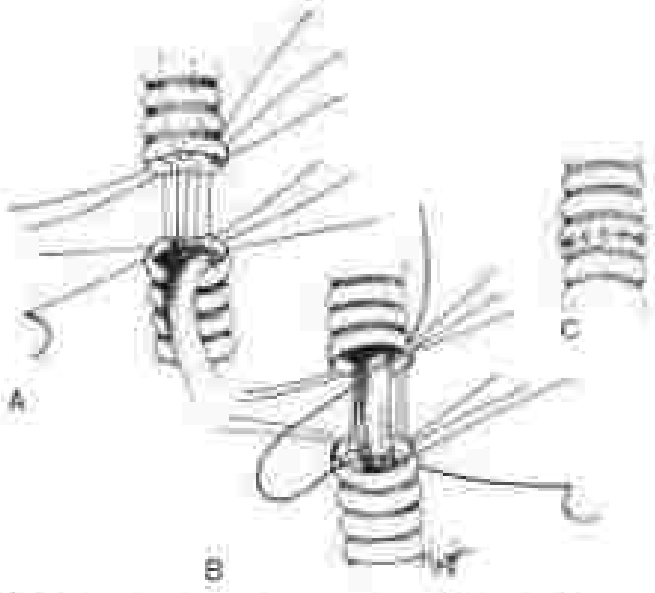

FIG. 2 Tracheal resection and reconstruction. (A) Endotracheal tube withdrawn into the proximal airway and sterile ventilatory tubing placed in distal airway; (B) placement of laryngeal anastomic sutures and replacement of endotracheal tube; (C) completed tracheal anastomosis. [From Mathisen DJ: Surgery of the trachea. In Iglesias Cort Pedro S (ed): ... p. 215.]

The goal of tracheal resection and reconstruction is for the patient to be extubated in the operating room. If the patient requires mechanical ventilation after surgery, usually due to postoperative laryngeal edema, a small, uncuffed endotracheal tube is placed with the plan to return to the operating room after 24 to 48 hours for an attempt at extubation. Failure to extubate should prompt a small tracheostomy placed two tracheal rings distal to the anastomosis. Alternatively, if the surgeon judges that timely extubation is unlikely, a tracheostomy may be placed in this location at the time of initial surgery.

SPECIAL CONSIDERATIONS

If the innominate artery is adjacent to the completed tracheal anastomosis, a strap muscle flap should be interposed between the artery and the tracheal anastomosis at the completion of reconstruction. For lesions that are too far below the sternum to be accessible through a collar incision, the exposure can be increased by making a T incision to which the vertical arm extends downward to a point 4 cm below the sternal angle. The manubrium is divided at the sternomanubrial junction and separated with a pediatric chest spreader. The upper sternal division provides access to the lower trachea; exposure is not further augmented by a complete sternotomy because of the tracheal extension behind the great vessels and heart. However, in certain circumstances for exposure of the distal tracheal or carina, a sternotomy can be performed and the distal airway exposed through a transpericardial approach, reflecting the ascending aorta to the left, the superior vena cava to the right, and opening the posterior pericardium just above the right main pulmonary artery. However, in general, the distal trachea and carina are best exposed by a right posterolateral thoracotomy, entering in the fourth or fifth interspace.

Laryngeal and hilar release maneuvers can be performed if additional mobilization is required to achieve a tension-free anastomosis. As discussed above, pretracheal dissection and neck flexion should be a routine part of every tracheal resection and provide adequate mobilization in the vast majority of cases. When mobilization is required to the proximal trachea, a suprahyoid laryngeal release can produce 1.5 to 2 cm of additional tracheal length. For distal tracheal and carinal lesions, a hilar release provides the same degree of mobility to the distal airway. The suprahyoid release involves division of the suprahyoid laryngeal respiratory attachments: the stylohyoid, mylohyoid, geniohyoid, genioglossus muscles and division of the hyoid bone anterior to the digastric muscle attachments bilaterally. The major complication of both maneuvers is a common occurrence of postoperative dysphagia and aspiration, and thus they should only be performed when routine mobilization techniques are inadequate to provide a low-tension anastomosis. Hilar release maneuvers are not often used for proximal tracheal resections as they provide little mobility to the upper cervical trachea. However, they allow for significant cephalad mobilization of the distal trachea, carina, and mainstem bronchi. This entails division of the pulmonary ligament, division of the pericardium around the inferior aspect of the inferior pulmonary vein, and division of the raphe attachment of the pericardium to the left atrium below the vein.

POSTOPERATIVE MANAGEMENT

During emergence from anesthesia, it is critical to manually support the flexed position because the guarding nature is an effective reminder when the patient is awake and alert, but before this time they may inadvertently pull against the guarding suture without recognizing painful feedback. Dry heaving and emesis are potentially catastrophic events in a patient with a fresh tracheal anastomosis given the association with sudden neck hyperextension and the potential for aspiration of gastric contents. Prevention and management of postoperative nausea, both by encouraging minimization pain management and with liberal use of antiemetics, is an important component of the postoperative management.

COMPLICATIONS OF TRACHEAL SURGERY

Meticulous operative technique in avoiding devascularization and ensuring a low-tension anastomosis are the key to minimizing complications. One of the most common complications in the immediate postoperative period is laryngeal edema which manifests within 24 to 72 hours and typically resolves without any intervention. If subcutaneous emphysema develops after surgery, this is likely an indication of anastomotic dehiscence and should be treated as a surgical emergency. The patient should be returned to the operating room immediately and the airway secured. A bronchoscopic evaluation is performed to evaluate the anastomosis. If an anastomotic dehiscence is confirmed, the patient should undergo surgical exploration with repair attempted if it is a small area of dehiscence. If the anastomotic dehiscence is not amenable to repair, the mainstay of management is a tracheostomy or a T tube, although an endobronchial stent is occasionally useful for a small dehiscence later in the postoperative course. A local muscle flap should be used to buttress the repair, tracheostomy or T tube.

RESULTS

The most in-depth analysis of patient outcomes after tracheal surgery in patients with postintubation stenosis was reported by Grillo and colleagues in a series of 503 patients who underwent tracheal resection and reconstruction from 1965 to 1992. A total of 521 resections were done, 19 for restenosis after initial repair. Lengths of resection averaged 3.5 cm and extended up to 7.5 cm. Laryngeal release maneuvers were only performed in 46 patients. Results were good to 87.5% and satisfactory in 6%; failure occurred in 6% and deaths in 2.4%. Failures were treated with tracheostomy in 31 patients, with T tubes in 7 patients, and with dilations in 3 patients. Prior resection

increased the failure rate from 2.1% to 9.7% and the mortality rate from 2.1% to 3.8%. The extent of airway resection is also a predictor of failure. A subsequent publication identified the risk factors for anastomotic failure: length greater than 4 cm, diabetes, age younger than 17 years, preoperative tracheostomy, reoperation, and laryngeal anastomosis.

Airway surgery experience, meticulous surgical technique, and attention to the limits of tracheal surgery—resect to normal airway, maintain tracheal blood supply, and use of progressive maneuvers for achieving a low-tension anastomosis—are critical for optimal results after a trachea resection and reconstruction.

Management of Acquired Esophageal Respiratory Tract Fistula

Abhi Pandia, MD, Travis Hall, MD, PhD, and Christo Ilan Morse, MD

OVERVIEW

A tracheoesophageal fistula (TEF) is defined as any communication between the respiratory tract and esophagus. In adults, benign fistulas are most commonly acquired as a result of prolonged endotracheal intubation in mechanically ventilated patients and are typically managed with surgery. Malignant fistulas are challenging to manage, and a conservative approach directed at patient palliation remains the mainstay of therapy. This chapter reviews the cause, clinical manifestation, diagnosis, approach, and surgical management of acquired TEF.

PATHOGENESIS

An acquired TEF is caused by tissue necrosis and breakdown of the respiratory tract and esophagus, resulting in an extraluminal communication most commonly located in the upper one-third of the esophagus where the membranous wall of the trachea lies adjacent to the esophagus. The cause of TEF can be broadly classified as benign or malignant. The latter is the most common cause of acquired TEF, and esophageal carcinoma, particularly squamous cell carcinoma, is responsible for approximately 70% of cases. However, direct invasion secondary to bronchogenic or thyroid carcinoma is also a possible cause, as is mediastinal lymphoma. In addition, radiation therapy itself, often necessitated by these malignancies, poses an increased risk for TEF. Benign TEF can be subclassified as iatrogenic, infectious, or traumatic based on the cause.

Iatrogenic

The most common cause of benign TEF is long-term mechanical ventilation whereby an endotracheal tube leads to pressure-mediated ischemic necrosis of the posterior membranous tracheal wall and anterior esophagus. This often leads to circumferential necrosis of the trachea and is potentiated by a rigid tube, such as a nasogastric tube or temporary probe, in the esophagus, or in patients with impaired wound healing, such as the immunocompromised, long-term steroid users, or those with poorly controlled diabetes. Because this is usually a long-term process, gross contamination of the mediastinum is less likely.

Other iatrogenic causes of TEF include injuries from intubation, tracheostomy tube placement, and esophageal or laryngeal resection. Perisurgical anastomotic leak or devascularization of the trachea from close bilateral paratracheal dissection potentiates the risk for TEF, as does dilation of benign esophageal strictures or surgical anastomoses of the trachea or esophagus. Moreover, stenting of the trachea or esophagus can result in erosion or injury, especially if placement or extraction of the stent is difficult or traumatic.

Infectious

Infectious TEF is most commonly seen with pathogens that cause granulomatous inflammation, including histoplasmosis and tuberculosis, which is both more common and severe in patients with immunodeficiency syndromes, including human immunodeficiency virus.

Traumatic

TEF acquired as a result of a traumatic process such as foreign body impaction and erosion, ingestion of caustic agents, batteries, or poisons and penetrating or blunt trauma to the neck often lead to extensive gross contamination of the mediastinum because of their acute nature. It is important to recognize that, in cases of polytrauma, the diagnosis of TEF may be delayed during the treatment of other life-threatening injuries. As is discussed in this chapter, the surgical management of traumatic TEF may therefore follow an alternate algorithm.

CLINICAL FEATURES

Despite the broad spectrum of causes, the clinical features of acquired TEF in adults are similar and represent the sequelae of an abnormal connection between the upper respiratory and gastrointestinal tracts. Patients generally present with chronic cough, often exacerbated by oral intake, and with expectoration of food. Secondary to recurrent aspiration across the TEF, they often develop recurrent bronchopulmonary infections, which may manifest as hemoptysis, fevers, or frank and life-threatening pneumonia or mediastinitis, the latter is more likely in an acutely acquired TEF. Notably, TEF caused by malignancy often becomes apparent after chemotherapy or radiotherapy treatment of the primary tumor.

increased the failure rate from 2.1% to 9.7% and the mortality rate from 2.1% to 3.8%. The extent of airway resection is also a predictor of failure. A subsequent publication identified the risk factors for anastomotic failure: length greater than 4 cm, diabetes, age younger than 17 years, preoperative tracheostomy, reoperation, and laryngeal anastomosis.

Management of Acquired Esophageal Respiratory Tract Fistula

Nikhil Panda, MD, Travis Hall, MD, PhD, and Christopher R. Morse, MD

OVERVIEW

A tracheoesophageal fistula (TEF) is defined as any communication between the respiratory tract and esophagus. In adults, benign fistulas are most commonly acquired as a result of prolonged endotracheal intubation in mechanically ventilated patients and are typically managed with surgery. Malignant fistulas are challenging to manage, and a conservative approach directed at palliative palliation remains the mainstay of therapy. This chapter reviews the cause, clinical manifestation, diagnosis, approach, and surgical management of acquired TEF.

PATHOGENESIS

An acquired TEF is caused by tissue necrosis and breakdown of the respiratory tract and esophagus, resulting in an extraluminal communication most commonly located in the upper one-third of the esophagus where the membranous wall of the trachea lies adjacent to the esophagus. The cause of TEF can be broadly classified as benign or malignant. The latter is the most common cause of acquired TEF, and esophageal carcinoma, particularly squamous cell carcinoma, is responsible for approximately 70% of cases. However, direct invasion secondary to bronchogenic or thyroid carcinoma is also a possible cause, as is mediastinal lymphoma. In addition, radiation therapy itself, often necessitated by these malignancies, poses an increased risk for TEF. Benign TEF can be subclassified as iatrogenic, infectious, or traumatic based on the cause.

Iatrogenic

The most common cause of benign TEF is long-term mechanical ventilation whereby an endotracheal tube leads to pressure-mediated ischemic necrosis of the posterior membranous tracheal wall and anterior esophagus. This often leads to circumferential necrosis of the trachea and is potentiated by a rigid tube, such as a nasogastric tube or temporary probe, in the esophagus, or in patients with impaired wound healing, such as the immunocompromised, long-term steroid users, or those with poorly controlled diabetes. Because this is usually a long-term process, gross contamination of the mediastinum is less likely.

Other iatrogenic causes of TEF include injuries from intubation, tracheostomy tube placement, and esophageal or laryngeal resection. Perisurgical anastomotic leak or devascularization of the trachea from close bilateral paratracheal dissection potentiates the risk for TEF, as does dilation of benign esophageal strictures or surgical anastomoses of the trachea or esophagus. Moreover, stenting of the trachea or esophagus can result in erosion or injury, especially if placement or extraction of the stent is difficult or traumatic.

Infectious

Infectious TEF is most commonly seen with pathogens that cause granulomatous inflammation, including histoplasmosis and tuberculosis, which is both more common and severe in patients with immunodeficiency syndromes, including human immunodeficiency virus.

Traumatic

TEF acquired as a result of a traumatic process such as foreign body impaction and erosion, ingestion of caustic agents, batteries, or poisons and penetrating or blunt trauma to the neck often lead to extensive gross contamination of the mediastinum because of their acute nature. It is important to recognize that, in cases of polytrauma, the diagnosis of TEF may be delayed during the treatment of other life-threatening injuries. As is discussed in this chapter, the surgical management of traumatic TEF may therefore follow an alternate algorithm.

CLINICAL FEATURES

Despite the broad spectrum of causes, the clinical features of acquired TEF in adults are similar and represent the sequelae of an abnormal connection between the upper respiratory and gastrointestinal tracts. Patients generally present with chronic cough, often exacerbated by oral intake, and with expectoration of food. Secondary to recurrent aspiration across the TEF, they often develop recurrent bronchopulmonary infections, which may manifest as hemoptysis, fevers, or frank and life-threatening pneumonia or mediastinitis, the latter is more likely in an acutely acquired TEF. Notably, TEF caused by malignancy often becomes apparent after chemotherapy or radiotherapy treatment of the primary tumor.

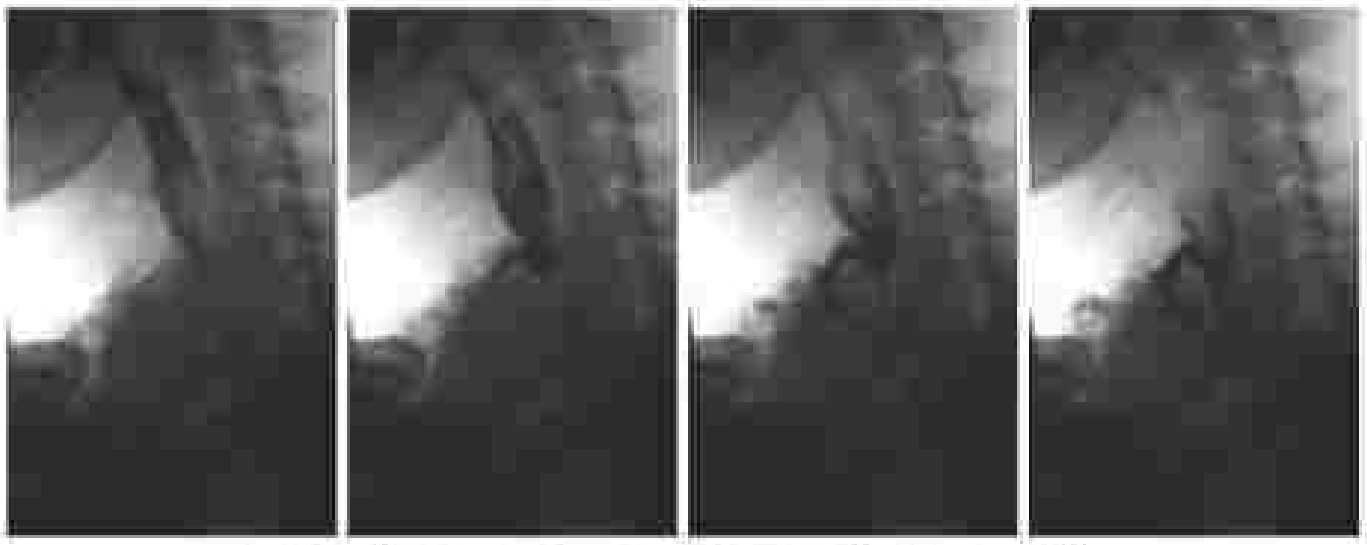

FIG. 1 Barium contrast esophagram showing fistulous communication between esophagus and airway.

In the mechanically ventilated patient, signs suggestive of TEF include inadequate return of tidal volumes, often in the setting of gastric abdominal distension on physical examination or a large gastric bubble on abdominal imaging. Additional clues include increased secretions, aspiration of tube feeds from the airway on manual suction, difficulty maintaining seal with the cuff of the endotracheal tube, or persistent sepsis, pneumonia, or pulmonary infiltrates not attributable to other causes.

DIAGNOSIS

In patients with a symptom complex suspicious for TEF, diagnostic workup begins with chest radiographs, which may reveal sequelae of a TEF, including aspiration pneumonitis or a dilated stomach and distal esophagus in patients on gastric pressure ventilation. In patients with recurrent aspiration pneumonitis, swallow evaluation may be beneficial to rule out oropharyngeal dysphagia as a cause. Small fistulas (<1 cm) are difficult to diagnose and are best detected with barium swallow using dilute barium (Fig. 1). Large fistulas are best diagnosed with bronchoscopy and esophagoscopy. Bronchoscopy is essential to locate the fistula and to perform a mucosal survey. Rigid bronchoscopy allows for complete inspection of the airway, including careful measurements such as fistula size and distance between the fistula and the vocal cords proximally, as well as the carina distally. Bronchoscopy also provides the opportunity for biopsy if malignancy is suspected and cultures to guide antibiotic therapy if necessary. Although esophagoscopy is less reliable in the diagnosis of TEF, it can be used in conjunction with bronchoscopy to instill air and methylene blue to define the anatomy, particularly for small fistulas. Further imaging with modalities such as computed tomography scanning is not necessary or helpful in benign disease, but it is useful in TEF secondary to a suspected or confirmed malignant process.

TREATMENT

Preoperative Care

The treatment of acquired TEF begins with preoperative planning and patient optimization. Preoperative chest radiography, barium swallow, bronchoscopy, and esophagoscopy must be reviewed to determine the anatomy of the fistula, which will guide surgical exposure. Patients with pulmonary sepsis as a result of chronic airway contamination from aspiration of enteric contents should be adequately treated with antibiotics and stabilized before surgery. In situations where mechanical ventilation can be weaned, it is paramount to delay surgery until ventilation can be definitively ceased to minimize postoperative manipulation and positive pressure within the reconstructed trachea. In patients who are intubated, it is important to advance the endotracheal tube below the level of the fistula and inflate the cuff to prevent further contamination. Nutrition should be optimized with nasoenteral or transmural feeding tubes to minimize further esophageal trauma. Lastly, preoperative coordination with an experienced team of anesthesiologists familiar with the challenges of induction and intraoperative ventilation during tracheal resections is paramount.

Operative Management of Benign Acquired Tracheoesophageal Fistulas

Benign TEF are managed primarily with surgery. Exposure is achieved via an anterior collar incision, which may include a tracheostomy if necessary (Fig. 2). Alternatively, a left cervical incision along the anterior border of the sternocleidomastoid can be used. Importantly, both approaches may be extended to include a sternotomy for exposure of the distal trachea and for proximal control of the great vessels. For more distal TEF or bronchoesophageal fistulas, a right posterolateral thoracotomy through the fourth or fifth interspace provides adequate exposure.

Conservative surgical management includes two stages: initial tracheal resection and reconstruction with esophageal diversion via cervical esophagostomy, followed by subsequent interval primary esophageal reconstruction. Such an approach may be appropriate for patients with traumatic TEF, where the degree of local contamination, loss of viable tissue, or other traumatic injuries may preclude a single stage repair. When feasible, a single stage repair is advisable because it avoids stoma reoperation, as well as loss of esophageal length during the takedown of the cervical esophagostomy.

Principles of single stage surgical repair as originally described by Herbert Griffin include complete dissection and division of the fistula with tracheal transection to expose the esophagus, two layer esophageal closure, mansentimento of the trachea, and buttressing the repair with a pedicled tissue flap. There are several technical considerations in each of these steps. First, during the exposure and dissection of the fistula, where in most cases the fistula is acquired from long-term mechanical ventilation, the trachea often requires segmental resection with distal tracheal intubation given the circumferential damage from the endotracheal or tracheostomy tube cuff. This provides adequate exposure to the esophagus (Fig. 3). During this dissection, care must be taken to avoid damage to the recurrent laryngeal nerves that

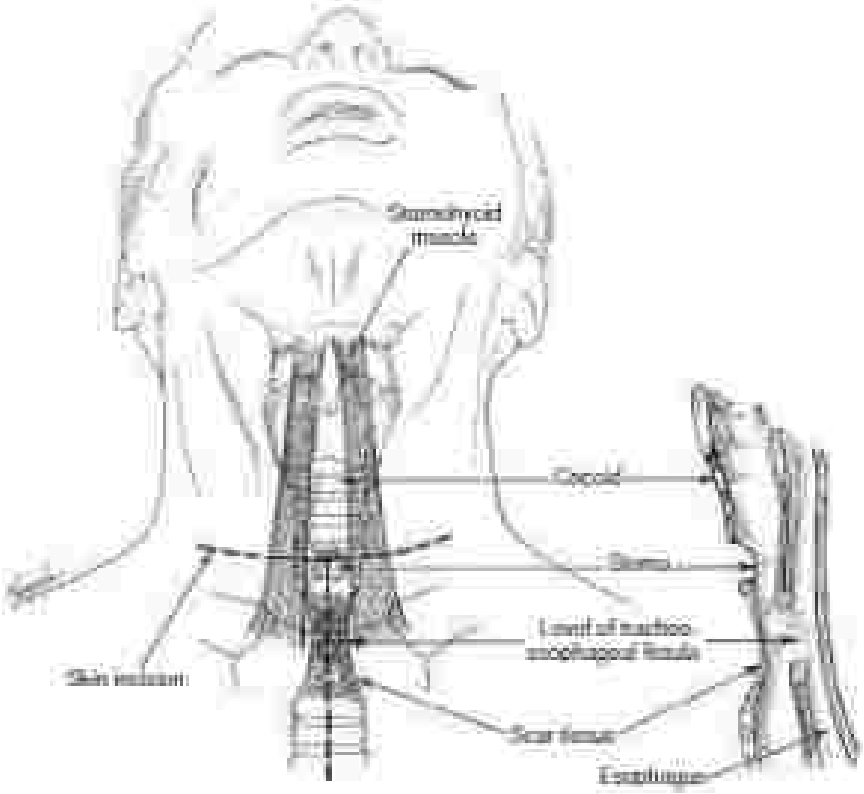

FIG. 3 Surgical exposure for repair of tracheoesophageal fistula. Both a transverse anterior collar incision incorporating a tracheostomy or left cervical incision provides necessary exposure. Additional exposure for distal fistulae can be obtained with division of the manubrium.

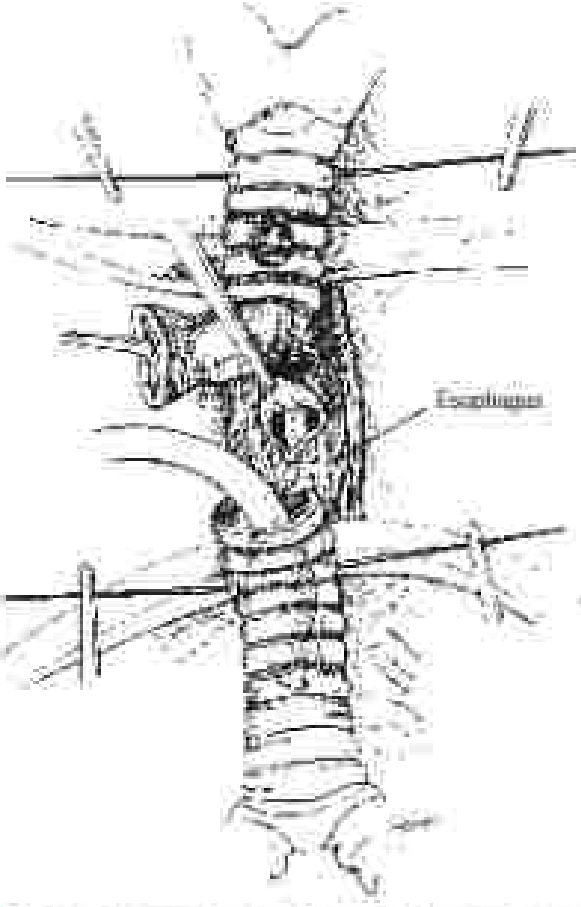

FIG. 4 Tracheal resection. Esophageal exposure after segmental tracheal resection in cases of isolated proximal tracheoesophageal fistula.

lie within the tracheoesophageal groove on either side. The nerves may be identified cranially or caudally from the location of the fistula, where identification can be challenging from local inflammation and scarring.

Second, once identified and divided, the esophagus is closed over a nasogastric tube to avoid narrowing the lumen. We advocate for a two-layer closure with interrupted nonabsorbable sutures in the inner layer to approximate and invert the esophageal mucosa, with an outer layer of approximated esophageal musculature to cover the inner repair (Fig. 4). It is important to debride the esophageal defect to healthy tissue to ensure the integrity of this primary repair.

Third, during tracheal repair, we recommend the use of interrupted absorbable sutures with the knots outside the lumen of the trachea. This minimizes the formation of postoperative granulomas at the suture line (Fig. 5). Fourth, in cases of long segment tracheal damage and resection where simple neck flexion does not allow for primary repair, the trachea may be repaired over a T tube. Alternatively, experienced surgeons may perform a variety of release maneuvers, including a suprahyoid laryngeal release, right pulmonary hilar mobilization, or pericardial release.

Last, the use of a pedicled muscle flap to buttress both the esophageal repair and tracheal reconstruction is paramount to prevent recurrence of the TEF from the abutting suture lines. An available neck muscle, typically the sternohyoid, is of adequate length and size to be secured to the repair with interrupted nonabsorbable sutures (Fig. 6).

At the conclusion of the repair, a subcutaneous drain is placed before the incision is closed. The nasogastric tube is gently removed from the esophagus and a "guardian suture" is placed from the chin to the sternal angle to maintain neck flexion at approximately 30 degrees. The patient is extubated to prevent prolonged positive pressure ventilation within the reconstructed trachea. In situations where mechanical ventilation is necessary after surgery, a tracheostomy tube may be placed at least two tracheal rings below the level of the repair.

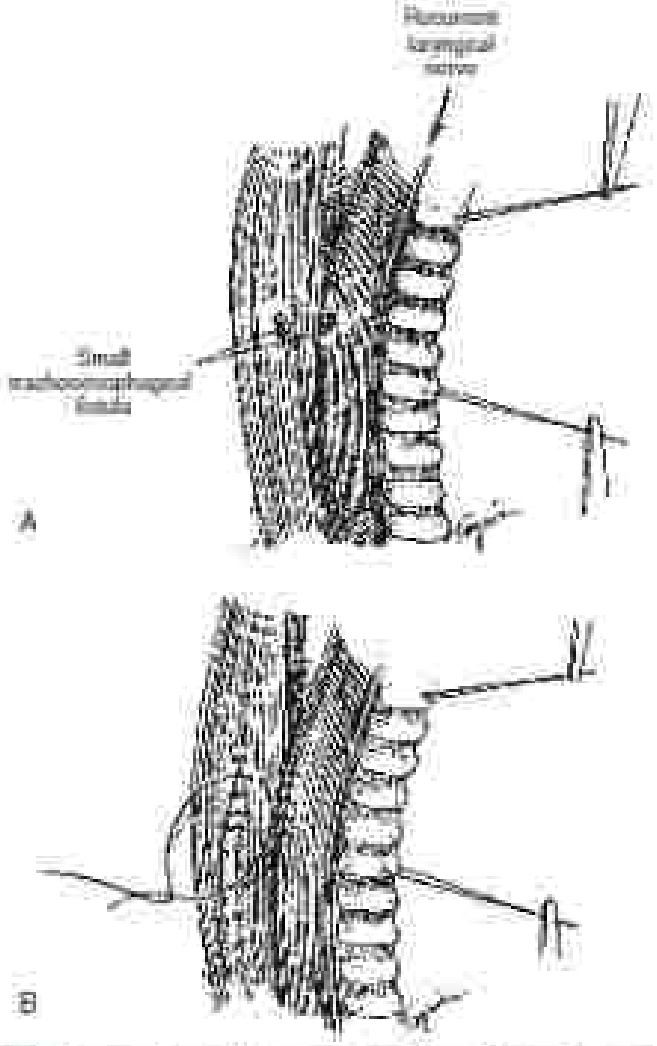

FIG. 4 Esophageal repair. (A) Lateral cervical approach to a small proximal tracheoesophageal fistula. (B) The esophageal defect is repaired in a two-layer fashion with interrupted sutures. The defect in the membranous wall of the trachea is repaired with a single layer of interrupted sutures.

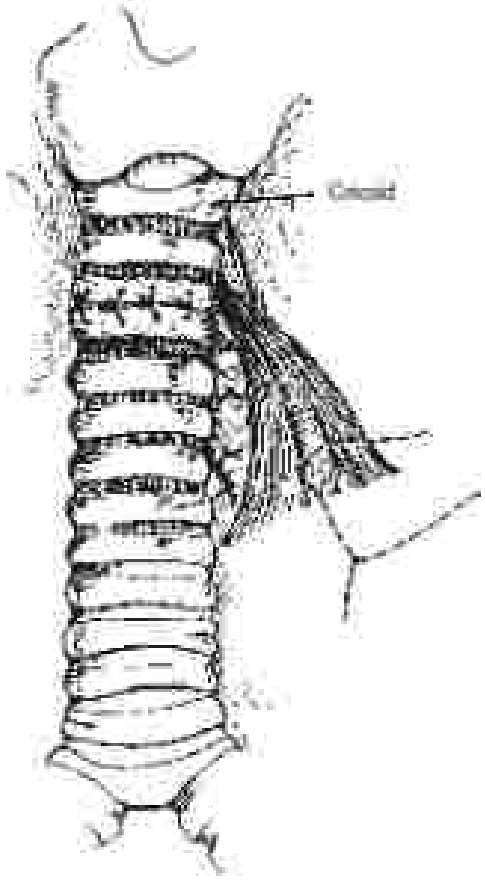

FIG. 5 Tracheal reconstruction. Placement of interrupted nonabsorbable sutures for tracheal reconstruction.

Postoperative Management

Postoperative care is focused on pain and nausea control to prevent cough or emesis. The patient is maintained nil per os; nutrition is provided via preoperative enteral access or parenteral nutrition. The patient returns to the operating theater 7 days after surgery for bronchoscopic surveillance of the tracheal reconstruction, at which time the guardian suture is removed. A barium swallow is also performed to confirm the integrity of the esophageal repair before initiating a liquid diet.

Management of Malignant Tracheoesophageal Fistulas

The management of malignant TEF is aimed at palliation. As opposed to benign TEF, where surgical interventions restore the integrity and continuity of the airway and intestine, malignant fistulas represent the sequelae of advanced metastatic esophageal or bronchogenic carcinomas. Surgery, in many of these cases, is not within the initial oncologic principles of management. Furthermore, these patients are often significantly deconditioned and malnourished as a result of their disease burden, systemic chemotherapy, and local radiation. For these reasons, outcomes from radical and palliative surgery to address malignant TEF result in significant rates of morbidity and mortality.

In cases of incurable disease, airway and esophageal stenting has emerged as a viable option to achieve palliation. Either individual or a combination of stents across the fistula is placed to prevent further spillage of enteric contents across the fistula, thus minimizing pulmonary contamination and alleviating the symptoms of chronic aspiration and pulmonary sepsis.

The principals of preoperative planning in benign TEF also apply to patients with malignant disease. Preoperative imaging, including barium swallow, should be obtained to determine the anatomy and level of the fistula. Pulmonary sepsis should be treated with antibiotics, mechanical ventilation should be weaned as allowed, and nutrition should be optimized.

Most malignant TEF may be sealed using a self-expanding covered or partially covered metal or plastic esophageal stents. These stents are typically placed under direct endoscopic guidance with the assistance of bedside fluoroscopy. In some cases, tracheal stents may also be needed and should be placed under bronchoscopic vision before the esophageal stent. This technique decreases the incidence of tracheal narrowing from initial esophageal stenting.

For fistulas located at or above the cricopharyngeus, the placement of a stent is not recommended because a foreign body in the pharynx or larynx results in significant patient discomfort and the inability to swallow. In such cases, a definitive tracheostomy tube with inflatable cuff to protect the distal airways may be placed. Likewise, fistulas to the lobar or segmental bronchi are difficult to seal via bronchial stenting because there is a lack of healthy tissue proximally and distally. Typically treated with an esophageal stent alone, these peripheral fistulae may also be managed with the addition of a tracheobronchial stent.

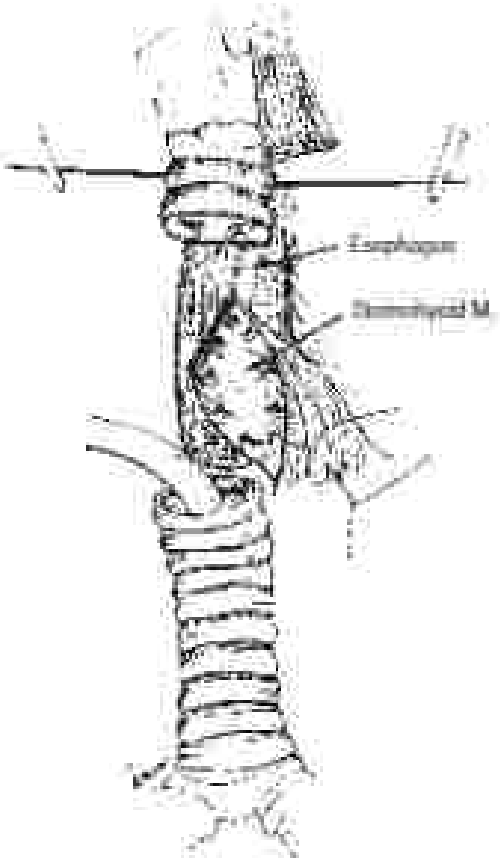

FIG. 6 Placement of partially retrograde stent inserts in between tracheal and esophageal tissues does to buttress repair and prevent fistula recurrence.

The placement of self expanding stents, whether in the esophagus or airway, can be safely accomplished with minimal intravenous sedation and the use of topical or nebulized anesthetic. Although well tolerated, patients should be counseled on the complications of esophageal and airway stenting, from minor to devastating. This includes bleeding, migration, erosion, and further progression of the fistula, leak, and occlusion.

OUTCOMES

Surgical treatment of benign TEF is successful in fistula closure and is associated with minimal morbidity and mortality. In the largest recent series reporting the outcomes of a cervical approach to primarily postintubation TEF repair, successful fistula closure occurred in 95% of patients. Approximately 83% of patients resume alimentation, and 72% are free from a tracheostomy or T tube. Other sources of postoperative morbidity include fistula recurrence, pneumonia, wound infection, and postoperative tracheal stenosis. Death after TEF repair is rare.

Patient survival in malignant TEF is poor regardless of supportive care, stent placement, or aggressive surgical treatment. Life expectancy is on the order of weeks to months. Symptomatically, however, self expanding stents have successfully palliated and provided relief of dysphagia for a majority of patients with malignant TEF.

SUMMARY

Most benign acquired TEF are amenable to surgical repair. We emphasize the importance of a comprehensive preoperative evaluation to determine the anatomy of the fistula and optimize respiratory status and nutrition. A single stage repair with division of the fistula, two layer esophageal closure, tracheal resection and reconstruction, and buttressing the repair with a pedicled intercostal muscle flap has demonstrated excellent results. Malignant TEF remain a challenging clinical entity and are primarily managed nonsurgically with the use of self expanding stents to maximize patient palliation.

Repair of Pectus Excavatum

Paul D. Danielson, MD, FACS, FAAP,
and Paul M. Colombani, MD, MBA, FACS, FAAP

Pectus excavatum (PE), historically known as "funnel chest," is the most common chest wall deformity. It occurs in approximately 1 in 500 live births, with a male predominance of 2:1 to 5:1 in various series. The sternum is depressed toward the vertebral column, with the greatest depression typically at the level of the xiphoid process. The implications of PE may range from cosmetic deformity with psychologic distress to significant cardiopulmonary impairment from decreased thoracic cavity capacity and compression of the heart. Although the exact cause of PE is unclear, the condition is believed to result from abnormal development of the costal cartilages. Overgrowth or increased flexibility of the costal cartilages, especially cartilages 4 through 7, leads to progressive dorsal displacement of the sternum. PE is associated with connective tissue disorders such as Marfan syndrome. PE often runs in families, but no specific genetic cause has been identified.

EVALUATION OF THE PATIENT WITH PECTUS EXCAVATUM

Initial evaluation of the patient with PE requires a careful history and physical examination. One third of patients with PE have a defect evident from early childhood, and the remainder first appreciate the problem during the adolescent growth spurt. A history of worsening

Repair of Pectus Excavatum

Paul D. Danielson, MD, FACS, FAAP,
and Paul M. Colombani, MD, MBA, FACS, FAAP

Pectus excavatum (PE), historically known as *funnel chest*, is the most common chest wall deformity. It occurs in approximately 1 in 500 live births, with a male predominance of 2:1 to 5:1 in various series. The sternum is depressed toward the vertebral column, with the greatest depression typically at the level of the xiphoid process. The implications of PE may range from cosmetic deformity with psychologic distress to significant cardiopulmonary impairment from decreased thoracic cavity capacity and compression of the heart. Although the exact cause of PE is unclear, the condition is believed to result from abnormal development of the costal cartilages. Overgrowth or increased flexibility of the costal cartilages, especially cartilages 4 through 7, leads to progressive dorsal displacement of the sternum. PE is associated with connective tissue disorders such as Marfan syndrome. PE often runs in families, but no specific genetic cause has been identified.

EVALUATION OF THE PATIENT WITH PECTUS EXCAVATUM

Initial evaluation of the patient with PE requires a careful history and physical examination. One third of patients with PE have a defect evident from early childhood, and the remainder first appreciate the problem during the adolescent growth spurt. A history of worsening

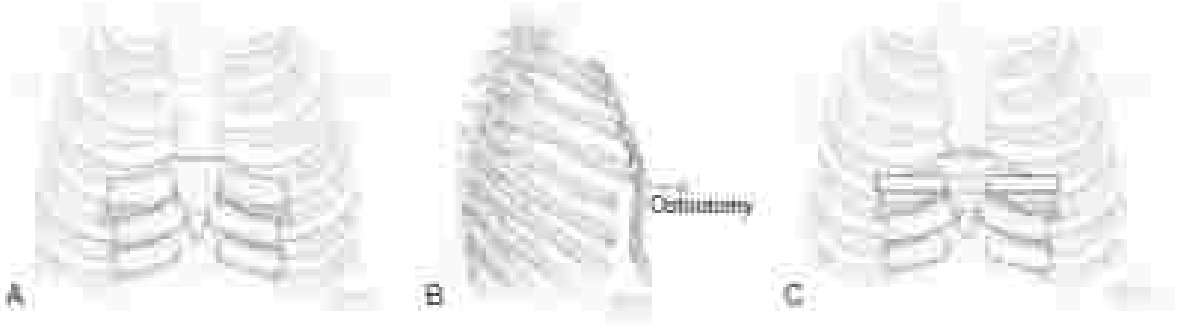

FIG. 1 *Open repair of pectus excavatum.* Following a transverse infraumbilical incision and bilateral elevation of the pectoralis major muscles, costal cartilages are freed circumferentially from the perichondrium and divided at the junctions with the sternum and with the ribs (A). A transthoracic osteotomy allows the sternum to rise to a more anterior position (B). An Adkins strut in place maintains elevation (C). (Courtesy John P. Kelly, Chicago, Illinois. Reproduced from Kelly RE Jr, Obermeyer RJ, Nuss D, et al. Pectus excavatum. In: Mattox KL, Feliciano DV, Moore EE, eds. *Trauma*. 8th ed. New York: McGraw-Hill Education; 2017.)

deformity around this time is often elected. Symptoms at rest are rare, but the patient may report impaired exercise tolerance with shortness of breath. On physical examination, the chest should be examined for symmetry and location of the deepest point of the pectus. Asymmetry is not uncommon, and the defect is often slightly skewed to the right side. Patients with PE have a typical kyphotic posture with a protuberant abdomen and flaring of the costal margin. Calipers can be used to measure the chest diameter at both the deepest point of the deformity and the lateral chest wall to get an approximate indication of the severity of the pectus. Caliper measurement demonstrating greater than 2.5 cm difference indicates a significant deformity. Stigmata of collagen vascular disease, such as long fingers and toes, myopia, and easy bruising, may be observed. Patients who have clinical signs of Marfan syndrome but do not carry this diagnosis may benefit from referral for diagnostic evaluation.

Further diagnostic examination, including chest computed tomographic (CT) scanning, pulmonary function tests (PFT), and transthoracic echocardiography, is indicated to assess the degree of cardiopulmonary impairment caused by the PE. A chest CT scan without intravenous contrast allows the calculation of the Haller index, a quantification of the severity of the PE defect. Magnetic resonance imaging can also be used to minimize radiation exposure. For determination of the Haller index, the anteroposterior (AP) diameter of the chest is measured from the inner ribcage to the spine at the greatest point of the defect. The transverse diameter of the chest is measured from the inside of the ribs at the same location. The index is the ratio of the transverse to the AP diameters of the chest. PE repair is generally recommended at a Haller index of 2.5 or greater. An exercise PFT is performed for assessment of lung volumes at rest and exercise. Typically, a mild to moderate restrictive defect is seen in these patients at rest. With exercise, a significant decrease in O_2 pulse and maximal exercise capacity (VO_2 max) may be present. This indicates decreased diastolic filling secondary to compression. Finally, echocardiography may show right ventricular compression or mitral valve prolapse. A subset of patients with PE with narrow chests exists for whom the Haller index underestimates the severity; an improved corrective index has been developed to help evaluate this cohort of patients.

The extent of cardiopulmonary involvement in PE remains a subject of debate. Increasing Haller index has been associated with worse impairments in pulmonary function, but many patients with PE have spirometry values within the normal range. Many patients report subjective improvement in exercise tolerance after repair despite having normal PFT values both before and after surgery. In many cases, third-party payers require documentation of objective measures of cardiopulmonary impairment or significant PE–related symptoms before authorization of repair. The operation is otherwise considered cosmetic in nature and is not covered.

OPEN REPAIR

The first widely adopted technique for repair of PE was the Ravitch operation. In this procedure, a fourth intercostal transverse incision is performed, and skin and muscle flaps are elevated to expose the sternum and the costal cartilages. The abnormal costal cartilages are resected to the subperichondrial plane. An anterior sternal wedge osteotomy is performed to elevate the sternum. A metal strut is placed retrosternally to provide more secure fixation. Historically, the Ravitch procedure was performed as early as age 4 years. However, a very small but significant subset of patients who underwent repair at such an early age subsequently acquired lesser syndromes (asphyxiating thoracic dystrophy) as they progressed through puberty. These patients' thoracic cavities failed to expand with growth, presumably as a result of abnormal fixation of the growth plates in the costochondral joints. Correction of acquired lesser syndrome is complex and often unsatisfying. Most authors recommend delay of open PE repair until puberty to avoid this complication (Fig. 1).

MINIMALLY INVASIVE REPAIR (NUSS PROCEDURE)

In 1987, Nuss introduced a minimally invasive approach to PE repair. This approach relies on the natural flexibility of the costal cartilages to enable repair from the inside of the chest. Advantages include a shorter operative time and less disfiguring scar. The patient is placed supine with arms extended. The site of deepest depression of the sternum is identified and traced laterally. After intravenous antibiotic prophylaxis, incisions of 4 cm in length are made bilaterally along this line at its intersection with the anterior axillary line and are deepened until the pleura are entered with direct vision. In the original description, an introducer is then passed with thoracoscopic guidance from the left chest just retrosternally into the right chest. The thoracoscope is transferred to the right chest to observe passage of the introducer. Remaining strictly in the immediate retrosternal plane and using thoracoscopic guidance minimizes the chance of cardiac perforation or other mediastinal injury. However, in the authors' practice, thoracoscopy is no longer used during passage of the introducer. With use of digitally tunneled techniques, the pericardium is seen and the bar passed from the left without difficulty. In difficult cases, sternal elevation can be used to facilitate transmediastinal passage of the introducer. An umbilical tape is tied to the introducer as the tip exits the right lateral skin incision. The introducer is then withdrawn back through the left chest so that the umbilical tape traces its transthoracic passage. A pectus bar is selected based on the patient's body habitus. Ideally, the bar should extend beyond the edge of the rib cage on each side without protruding too far beyond the ribcage, typically 2.5 cm shorter than the distance between the midaxillary lines. The exact degree of

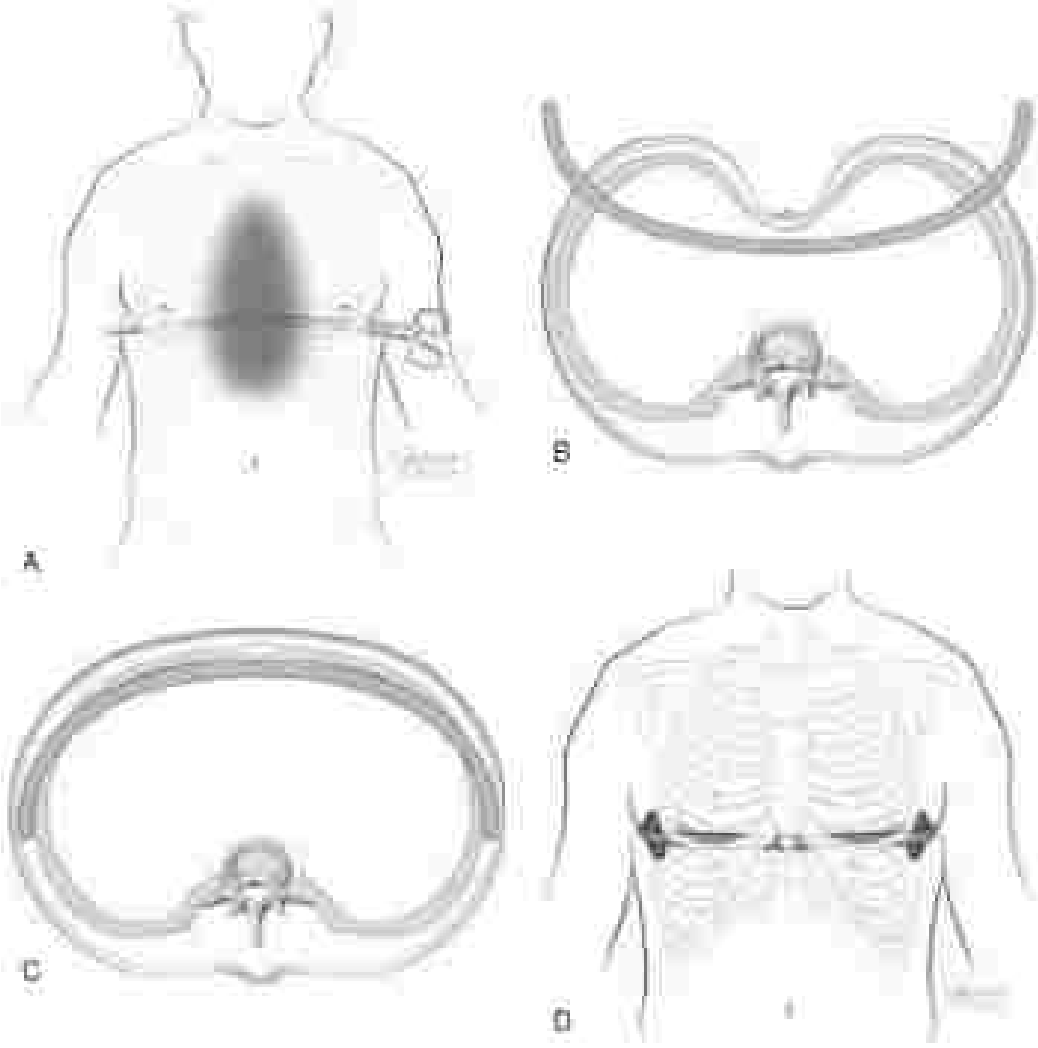

FIG. 2. Minimally invasive pectus excavatum repair. (A) Schematic of bar being passed posterior to the sternum through bilateral thoracic incisions. (B) Initial orientation of bar after passage through chest. (C) Position of bar after flipping. (D) Bar stabilizers in position. (Courtesy John Hopkins University Center for Pediatric [illegible], Baltimore, MD, 2014.)

bend that must be applied to each side of the bar is a matter of judgment, but the goal is to slightly overcorrect the sternum rather than undercorrect it. The umbilical tape is tied to one end of the bar and then withdrawn through the chest with the bar upside down (concave side up). After the bar is grasped exiting the right chest, it is flipped 180 degrees so that the convex side is elevating the sternum. Many techniques for bar fixation have been described. Stabilizers can be placed over the end of the bar on one or both sides to secure the implant above the rectus. Wire or heavy polydioxanone suture fixation of the stabilizers around the ribs can also be used bilaterally to avoid bar displacement. Patients with complex asymmetric defects, patients with Marfan syndrome, and patients with suboptimal elevation of the sternum after placement of a single bar may benefit from placement of a second bar to improve sternal elevation. Placement of a second bar follows the principles of placement of the initial bar. A chest x-ray film is obtained routinely in the recovery room. Small bilateral pneumothoraces are commonly observed as a result of air introduced during bar placement and in general may be managed expectantly without further imaging as long as the patient is clinically well (Fig. 2).

Preoperative counseling is essential before repair. Postoperative pain can be considerable during the first few postoperative weeks, and some patients continue to experience pain for the entire period while the bar is in place. In severe cases, this can require removal of the bar with likely recurrence of the PE defect. Postoperative use of ketorolac and gabapentin can limit the use of narcotic analgesics. In general, the authors limit physical activity for the first 6 weeks after bar placement. After this point, there are no specific activity restrictions.

The ideal age for minimally invasive PE repair continues to be debated. A shift has been seen over the years toward repair at an older age, especially late adolescence into early adulthood. The authors typically perform the repair at 14 years of age. Recent reports suggest that patients over 30 years of age are more likely to require placement of two bars.

The correct length of time for the bar to remain in place remains debated. At least 2 years is recommended to allow adequate time for the costal cartilages to remodel in their new position. The authors have had rare immediate recurrences with bar removal at 2 years that have led them to favor leaving the bar in position for 3 years. Patients with Marfan syndrome and other connective tissue disorders should have bars in for 5 years. At this point, the bar may be removed as an outpatient procedure. With general anesthetic, the previous incisions are reopened, and any wires or stabilizers used for fixation are removed. The bar ends on either end of the bar are removed, and the bar can then be pulled out of one side of the chest. The deep layers of the incision are closed with 2-0 polyglycolic acid suture and final while

a Valsalva maneuver is performed to evacuate any introduced air. After routine subcuticular skin closure, the patient is returned to the recovery room. A postoperative chest radiograph is obtained. Small bilateral pneumothoraces may be seen and do not require intervention in the absence of clinical symptoms. The patient is discharged home with narcotic analgesia after a suitable observation period in recovery.

COMPLICATIONS OF MINIMALLY INVASIVE REPAIR

Although asymptomatic pneumothorax is commonly observed after PE repair, symptomatic pneumothorax may rarely result from inadvertent injury to lung parenchyma during bar placement. Enlarging pneumothorax in the setting of clinical deterioration requires placement of chest tubes, often bilaterally. Urinary retention is frequently noted after surgery at a rate that exceeds that seen with other operations. The cause of this finding is uncertain, but this generally resolves within several days.

Intraoperative cardiac perforation is the most dreaded complication of minimally invasive repair. Although this is exceptionally rare, it is highly lethal. Immediate median sternotomy and cardiac repair are indicated in this setting.

Displacement of the bar can occur in as many as 5% of patients, often leading to immediate recurrence. Reoperation is required to flip the bar back into the appropriate position and reconcave the bar to the rib cage. Additional wires may be necessary to adequately secure the bar in position. Wound infection is rare, occurring in less than 2% of patients, and can often be treated with antibiotics. Surgical drainage is sometimes necessary for more extensive infections.

Most pectus bars are composed of stainless steel, although titanium bars are available by special order. Unsuspected allergy to nickel may lead to localized skin reaction at the incisions or pericarditis. Symptoms may not occur for many months after placement, and these patients can often be treated medically with corticosteroids until it is time to remove the bar. Metal salt patch testing can be used before surgery to identify patients with allergies if a history of sensitivity is present. A titanium bar is used in these individuals; however, it cannot be bent to shape as with a stainless steel bar. It must be molded to the correct shape by the manufacturer with guidance from the preoperative CT scan.

OUTCOME OF PE REPAIR

Neither the open nor the minimally invasive technique of PE has been shown to be clearly superior in the repair of PE. Both have a higher than 90% success rate in improving psychologic perceptions and subjective assessment of exercise tolerance. No difference is seen in length of stay, although the rate of pneumothorax and reoperation is higher in the minimally invasive repair. Since its introduction, the minimally invasive repair has far surpassed the open repair in popularity and is used for the majority of PE repairs. However, the open repair may still be preferable in patients with severely asymmetric defects and in patients with mixed carinatum/excavatum phenotype. Failures of open repair have been successfully corrected with the minimally invasive approach, as have previous failures of minimally invasive repairs.

Open Repair of Abdominal Aortic Aneurysms

Bruce A. Perler, MD, MBA

A[illegible] aneurysm ... [illegible] ... are increasingly encountered by vascular specialists in the future. In fact, it has been estimated that the incidence of AAAs may be as high as [illegible]% to 15% in high risk patients. [illegible] risk factors for AAAs include advanced age, male gender, white race, positive family history of AAAs, and history of cardiovascular and peripheral arterial occlusive disease and their associated risk factors.

Rupture of an AAA, its most serious complication, occurs in roughly 15,0[illegible] individuals annually in the United States. Risk factors for rupture include chronic obstructive pulmonary disease, [illegible] hypertension, rapid increase in aneurysm size, and absolute aneurysm size. The key to minimizing mortality due to aortic aneurysm disease is early diagnosis and timely intervention in the elective setting. The introduction and in recent years significant technologic refinement of less invasive endovascular aortic aneurysm repair (EVAR) has allowed repair to be carried out in increasing numbers of individuals who formerly may have been considered to be too high risk for conventional open repair. In fact, in contemporary practice it is estimated that 70% to [illegible]% of elective and even ruptured aortic AAA repairs are undertaken with EVAR. Nevertheless, there is still a role for traditional open AAA repair in practice today and this expertise should be in the armamentarium of every vascular surgeon. This chapter will outline the key principles in safely performing open AAA repair.

[illegible]

The majority of AAAs are diagnosed by routine physical examination or are detected on radiologic studies performed in the evaluation of other conditions. While the presence of a pulsatile abdominal mass is highly suggestive of an AAA, physical examination is not consistently reliable. Specifically, the likelihood of detecting an AAA on physical examination is inversely correlated with the patient's body mass index and directly correlated with the aneurysm diameter. The simplest radiologic study to confirm the presence of an AAA is a plain lumbosacral spine radiograph using lateral technique. At least 70% of atherosclerotic AAAs contain sufficient calcium within the aneurysm walls to allow detection and fairly accurate estimation of the extent of the aneurysm, as well as its anterior–posterior diameter. Abdominal ultrasound is a noninvasive and highly reliable method to confirm the presence of an AAA and depict its diameter, although ultrasound tends to overestimate the diameter by about 20%. Nevertheless, this modality is highly reliable and very reproducible, cost effective, and therefore is the technique of choice for serial follow up of the patient with a small aneurysm being managed nonoperatively. Computed tomography (CT) is more accurate in depicting aneurysm size, although it is more time consuming, expensive, and entails radiation exposure. CT is much more accurate than ultrasound in confirming the juxtarenal or suprarenal extent of the aneurysm and can provide other key anatomic features relevant to the planning of EVAR. CT is also valuable in detecting associated anatomic features that might impact on open repair, such as an iliac aneurysmal aneurysm, evidence of a leak, retroperitoneal fibrosis, a horseshoe kidney, retroaortic renal vein or other venous anomalies, or multiple renal arteries. Magnetic resonance imaging (MRI) will also provide accurate information with respect to aneurysm size and extent, and associated vascular anomalies, although it seems inferior to CT in this clinical setting. CT angiography has largely obviated a need for contrast angiography in planning open AAA repair, unless there are specific indications for angiography such as a suspicion of significant renal or visceral artery lesions, or iliofemoral or femoral-popliteal occlusive disease for which the surgeon may elect endovascular intervention before open AAA repair.

Indications for Repair

The overwhelming majority of patients with AAAs are completely asymptomatic, and the decision to proceed with repair depends on the size (diameter) of the aneurysm and the patient's overall comorbidity and risks for surgical intervention. As noted above, in contemporary practice the less invasive EVAR option has allowed surgery to be performed on patients who might have had prohibitive risks for conventional open repair (see below).

The current clinical recommendations for elective intervention in the asymptomatic patient are based on several clinical trials. The UK Small Aneurysm Trial randomized 1090 patients between the ages of 60 and 76 years with aneurysms ranging from 4.0 to 5.5 cm in diameter to open repair versus surveillance, and the Aneurysm Detection and Management trial randomized 1136 patients between the ages of 50 and 79 at Veterans Administration medical centers with aneurysms ranging from 4.0 to 5.4 cm in diameter to open repair versus surveillance. Based on these trials and a subsequent Cochrane review, in contemporary practice the threshold for elective repair is an AAA diameter of 5.5 cm in men and 5.0 cm in women, due to

the smaller normal aortic diameter in women and the slightly higher rupture rate. Neither of these studies provided evidence to support elective repair of small AAAs, although a significant proportion of the patients in the surveillance groups ultimately underwent AAA repair due to increase in size of the AAA or the development of symptoms. There is no substantive evidence to suggest that the size threshold for intervention should be influenced by the method of repair; that is, it should not be lowered if EVAR is an option. According to the Society for Vascular Surgery (SVS) guidelines, patients with smaller aneurysms should undergo preoperative surveillance: every 3 years if 3.0 to 3.9 cm, every 12 months if 4.0 to 4.9 cm, and every 6 months if 5.0 to 5.4 cm in diameter. Ultrasound is the most cost-effective imaging modality for long-term surveillance.

Commonly, symptoms of abdominal or back pain suggestive of rapid aneurysm expansion or impending rupture or actual rupture is an indication for urgent repair irrespective of size. Less commonly, patients may present with peripheral ischemia due to distal embolization of aneurysmal mural thrombosis or aberrant flow, or acute aneurysm thrombosis, which typically occurs in smaller aneurysms, and is an indication for repair irrespective of aneurysm diameter.

INDICATIONS FOR OPEN REPAIR

In contemporary practice, it is estimated that 70% to 80% of patients undergoing AAA repair undergo EVAR. Nevertheless, while further advances in endovascular therapy, such as the availability of fenestrated endovascular aneurysm repair, and other techniques, such as so-called snorkel/chimney grafts, have allowed treatment of juxtarenal and even suprarenal AAAs that formerly would be treated endovascular repair, there are specific anatomic considerations for which open repair may be the most appropriate treatment. Therefore vascular surgeons should be trained and feel competent in performing open AAA repair. These anatomic features include a very short, excessively angulated, trapezoidal, heavily calcified, or thrombus-filled infrarenal aortic neck. In addition, severe iliac artery occlusive disease and especially iliac artery occlusions may be an indication for open repair. Finally, patient preference, especially in the relatively young patient who wishes to delay the lifelong radiographic surveillance following EVAR may be an indication for open repair.

PREOPERATIVE EVALUATION AND MEDICAL MANAGEMENT

Cardiac and pulmonary diseases remain the major etiologies of perioperative morbidity and long-term mortality in AAA patients, so a thorough history should be obtained prior to open repair. According to the most recent SVS guidelines, all patients should undergo a 12-lead electrocardiogram. Among patients who are functionally active, no further cardiac evaluation is necessary prior to open repair. An echocardiogram is indicated for patients with active symptoms of dyspnea or a history of congestive heart failure (CHF). In patients with three or more clinical risk factors such as angina pectoris, a prior myocardial infarction, compensated or history of CHF, diabetes mellitus, or renal insufficiency, noninvasive cardiac testing is indicated preoperatively. Further, for patients with active cardiac symptoms of unstable angina, a recent myocardial infarction, active arrhythmias or valve disease, formal cardiology evaluation and possible catheterization may be indicated. Pulmonary function testing is indicated for patients with active symptoms of COPD, and aggressive bronchodilator therapy should be instituted for 2 weeks prior to operation.

The most significant aspect of perioperative medical management include continuation of β-blockers, although one should not initiate β-blockade therapy preoperatively since this has been associated with an increased risk of stroke and all-cause mortality. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should be held on the morning of surgery, as they can be associated with hypotension with the induction of anesthesia and dehydration in patients with preexisting renal insufficiency. Aspirin should be continued.

OPERATIVE THERAPY

Operative Exposure

AAA repair may be carried out via a midline abdominal transperitoneal incision or extended left retroperitoneal approach. Each approach has its advantages for specific anatomic considerations and potential disadvantages.

Transperitoneal Approach

The traditional midline abdominal transperitoneal incision allows excellent exposure of the distal common iliac arteries and the external, and if necessary, internal iliac arteries bilaterally. Since the patient is placed in the supine position, laparotomy can be expeditiously achieved, which is of benefit in the emergency setting. The surgeon is able to perform an exploratory laparotomy prior to aneurysm repair, identify unsuspected intra-abdominal pathology, assess bowel viability following aneurysm repair, and if necessary perform associated surgical procedures such as cholecystectomy. A drawback to this approach is it may provide limited exposure and control of a relatively short infrarenal aorta, such without excessive aneurysm manipulation, especially with a very large aneurysm or in the case of a juxtarenal aneurysm where suprarenal or supraceliac control is necessary. In this setting, medial visceral rotation may be required (see below). Further, this approach can be associated with a significant postoperative ileus and may compromise lung function in patients with limited pulmonary reserve.

Technical Details

The patient is prepped and draped from the xiphoid to the knees. A midline incision is carried out from the xiphoid to the pubis and the peritoneum entered. The small bowel and transverse colon are packed in moist towels out of harms way. The ligament of Treitz is divided and the duodenum mobilized to the right. The lymphatic tissues over the aorta are divided along the anterior surface of the aorta with care to carefully identify the inferior mesenteric artery, and the inferior mesenteric vein. The dissection should be continued to the level of the renal arteries, dictated by the crossing left renal vein (Fig. 1). The renal vein can be mobilized in a cephalad direction to facilitate exposure of the aortic neck for clamping, and the gonadal, adrenal, and lumbar branches can be divided. One should avoid dividing the left renal vein since this can lead to renal dysfunction. If absolutely necessary to divide the left renal vein for exposure, it is critical to preserve the aforementioned branches. If the left renal vein is not identified, this may reflect its retroaortic position and this must be confirmed to avoid injury during clamping, which can lead to severe bleeding.

If suprarenal exposure is made easy, the suprarenal aorta can be exposed by dividing the lesser omentum and gastrohepatic ligament. A nasogastric tube will identify the esophagus, which should be retracted to the patient's left. Although usually not necessary, the left lobe of the liver can be mobilized by dividing the left triangular and coronary ligaments and the falciform ligament.

Alternatively, a medial visceral rotation can be carried out. The left colon is mobilized to the right by incising the posterior peritoneum lateral to the line of Toldt. This incision is continued cephalad through the phrenicocolic ligament and to the aortic hiatus. A plane is developed along the posterior abdominal wall to allow mobilization of the colon, pancreas, spleen, and left kidney (Fig. 2). However, we believe that juxtarenal and suprarenal aortic exposure is most easily accomplished through the extended left retroperitoneal approach (see below).

Extended Left Retroperitoneal Approach

AAA repair may also be performed via the extended left retroperitoneal approach. There are several advantages of this approach, which

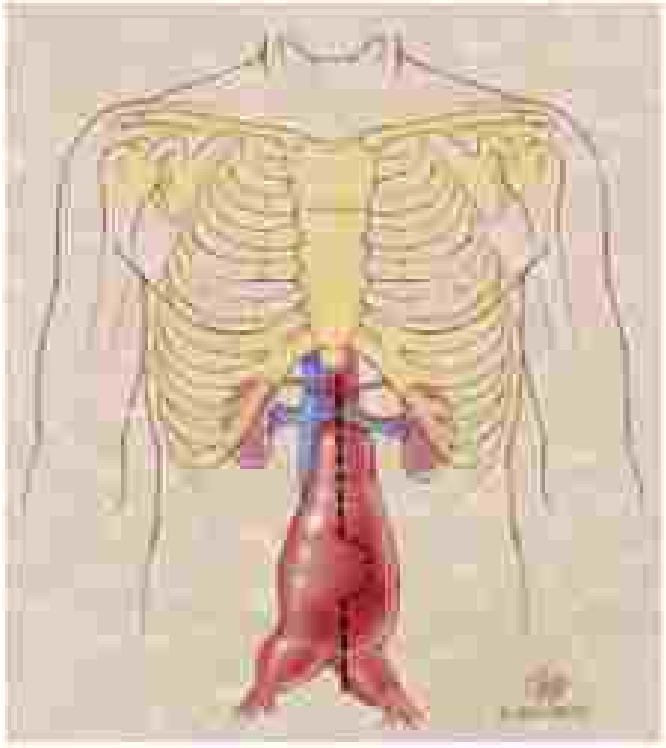

FIG. 1 The transperitoneal approach allows exposure from the ili[illegible] artery [illegible] to the renal arteries. To access the [illegible] aneurysm, the [illegible] must be mobilized to reveal the aneurysm, [illegible]. [illegible] (Reprinted courtesy Mayo Foundation.)

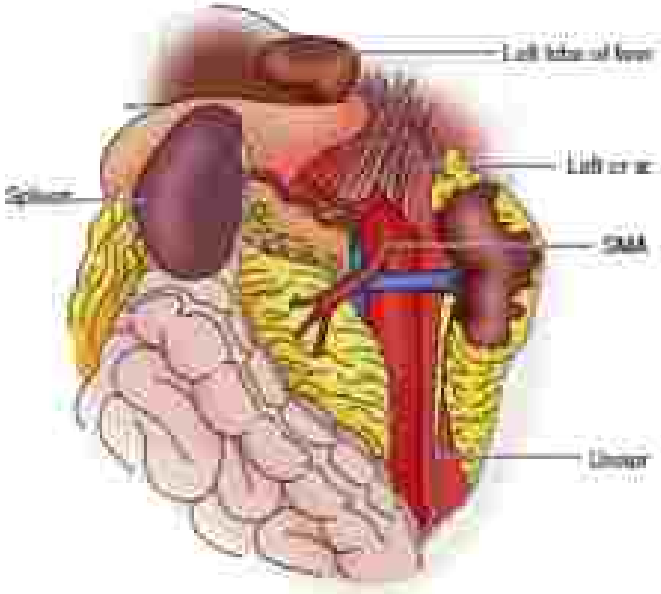

FIG. 2 Medial visceral rotation flexes the left colon and pancreas, spleen, and left kidney medialward inferiorly to allow superomedial [illegible] exposure of the [illegible] superior mesenteric artery. [illegible]

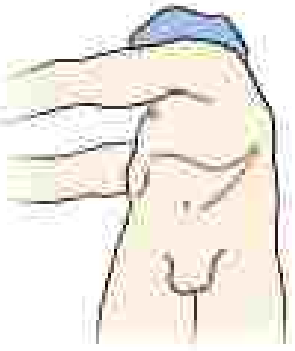

FIG. 3 The patient is placed in the lateral position with the hips swung [illegible]. [illegible]

makes it my preferred method for most patients undergoing open AAA repair. Proximal infrarenal aortic control is easily achieved without aneurysm manipulation. This is particularly useful in the patient with an inflammatory aneurysm. It also is useful in the very obese patient or if there is a colostomy or other previous abdominal surgery producing a so-called hostile abdomen. The duodenum and left renal vein are not exposed and therefore protected from injury. In the case of a juxtarenal aneurysm or if there is suprarenal extension, suprarenal or supraceliac aortic exposure and control can be easily achieved. Occlusive disease of the renal and/or mesenteric vessels can undergo transaortic endarterectomy when indicated without additional dissection. Further, the retroperitoneal approach is associated with less physiologic stress, with minimal or no postoperative ileus. There also is less respiratory compromise so that this approach is particularly appropriate for patients with COPD. One disadvantage of this approach is that exposure and control of the distal right iliac axis is difficult, especially with a large right common iliac artery aneurysm. This may require intraluminal balloon vascular control or performing the distal anastomosis to the right common femoral artery, although right groin exposure through this approach is more difficult than when aneurysm repair is carried out via a midline approach.

Technical Details

The patient is placed in the lateral position on a surgical beanbag with the left side up and the hips free with the iliac crest over the break in the table, which is extended to open the space between the left iliac crest and the lower left rib margin (Fig. 1). The incision extends from just below the umbilicus and lateral to the left rectus to the 11th intercostal space. With known suprarenal extension mandating more proximal exposure, the incision can be carried to the 10th intercostal space. The incision is deepened through the external oblique, internal oblique, and transversalis abdominis muscles, with care taken not to enter the peritoneal cavity. The peritoneal contents and left kidney are bluntly mobilized medially. The paraaortic lymphatics are ligated and divided, and a descending branch of the left renal vein should be identified and ligated to avoid troublesome bleeding. The left ureter, which courses over the left common iliac artery, should also be identified. If more proximal aortic exposure is necessary, the crus of the diaphragm can be divided with cautery to expose the suprarenal aorta. Further, if a mesenteric bypass is planned, more proximal aortic control is obtained with the left kidney mobilized anteriorly; it can be brought back posteriorly to allow exposure of the proximal celiac and superior mesenteric arteries anterior to the left kidney.

[illegible]

Irrespective of the surgical approach, the fundamental principles of operative repair are the same, and critical to the safe and effective conduct of the operation. Adequate exposure and vascular control proximal and distal to the aneurysm is essential. The aortic neck

RESULTS

Perioperative Mortality

With the introduction and growth in the performance of EVAR in contemporary practice, open AAA repair is increasingly being performed in patients with more anatomically complex aneurysms and not infrequently requiring suprarenal and supraceliac cross clamping. Despite this, and an increasingly ageing patient population with aneurysmal disease undergoing open surgery, open repair of AAAs has become increasingly safe in modern practice. Recent randomized controlled clinical trials have documented a perioperative mortality rate of 3.5%. This is paralleled by a mortality rate of approximately 3% in population-based studies. In a meta-analysis of 20 series with a minimum of 100 patients, perioperative mortality was 3.4%. In studies at Johns Hopkins as well as those done by others, it seems clear that the best results are achieved by surgeons with the highest operative volumes and in the highest volume centers, although an absolute minimum annual case volume is difficult to define. In a review of seven series of patients undergoing open AAA repair requiring suprarenal aortic cross clamping, and with at least 50 cases, perioperative mortality ranged from 1.9% to 3.6%, with mortality 3% or less in five of the seven series.

Perioperative Complications

Perioperative complications are not uncommon following open AAA repair, the incidence correlates with the complexity of the operation (Box 1). In one recent population-based registry, serious adverse events occurred in 26% cases and major adverse events in 11% of cases.

The majority of perioperative deaths result from cardiac complications. Better perioperative evaluation and perioperative medical management, including β-blocker use, have reduced the incidence of cardiac morbidity. Nevertheless, myocardial ischemia may be seen in up to 10% of patients in the early postoperative period. The incidence of respiratory complications correlates with the complexity and duration of the procedure and associated blood loss and fluid administration; patients benefit for aggressive early diuresis and extubation as soon as clinically safe in the early postoperative period to minimize pulmonary morbidity. Nevertheless, postoperative pneumonia may occur in 1–6% of patients following open AAA repair. The incidence of renal insufficiency following open AAA repair has declined significantly in recent years, but remains a potential complication, especially in cases requiring suprarenal or supraceliac aortic cross clamping. In a series of Medicare patients, the incidence of renal functional deterioration was 10%. In a meta-analysis of patients undergoing juxtarenal aortic aneurysm repair, postoperative dialysis was required in

BOX 1 Postoperative Complications

Early

Myocardial ischemia
Respiratory insufficiency
Respiratory failure
Pneumonia
Renal insufficiency
Ischemic colitis

Late

Sexual dysfunction in males
Impotence
Retrograde ejaculation
Aortoiliac/aortic fistula
Graft infection
Abdominal wall hernia

only 3.5% of patients. As noted above, administration of furosemide and mannitol to generate a brisk diuresis before aortic clamping is protective. Peripheral perfusion should be assessed before the patient leaves the operating room by palpating the peripheral pulses and performing a Doppler examination. Limb ischemia typically results from intraoperative distal embolization of aneurysmal thrombus or atherosclerotic debris. Application of the distal clamps before the aortic clamp and minimizing aortic dissection before clamping is protective. If backbleeding from the distal vessel seems inadequate, an embolectomy catheter should be passed distally before completing the distal anastomosis. The development of acute limb ischemia in the early postoperative period usually results from a technical error or clamp injury and warrants immediate exploration.

Although less commonly encountered than after repair of ruptured AAAs, ischemic colitis may complicate elective repair. Ligation of a patent IMA, occlusion of hypogastric artery flow, severe iliofemoral arterial occlusive disease, mesenteric arterial occlusive disease, and intraoperative atheroembolism are predisposing factors. The development of abdominal pain, fever, leukocytosis, and bloody gastric positive stools should warrant immediate sigmoidoscopy. This complication usually presents from 1 to 4 days postoperatively and can range pathologically from mucosal edema and hemorrhage to transmural infarction. When diagnosed early, mild to moderate colon ischemia may resolve, albeit with late stricture formation in some cases. Conservative medical therapy including cessation of oral intake, nasogastric suction, administration of broad spectrum intravenous antibiotics, and serial sigmoidoscopic examinations. Mortality with severe ischemic colitis has been reported in 25% to 50% of cases.

Sexual dysfunction in the male patient is a potential complication of open AAA repair, which should be discussed with the patient preoperatively. Difficulty with achieving or maintaining an erection may result from occlusion of internal iliac artery flow. Further, as many as 40% of male patients may experience retrograde ejaculation due to disruption of autonomic nerve fibers at the aortic bifurcation. One should minimize dissection at the aorto-bifurcation to minimize the incidence of this complication.

Less commonly, aorto-enteric fistula formation may complicate 1% to 2% of open AAA repairs and may present from a few months to several years following surgery. Closure of the residual aneurysm wall and coverage with omentum when operating through the transperitoneal approach are important to reduce the incidence of this complication. Further, it appears that the extended left retroperitoneal approach may be associated with a reduced incidence of this very serious complication. Likewise, prosthetic graft infection may complicate 1% to 2% of open AAA repairs and may present in the early postoperative period or several years postoperatively. Careful attention to intraoperative hemostasis to avoid postgraft hematoma formation, careful wound closure, and perioperative broad spectrum antibiotic administration are key to preventing this complication. These principles will also minimize the development of abdominal wall hernias following the transperitoneal approach or abdominal wall laxity following the left retroperitoneal approach.

Endovascular Treatment of Abdominal Aortic Aneurysms

[illegible] [illegible] [illegible] [illegible] [illegible]

Abdominal aortic aneurysm (AAA) is defined as a 50% increase in diameter compared with the baseline diameter of a given blood vessel. There is a strong male predominance, with a male to female ratio of 6:1. AAA is fairly common, affecting 12% of men over age 65 and accounting for approximately 15,000 deaths annually in the United States. The average rate of growth of an AAA is approximately 3 mm/yr. Smoking increases the average annual growth by 20% and also increases the risk of rupture twofold. Multiple trials have established that an AAA should be repaired once it reaches a threshold of 5.5 cm in men and 5 cm in women.

Endovascular aneurysm repair (EVAR) was first performed in 1990 by Juan Parodi in Buenos Aires. The first EVAR was performed using a stainless steel bare metal stent sutured to a Dacron graft, which was then mounted on a large angioplasty balloon and crimped inside a large sheath. The graft was then inserted and deployed through an open exposure to the common femoral artery. This successful first procedure paved the way for the current era of endovascular aneurysm repair.

In the 20 years since EVAR was first introduced, the techniques and devices have been refined and improved. In 2003 EVAR surpassed open aneurysm repair as the preferred method, and currently approximately 80% of AAAs are repaired using an endovascular technique. EVAR has been shown to have a lower perioperative mortality rate, shorter hospital length of stay, and lower rates of early complications.

Several randomized controlled trials have compared endovascular and open aneurysm repair. These include the EVAR 1 trial, the DREAM trial, and the OVER trial. The results of the 3 trials are consistent and lead to similar conclusions. First, EVAR has lower perioperative and 30-day morbidity and mortality rates compared with open aneurysm repair. Second, the short-term survival advantage of EVAR diminishes with time, and there are equal mortality rates between the techniques at 2 years and beyond. Finally, EVAR is associated with higher long-term device-related complications as compared with open aneurysm repair. Therefore, the planning, accuracy of deployment, and long-term follow-up with imaging are important to achieving a good long-term result.

Preoperative Planning

Precise preoperative planning is essential for short- and long-term outcomes after EVAR. Procedural success depends on several factors. Adequate ilio-femoral access for device delivery, adequate proximal seal zone below the renal arteries, adequate distal seal between the graft limbs and the iliac arteries, and adequate length of overlap between components of the graft. To assess the patient's anatomy

only 3.5% of patients. As noted above, administration of furosemide and mannitol to generate a brisk diuresis before aortic clamping is protective. Peripheral perfusion should be assessed before the patient leaves the operating room by palpating the peripheral pulses and performing a Doppler examination. Limb ischemia typically results from intraoperative distal embolization of aneurysmal thrombus or atherosclerotic debris. Application of the distal clamps before the aortic clamp and minimizing aortic dissection before clamping is protective. If backbleeding from the distal vessel seems inadequate, an embolectomy catheter should be passed distally before completing the distal anastomosis. The development of acute limb ischemia in the early postoperative period usually results from a technical error or clamp injury and warrants immediate exploration.

Although less commonly encountered than after repair of ruptured AAAs, ischemic colitis may complicate elective repair. Ligation of a patent IMA, occlusion of hypogastric artery flow, severe iliofemoral arterial occlusive disease, mesenteric arterial occlusive disease, and intraoperative atheroembolism are predisposing factors. The development of abdominal pain, fever, leukocytosis, and bloody gastric positive stools should warrant immediate sigmoidoscopy. This complication usually presents from 1 to 4 days postoperatively and can range pathologically from mucosal edema and hemorrhage to transmural infarction. When diagnosed early, mild to moderate colon ischemia may resolve, albeit with late stricture formation in some cases. Conservative medical therapy including cessation of oral intake, nasogastric suction, administration of broad spectrum intravenous antibiotics, and serial sigmoidoscopic examinations. Mortality with severe ischemic colitis has been reported in 25% to 95% of cases.

Sexual dysfunction in the male patient is a potential complication of open AAA repair, which should be discussed with the patient preoperatively. Difficulty with achieving or maintaining an erection may result from occlusion of internal iliac artery flow. Further, as many as 40% of male patients may experience retrograde ejaculation due to disruption of autonomic nerve fibers at the aortic bifurcation. One should minimize dissection at the aorto-bifurcation to minimize the incidence of this complication.

Less commonly, aorto-enteric fistula formation may complicate 1% to 2% of open AAA repairs and may present from a few months to several years following surgery. Closure of the residual aneurysm wall and coverage with omentum when operating through the transperitoneal approach are important to reduce the incidence of this complication. Further, it appears that the extended left retroperitoneal approach may be associated with a reduced incidence of this very serious complication. Likewise, prosthetic graft infection may complicate 1% to 2% of open AAA repairs and may present in the early postoperative period to several years postoperatively. Careful attention to intraoperative hemostasis to avoid perigraft hematoma formation, careful wound closure, and perioperative broad spectrum antibiotic administration are key to preventing this complication. These principles will also minimize the development of abdominal wall hernias following the transperitoneal approach or abdominal wall laxity following the left retroperitoneal approach.

Endovascular Treatment of Abdominal Aortic Aneurysms

Richard P. Cambria, MD, and Scott G. Prutkin, MD

Abdominal aortic aneurysm (AAA) is defined as a 50% increase in diameter compared with the baseline diameter of a given blood vessel. There is a strong male predominance, with a male to female ratio of 6:1. AAA is fairly common, affecting 12% of men over age 65 and accounting for approximately 15,000 deaths annually in the United States. The average rate of growth of an AAA is approximately 3 mm/yr. Smoking increases the average annual growth by 20% and also increases the risk of rupture twofold. Multiple trials have established that an AAA should be repaired once it reaches a threshold of 5.5 cm in men and 5 cm in women.

Endovascular aneurysm repair (EVAR) was first performed in 1990 by Juan Parodi in Buenos Aires. The first EVAR was performed using a stainless steel bare metal stent sutured to a Dacron graft, which was then mounted on a large angioplasty balloon and crimped inside a large sheath. The graft was then inserted and deployed through an open exposure to the common femoral artery. This successful first procedure paved the way for the current era of endovascular aneurysm repair.

In the 29 years since EVAR was first introduced, the techniques and devices have been refined and improved. In 2003 EVAR surpassed open aneurysm repair as the preferred method, and currently approximately 80% of AAAs are repaired using an endovascular technique. EVAR has been shown to have a lower perioperative mortality rate, shorter hospital length of stay, and lower rates of early complications.

Several randomized controlled trials have compared endovascular and open aneurysm repair. These include the EVAR 1 trial, the DREAM trial, and the OVER trial. The results of the 3 trials are consistent and lead to similar conclusions. First, EVAR has lower perioperative and 30-day morbidity and mortality rates compared with open aneurysm repair. Second, the short-term survival advantage of EVAR diminishes with time, and there are equal mortality rates between the techniques at 2 years and beyond. Finally, EVAR is associated with higher long-term device-related complications as compared with open aneurysm repair. Therefore the planning, accuracy of deployment, and long-term follow-up with imaging are important to achieving a good long-term result.

Preoperative Planning

Precise preoperative planning is essential for short- and long-term outcomes after EVAR. Procedural success depends on several factors. Adequate iliofemoral access for device delivery, adequate proximal seal zone below the renal arteries, adequate distal seal between the graft limbs and the iliac arteries, and adequate length of overlap between components of the graft. To assess the patient's anatomy

before the procedure, a computed tomography (CT) angiogram with fine cuts (~2.5 mm) is a necessity. The axial, coronal, and sagittal images should be reviewed, along with three-dimensional (3D) reconstructions to perform pre-procedural measurements. There are several commercially available third-party software programs that can be used to create these reconstructed images. These programs include Vitrea, 3mensio, Terarecon, and Intellispace. These reconstructions show detailed images of the aortic lumen, branches, and aortic wall. The software can be used to generate a centerline through the aorta into both external iliac arteries, allowing for precise measurement of the distances between branch vessels to make an accurate plan in terms of the type and size of device. The length of the main body and corresponding iliac limbs are dictated by these careful centerline measurements performed using three-dimensional reconstructions. The CT angiogram is also used to carefully inspect the aortic neck morphology in terms of calcification, mural thrombus, and diameter. It is also important to carefully assess the iliofemoral access to safely introduce and deploy the endovascular device.

Assessing Access Vessels

Current endovascular technology requires bilateral access for device delivery, with the most common site of entry being the common femoral arteries. It is important to assess the iliofemoral vessels for patency, diameter, calcification, thrombus, and tortuosity. If there is significant common femoral disease, an endarterectomy may be required to facilitate placement of the delivery sheath. Luminal diameter should be carefully measured to ensure that it is sufficient for placement of the device sheath safely. Iliac stenosis can be managed with angioplasty before device sheath placement. Patients with small external iliac vessels may require the creation of an iliac conduit through a retroperitoneal incision using a 10 mm Dacron graft on the distal common iliac artery. Alternatively, an endoconduit can be performed by placing a 10 mm covered stent graft followed by angioplasty. Tortuous iliac arteries are generally straightened with the use of a stiff guidewire; however, severe tortuosity may preclude safe delivery of the device.

Proximal Aortic Seal

Achieving appropriate proximal seal between the endovascular device and the aorta depends on adequate apposition between the graft and nonaneurysmal aorta. The minimum length required for adequate seal varies between 10 and 15 mm depending on the device (Table 1). Adequate seal is assessed by measuring the aortic diameter below the level of the lowest renal artery and in 5 mm increments cranially to assess for a conical neck. The seal zone should be assessed for angulation relative to the adjacent aorta, calcification, and mural thrombus. It is important to perform these measurements in centerline, perpendicular to the wall of the aorta to ensure adequate graft sizing. If measurements are made on axial CT angiography without taking into account the centerline, the aortic neck diameter can be overestimated, leading to oversizing of the endograft and fabric infolding, resulting in possible type Ia endoleak. The proximal endograft is then oversized approximately 10% to 20% relative to the diameter of the aorta and the seal zone.

Distal Iliac and Junctional Seal

A nonaneurysmal distal seal zone is required in the common iliac artery for adequate distal fixation. The current devices require either 10 or 15 mm of length for adequate seal. If the common iliac artery is aneurysmal and adequate seal cannot be achieved, the graft may be landed in the external iliac artery. If the graft is sealing in the external iliac artery, the internal iliac artery must be embolized either before or as part of the aneurysm repair to prevent endoleak. In patients for whom it is important to preserve blood flow to one or both of the internal iliac arteries, there is a commercially available iliac branch endograft that places a second bifurcated component into the external and internal iliac arteries to preserve pelvic flow. Iliac artery diameter measurements should be taken perpendicular to the wall of the artery, again taking advantage of the 3D reconstruction software and using the centerline measurement. Iliac limbs should be oversized between 10% and 20% just as in the proximal aortic fixation. Junctional seal should be maintained between components, generally about 3 cm of overlap, depending on the device. Once the device is placed, angioplasty should be performed on the overlap zone to prevent type III endoleak.

Patient Selection

As mentioned previously, the major selection criteria for endovascular aneurysm repair are anatomic factors that can be used to predict outcomes. These include the diameter of the aortic neck, the length of the neck, angulation, and the distal iliac seal zone. There are currently 6 commercially available endovascular aneurysm devices that are approved by the Food and Drug Administration in the United States (Table 1). These current devices recommend a neck length between 10 and 15 mm and angulation between 0° and 60 degrees. One exception is the neck angulation in the Anaconda device, which allows for neck angulation up to 90 degrees. Generally, neck diameters up to 32 mm can be accommodated by current grafts.

Adherence to the instructions for use is vital to good short- and long-term outcomes. In general, vascular surgeons have had low rates of adherence to the instructions for use. It has been shown that nonadherence leads to a higher rate of endoleak and corresponding AAA sac diameter growth at 5 years. This puts patients at risk for rupture and requires a higher intervention rate. Therefore patients who have anatomy that is not suitable for endovascular repair should be offered open surgical repair or fenestrated EVAR.

PROCEDURAL STEPS

Arterial Access

Open Femoral Access

Either a vertical or oblique skin incision is made overlying the common femoral pulse just below the inguinal ligament. The vertical incision includes the advantage of getting additional exposure to the iliac and femoral vessels if necessary; however, the oblique incision is favored by many surgeons due to a lower incidence of wound complications. The common femoral artery is dissected distal to the inguinal ligament and controlled with vessel loops. An 18 gauge access needle is then inserted into a distinct free portion of the artery, and a 0.035" starter wire is advanced into the proximal aorta. A short sheath is placed over the wire and into the common femoral artery. A stiff wire, either an Amplatz or Lunderquist wire, is inserted into the descending thoracic aorta. A pigtail catheter with multiple 1 cm markers is introduced on the contralateral side in place just above the renal arteries. The patient is then systemically heparinized.

Percutaneous Femoral Access

Percutaneous access for EVAR has increased in popularity over the past 10 years. This approach has the advantage of shorter procedure times, less postoperative pain, and decreased risk of wound complications. Disadvantages of this approach include increased hospital costs and occasional urgent conversion to open access and arterial repair. We recommend routine use of ultrasound guidance with percutaneous access to help identify an area on the anterior wall of the common femoral artery that is free of atherosclerotic plaque. A small transverse stab incision is made with an 11 blade just below the probe. The tract is then dilated above the artery using blunt dissection with a hemostat. A micropuncture needle is then inserted into the common femoral artery under ultrasound guidance, followed by the micropuncture wire and sheath. At this point arteriography is performed to ensure adequate positioning of the arterial access in the common femoral artery before ejecting the sheath. If satisfied with the access

TABLE 1 Characteristics of Currently Available Endovascular Devices

Device	Graft/Stent Material	Treatable Aortic Neck Diameter (mm)	Main Body Diameter (mm)	Delivery System and Main Body Size (Fr)	Proximal Neck Angulation and Length	Distal Fixation Length (mm)	Fixation	Design Features
Endurant	ePTFE stent	19–32	23–36	14–16/22–25	>15 mm and ≤60 degrees	8–25	10	Infrarenal	Repositionable proximal delivery system to achieve accurate proximal landing zone
Zenith Flex	4 mm polyester stainless steel	18–32	22–36	21/14–16	≥15 mm and ≤60 degrees	7.5–20	>10	Suprarenal	Partial proximal repositioning; shortened Z-stents inhibit kinking
Endurant II	4 mm polyester stent	19–32	23–36	18/14–16	>10 mm and ≤60 degrees or ≥15 mm and ≤75 degrees	8–25	≥15	Suprarenal	Approved for treatment of 10 mm proximal aortic neck
AFX	ePTFE cobalt chromium alloy	18–32	25–38	1–39	≥15 mm and ≤60 degrees	10–20	≥10	Infrarenal or Suprarenal	Unibody device provides anatomic fixation on aortic bifurcation
Ovation	ePTFE stent	16–30	20–34	14–15/22–25	>10 mm and ≤60 degrees or ≤10 mm and ≤45 degrees	8–25	>10	Suprarenal	Smallest delivery sheath; proximal sealing ring with Polymer
Aorfix	4 mm polyester stent	19–29	24–36	22/26	≥15 mm and ≤90 degrees	—1,	≥15	Infrarenal	Ability to treat aortic necks with severe angulation

this, a 0.035 guidewire is placed, followed by a sheath. Next, the sheath is removed, the Proglide is placed over the wire, and the wire is removed. The first Proglide is deployed in the 10 o'clock position, and the sutures are clamped with a straight snap. The 0.035 wire is replaced, the Proglide is removed, and manual pressure is held while the next Proglide device is placed over the wire. The wire is again removed, and the sutures are deployed in the 2 o'clock position. The sutures are then clamped with a curved snap and the wire is again replaced. After the Proglide is removed, manual pressure is held, and an 8Fr sheath is placed for hemostasis. This is repeated on the contralateral side. The patient is then systemically heparinized. On the ipsilateral side the wire is exchanged for either an Amplatz or a Lunderquist wire to facilitate the placement of a large sheath. A marker pigtail catheter is placed just above the renal arteries on the contralateral side.

Device Deployment

We will describe the steps here for the deployment of a bifurcated modular graft because this is the most commonly used device. After bilateral open or percutaneous femoral access is performed, a floppy Glidewire is placed into the proximal thoracic aorta and exchanged over a catheter for a stiff wire, either Amplatz or Lunderquist. It is important always to visualize the tip of the stiff wire in the aortic arch to minimize inadvertent placement in the arch vessels, increasing the risk of stroke. A pigtail catheter is then placed through the contralateral side and placed just above the level of the renal arteries generally at about the T1 vertebral body. If there is a question about iliac occlusive disease or about the length of main body needed, an angiogram can be obtained now to make length measurements. However, usually the main body is inserted through the ipsilateral side in the undeployed position, and angiography is performed to confirm the position of the renal arteries.

To properly deploy the main body, the contralateral gate should be oriented under fluoroscopy before insertion. The orientation should be confirmed as the device is being advanced to avoid the gate spinning to a difficult position to cannulate. Once the undeployed graft is placed in the paravisceral aorta, angiography is performed to confirm the position of the lowest renal artery, which is then marked on the screen. Initial deployment should begin about 1 cm above the renal arteries, and, as the graft is deployed it is slowly pulled down below the lowest renal artery. After the proximal landing zone is established, the deployment continues until the contralateral gate is open. At this point, the bare metal suprarenal stent is deployed for the devices that have it.

The next step is cannulation of the contralateral gate. This is generally performed using a Glidewire and catheter. It is important to confirm that the wire tracked has passed through the contralateral gate. This can be done by either placing a pigtail into the main body to ensure that it goes easily because it will be constrained behind the graft if not through the gate or by inflating an angioplasty balloon at the level of the contralateral gate and spinning the gantry to confirm its position within the gate. Once this is done a stiff wire is placed, and the gantry is moved to 20-degree left anterior oblique for the right common iliac artery or right anterior oblique for the left common iliac artery. Angiography is then performed using the marker catheter to measure the length from the distal graft to the iliac bifurcation. The appropriate limb is then inserted with the least minimal overlap between device components and landed just above the takeoff of the internal iliac artery. At this point the ipsilateral limb is fully deployed, and, if necessary and depending on the device, an ipsilateral iliac limb extension is advanced and deployed in a similar manner to the contralateral limb.

Once the graft is fully deployed, a compliant balloon may be used for gentle angioplasty of the aortic neck, device overlap zones, and distal seal. It is important not to be overly aggressive with angioplasty so as not to cause proximal aortic or iliac artery rupture. After this, completion angiography is performed. The angiographic catheter is placed in the proximal aorta, and the following should be carefully inspected on the angiogram: patency of the renal and internal iliac arteries, position of the proximal seal zone, flow through the graft and iliac arteries bilaterally, and inspection for endoleak.

Once the surgeon is satisfied with the result, femoral closure is performed. If open access was performed, the wires and sheaths are removed, the arteries are clamped, and repair is performed, transversely with 5-0 Prolene suture. If percutaneous access was used, the sheath is removed, while leaving the wires in place to maintain access, and the ProGlide device sutures are cinched down. Once adequate hemostasis is obtained, the wires can be safely removed.

Follow-up

Patients return to the office for follow up at 1 month after surgery, at which time a CT angiography of the abdomen and pelvis is performed, which serves as the baseline study. Repeat CT angiography is performed at 1 year after surgery. Presence or absence of endoleak and aortic sac regression are determined by CT angiography, and follow up is performed annually. Patients with shrinking aneurysm sacs and no evidence of endoleak can be safely managed with yearly duplex ultrasound scanning. Patients with enlarging sacs or endoleaks are best monitored with yearly CT angiography.

COMPLICATIONS

Endoleak

Endoleak is defined as persistent blood flow to the aneurysm sac after endovascular aneurysm repair. This results in continued pressurization of the aneurysm sac, which places the patient at continued risk of aneurysm growth and ultimately rupture. Endoleaks can be classified in to one of five categories (Fig. 1), which help to determine the best course of treatment.

Type I Endoleak

Type I endoleak (Fig. 2) occurs as a result of an incomplete seal at either the proximal aortic sealing zone (Type Ia) or the distal iliac seal zone (Type Ib). This results in continued pressurization of the aneurysm sac, leading to sac growth. Type I endoleak is generally encountered at the time of stent graft placement or shortly thereafter, although it can be encountered at any time. Because this pressurization and aneurysm growth leads to continued risk of rupture, treatment of type I endoleak is mandatory. Proximal, Type Ia endoleak can be treated with angioplasty with a compliant balloon, proximal extension cuff if there is adequate length below the renal arteries, placement of a Palmaz stent, or with the use of the Aptus Endovascular

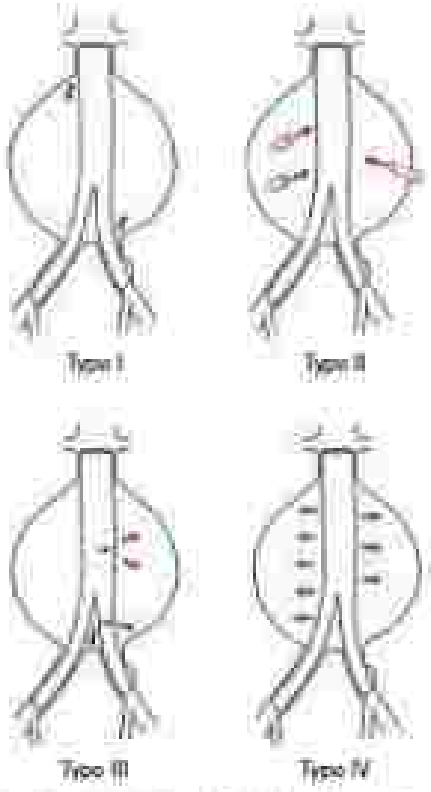

FIG. 2 Type I to IV endoleaks. Type I endoleak originates from an incomplete seal at the proximal (type Ia) and distal (type Ib) seal zone of the endograft. Type II endoleak, the site most commonly treated, results from retrograde flow of blood into the aneurysm sac from a patent branch vessel, such as the inferior mesenteric artery and lumbar arteries. Type III endoleak originates from a defect in the graft fabric and from junctional tears between graft components. Type IV endoleak results from porosity in the graft fabric.

FIG. 3 Type Ia (proximal) endoleak originating from the superior seal zone of an endograft.

Repair Systems. Treatment of type Ib endoleak can be done by deploying an iliac limb extension with embolization of the proximal iliac artery as necessary.

Type II Endoleak

Type II endoleak (Fig. 4) is defined as persistent sac filling from back bleeding side branches such as the inferior mesenteric artery, lumbar arteries, or middle sacral artery. Type II endoleak is relatively

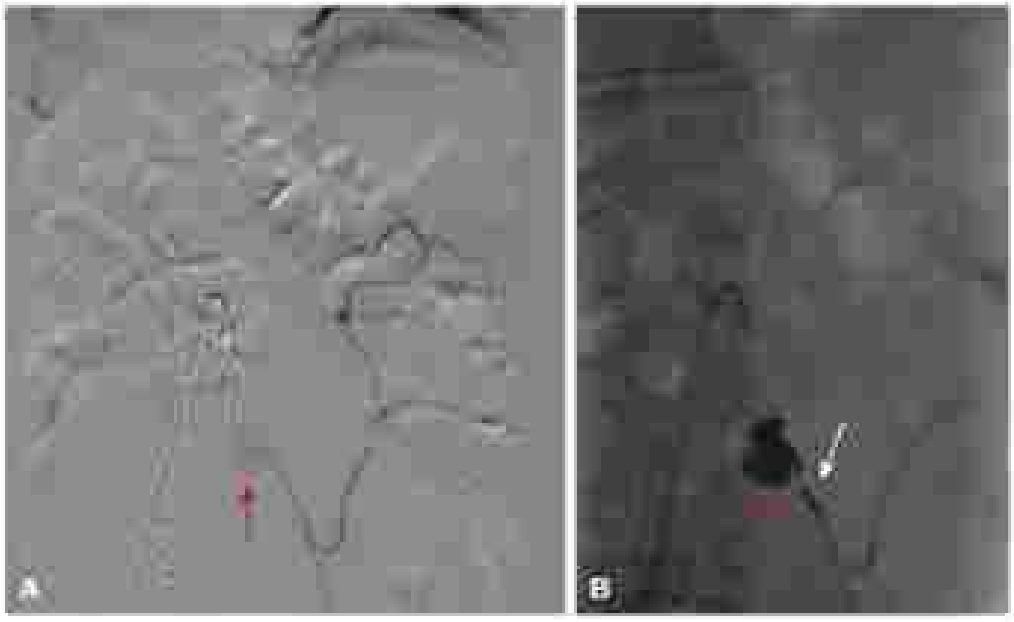

FIG. 4 Type II endoleak from the inferior mesenteric artery. (A) Angiography performed via retrograde catheter placement in the superior mesenteric artery demonstrates a filling defect at the origin of the inferior mesenteric artery feeding an enlarging abdominal aortic aneurysm sac. (B) Coil embolization of the endoleak with Onyx glue (red arrow) and coil embolization (white arrow) of the inferior mesenteric artery.

common and seen in between 10% and 20% of patients on CT angiograms after EVAR. Generally, there is a benign course with as many as 80% spontaneously resolving within 6 to 12 months of stent graft placement. It has been shown in multiple studies that the risk of aneurysm rupture due to type II endoleak is small. Therefore treatment is only performed if there is documented sac enlargement. Treatment is generally performed through endovascular means using coil embolization or Onyx Liquid Embolic System (ethylene vinyl alcohol copolymer). This embolization can be performed through a transarterial approach via the superior mesenteric artery or internal iliac arteries. It can also be performed from the iliac arteries and directly accessing the aneurysm sac from behind the iliac limb. If transarterial embolization is unsuccessful, embolization can be attempted via either a translumbar or transcaval approach. If embolization is unsuccessful by all means and the sac continues to grow, open sac intervention can be performed by explant of the graft and open repair or distal ligation of back bleeding vessels.

Type III Endoleak

A type III endoleak (Fig. 5) occurs when there is a tear in the fabric of the graft or flow between separate components of the graft. This leads to continued pressurization and sac enlargement increasing the risk of rupture as in type I endoleak. Therefore treatment of type III endoleak is again mandatory. Treatment involves placement of a cuff or a new limb to bridge the gap between separated components. Treatment may require relining the graft with a new stent graft, which is generally performed using an aorto-uni-iliac device along with a femoral-femoral bypass and coil embolization of the contralateral common iliac artery.

Type IV Endoleak

Type IV endoleak is related to flow through the graft due to the porosity of the fabric. It is rare to encounter this type of endoleak with the current generation of stent grafts. Typically, no treatment is necessary, and the endoleak resolves as the graft interstices thrombose.

Type V Endoleak

This type of endoleak is referred to as endotension and is defined as sac enlargement without an identifiable endoleak on imaging studies.

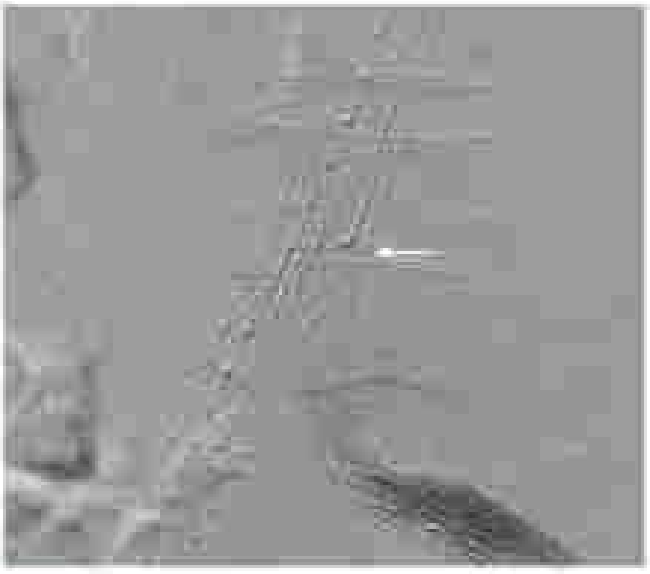

FIG. 5 Type III endoleak from separation of the limb from the main body of the graft (arrow).

There are several proposed theories behind type V endoleak. One theory is that the flow into the aneurysm sac is so slow that it cannot be detected with current imaging techniques. Another theory postulates that pressure is transmitted across thrombus in the aneurysm sac maintaining sac pressure. Regardless of the mechanism, continued sac pressurization leads to ongoing risk of rupture. Close follow-up is recommended to determine the rate of growth and the necessity of repair. Repair is performed through relining with a new graft or with explant and open repair.

Graft Limb Occlusion

Occlusion of one graft limb occurs in about 3% of patients and usually occurs in the first 6 months after EVAR. It is more common with

aortoiliac occlusive disease, a small distal aorta, or tortuous iliac arteries. It was more common in stent grafts with unsupported limbs; however, in the current generation of stent grafts, with supported limbs, lower limb occlusion rates have been noted. Most patients with limb occlusions present with buttock, thigh, or calf claudication. Rest pain or acute limb ischemia occur but are less common. Several approaches have been used to treat limb thrombosis including thrombolysis, angioplasty, and stent placement to straighten out kinks. Open surgical approaches include femoral-femoral bypass, axillary-femoral bypass, axillary-bifemoral bypass, or surgical thrombectomy.

Ischemic Complications

Ischemic complications after EVAR stem from one of several mechanisms, including direct vessel occlusion, atheroembolization during manipulation and device deployment, and inadequate collateralization of the mesenteric and pelvic circulations. Pelvic ischemia can present as buttock claudication, buttock necrosis, spinal cord ischemia, colon ischemia, and erectile dysfunction. Pelvic ischemia can occur frequently after EVAR, especially sexual dysfunction and buttock claudication, which should be discussed with the patient during the consent process. It generally occurs after embolization of one or both internal iliac arteries for the treatment of common iliac artery aneurysm. Buttock claudication can occur in more than 50% of patients with unilateral internal iliac artery embolization and more than 60% with bilateral internal iliac artery embolization. Erectile dysfunction occurs in 17% of patients with unilateral internal iliac artery embolization and 24% with bilateral embolization. Although the incidence of buttock claudication is relatively high, approximately two thirds of patients report resolution of symptoms within 1 year of EVAR. Although mesenteric ischemia has a high mortality rate after aneurysm repair, it is seen in less than 2% of endovascular procedures. Spinal cord ischemia is an extremely rare event after endovascular AAA repair and has been reported in less than 0.5% of cases.

Renal Artery Occlusion

Renal artery occlusion either occurs from coverage of the origin of the artery by the graft or through embolization. Upward movement of the graft after deployment is uncommon. Usually renal artery coverage is a complication that occurs as a result of deploying the graft too high, either from misjudging the location of the fabric relative to the radiopaque markers on the graft or due to parallax if there is improper gantry position. If coverage is detected on the completion angiogram, attempts should be made to salvage the kidney. If there is some flow identified over the top of the graft, this can usually be accomplished by placing a stent into the renal artery ostium, which is easiest from a left brachial approach. If the renal artery cannot be visualized and a wire cannot pass, it is sometimes possible to pull the graft down slightly to make a small channel for the wire. This can be accomplished with gentle traction downward with a compliant ball loon inflated to the main body or with a wire snared up and over, "flossing" the graft to allow for traction. If all of these techniques fail, open splenorenal or hepatorenal bypass may be necessary. Embolization to the renal arteries can present with early or delayed renal insufficiency. This is especially true when there is thrombus in the aorta neck and a graft with suprarenal fixation is used.

Management of Ruptured Abdominal Aortic Aneurysms

Andrew R. Ramaiah, MD, Sean P. Roche, MD, and Ross A. Clouse, Jr., MD

Delays in the diagnosis and treatment of patients presenting with a ruptured abdominal aortic aneurysm (rAAA) directly increase the risk of death and long-term morbidity. The establishment of aortic centers using a multidisciplinary team approach, established protocols for transfer, and expeditious treatment of acute aortic emergencies has improved patient care. For 50 years, the mortality rate of rAAA reaching a hospital has remained unchanged at 40% to 50%. However, in the last 2 decades, with a shift toward endovascular aneurysm repair (EVAR) for rAAA, this figure has decreased to around 20% to 30% in many studies. In 1991, the first use of endovascular methods for repair was reported and sparked interest in a resolution of a minimally invasive modality for rupture repair. Many hospitals have adopted preferential endovascular repair of ruptured abdominal aortic aneurysms (rEVAR), with only select individuals undergoing an attempt at open repair. Despite this, there have been four randomized studies that demonstrated no proven mortality benefit of rEVAR over open repair.

The best treatment is preventative or early detection. In the United States, The Centers for Medicare and Medicaid Services cover a one-time ultrasound screening for men aged 65 to 75 years who have smoked at least 100 cigarettes or anyone with a family history of abdominal aortic aneurysm (AAA). This highlights the fact that smoking is the strongest risk factor for aneurysm formation. Additional risk factors for rupture include size, rapid growth, tenderness over the aneurysm, chronic obstructive pulmonary disease, familial predisposition, and female sex.

PRESENTATION AND DIAGNOSIS

The classical triad defining the presentation of an rAAA is acute abdominal or back pain, hypotension, and a palpable abdominal

aortoiliac occlusive disease, a small distal aorta, or tortuous iliac arteries. It was more common in stent grafts with unsupported limbs; however, in the current generation of stent grafts, with supported limbs, lower limb occlusion rates have been noted. Most patients with limb occlusions present with buttock, thigh, or calf claudication. Rest pain or acute limb ischemia occur but are less common. Several approaches have been used to treat limb thrombosis including thrombolysis, angioplasty, and stent placement to straighten out kinks. Open surgical approaches include femoral-femoral bypass, axillary-femoral bypass, axillary-bifemoral bypass, or surgical thrombectomy.

Ischemic Complications

Ischemic complications after EVAR stem from one of several mechanisms, including direct vessel occlusion, atheroembolization during manipulation and device deployment, and inadequate collateralization of the mesenteric and pelvic circulations. Pelvic ischemia can present as buttock claudication, buttock necrosis, spinal cord ischemia, colon ischemia, and erectile dysfunction. Pelvic ischemia can occur frequently after EVAR, especially sexual dysfunction and buttock claudication, which should be discussed with the patient during the consent process. It generally occurs after embolization of one or both internal iliac arteries for the treatment of common iliac artery aneurysm. Buttock claudication can occur in more than 50% of patients with unilateral internal iliac artery embolization and more than 60% with bilateral internal iliac artery embolization. Erectile dysfunction occurs in 17% of patients with unilateral internal iliac artery embolization and 24% with bilateral embolization. Although the incidence of buttock claudication is relatively high, approximately two thirds of patients report resolution of symptoms within 1 year of EVAR. Although mesenteric ischemia has a high mortality rate after aneurysm repair, it is seen in less than 2% of endovascular procedures. Spinal cord ischemia is an extremely rare event after endovascular AAA repair and has been reported in less than 0.5% of cases.

Renal Artery Occlusion

Renal artery occlusion either occurs from coverage of the origin of the artery by the graft or through embolization. Upward movement of the graft after deployment is uncommon. Usually renal artery coverage is a complication that occurs as a result of deploying the graft too high, either from misjudging the location of the fabric relative to the radiopaque markers on the graft or due to parallax if there is improper gantry position. If coverage is detected on the completion angiogram, attempts should be made to salvage the kidney. If there is some flow identified over the top of the graft, this can usually be accomplished by placing a stent into the renal artery ostium, which is easiest from a left brachial approach. If the renal artery cannot be visualized and a wire cannot pass, it is sometimes possible to pull the graft down slightly to make a small channel for the wire. This can be accomplished with gentle traction downward with a compliant balloon inflated to the main body or with a wire snared up and over, "flossing" the graft to allow for traction. If all of these techniques fail, open splenorenal or hepatorenal bypass may be necessary. Embolization to the renal arteries can present with early or delayed renal insufficiency. This is especially true when there is thrombus in the aorta neck and a graft with suprarenal fixation is used.

Management of Ruptured Abdominal Aortic Aneurysms

Andrea R. Ramdass, MD, Sean P. Roddy, MD, and R. Clement Darling III, MD

Delays to the diagnosis and treatment of patients presenting with a ruptured abdominal aortic aneurysm (rAAA) directly increase the risk of death and long-term morbidity. The establishment of aortic centers using a multidisciplinary team approach, established protocols for transfer, and expeditious treatment of acute aortic emergencies has improved patient care. For 50 years, the mortality rate of rAAA reaching a hospital has remained unchanged at 40% to 50%. However, in the last 2 decades, with a shift toward endovascular aneurysm repair (EVAR) for rAAA, this figure has decreased to around 20% in many studies. In 1991, the first use of endovascular methods for repair was reported and sparked interest in a resolution of a minimally invasive modality for rupture repair. Many hospitals have adopted preferential endovascular repair of ruptured abdominal aortic aneurysms (rEVAR), with only select individuals undergoing an attempt at open repair. Despite this, there have been four randomized studies that demonstrated no proven mortality benefit of rEVAR over open repair.

The best treatment is preventative or early detection. In the United States, The Centers for Medicare and Medicaid Services cover a one-time ultrasound screening for men aged 65 to 75 years who have smoked at least 100 cigarettes or anyone with a family history of abdominal aortic aneurysm (AAA). This highlights the fact that smoking is the strongest risk factor for aneurysm formation. Additional risk factors for rupture include size, rapid growth, tenderness over the aneurysm, chronic obstructive pulmonary disease, familial predisposition, and female sex.

PRESENTATION AND DIAGNOSIS

The classical triad defining the presentation of an rAAA is acute abdominal or back pain, hypotension, and a palpable abdominal

mum. This full complement continues to infrequent, and there are many disorders that can be concomitant with an asymptomatic AAA or even mask the presentation. A perforated viscus, peptic ulcer disease, cholecystitis, cholecystitis, myocardial infarction, pericarditis, pancreatitis, and kidney stones are some of the differential diagnoses that should always be entertained. The converse is also true, because one always should have a high index of suspicion for rupture in any individual with an AAA. rAAAs can mimic other causes by presenting with pain radiating to the groin, dysuria, syncope, gastrointestinal bleeding, and bowel obstruction.

Initial evaluation follows airway, breathing, and circulation protocol. Depending on the acuity of the presentation, this may make the diagnosis challenging. Large bore intravenous access should be commenced with a full physical examination. Although many patients present with hypotension, we strongly believe in hypotensive hemostasis and do not give vigorous fluid resuscitation until the patient is in the operating room, where proximal arterial control can be expeditiously obtained. Abdominal ultrasonography, although sensitive enough for AAA, does not have the specificity to diagnose rupture. Upright chest radiography may be useful to rule out a perforated viscus and may show calcifications in the abdominal aorta. The best imaging to detect an rAAA is computed tomography (CT) with intravenous contrast of the abdomen and pelvis. CT scans give a definitive diagnosis and objective measurements on whether the rAAA is amenable to endovascular repair. (See Fig. 1 showing CT scans of a computerized AAA rupture, which is amenable to rEVAR.) In most emergency departments, CT scanning is readily available without delay. However, if the patient is unstable and there is suitable clinical evidence that the patient has an rAAA, then they should be transported directly to the operating room for expeditious treatment.

ENDOVASCULAR VERSUS OPEN REPAIR

As mentioned earlier, the NOTTINGHAM, IMPROVE, ECAR, and AJAX randomized rAAA trials compared open to endovascular repair for rAAAs and did not show any survival advantage for the rEVAR group. Reported results using EVAR for rAAA have been similar in most large single center series with around a 20% mortality rate, even to the series by Mayer et al where all consecutive rAAA were treated by an all EVAR approach. Most institutions have adopted an EVAR first approach, but any center taking on rAAA should be comfortable with both procedures. There may be some distinct advantage for EVAR. For example, rEVAR patients are more likely to be discharged home, with a lower incidence of blood loss and cardiac complications but a higher incidence of abdominal compartment syndrome. Limitations, to be amenable to endovascular repair, include several anatomic features:

- Aortic neck diameter less than 32 mm
- Aortic neck angulation less than 60 degrees
- Limited aortic neck thrombus/calcification (relative)
- Parallel wall and undilated neck length (1 cm or more) below low renal artery
- Iliac arteries usable and without excessive tortuosity to accommodate device delivery and a 10 mm end zone

However, many take a more liberal approach in evaluating suitability and one needs to acknowledge that these may be outside the official instructions for use and not universally accepted or approved by the United States Food and Drug Administration (FDA). There are currently six FDA approved infrarenal devices that are available for elective repair in the United States, all of which have various forms of data on their use with ruptured aneurysms. However, it is estimated that between one half to three quarters of rAAA are amenable to rEVAR. As the technology grows, adjuncts such as snorkel, chimney, stapled or even fenestrated or branch devices may broaden the choices for repair.

RUPTURE PROTOCOL

Time to aortic occlusion, or cessation of hemorrhage, is key and of the utmost importance. However, it is also important to transport the patient to the appropriate facility for definitive care. Warner et al demonstrated that transfer of patients to an aortic center from smaller regional hospitals with rAAA did not increase and maybe even decreased mortality rates. The caveat to this study was that there was an "all accept" policy and one number to call to facilitate transfer. Hinchliffe et al showed that CT does not delay time to operating room versus the French randomized trial, which suggested that EVAR delayed timing to surgery greater than twofold. The author's own institution has an average time to operation of 10 to 35 minutes. No other vascular surgery pathology has a more devastating consequence with delays. Lloyd et al showed that greater than 80% of patients died within 2 hours after diagnosis of a ruptured aneurysm. As a result, benefits of a contrast CT in the stable patient can be rewarding to determine the possibility of rEVAR inclusive of accessible neck and sizing, as well as ruling out other pertinent disease.

FIG. 1 (A) Transaxial imaging showing the large retroperitoneal hematoma (hematoma) draping over the vertebral body (B) Coronal image showing the extent of the hematoma

Unstable patients can be taken directly to the operating room. The concept of "hypotensive hemostasis" or permissive hypotension is contrary to the thought process of most physicians and health care employees, but the concept must be enforced to limit blood loss, rerupture, and further aortic tearing. On presentation, we are more concerned about end organ perfusion than strict blood pressure. If the patient is hemodynamically unstable with systolic pressures around 80 mm Hg, we complete the workup and preparations expeditiously on the way to the operating room. The endovascular first approach allows for aortic control with a percutaneously placed occlusion balloon in the descending thoracic aorta similar to the REBOA technique recently adopted in the trauma literature. The amenability to rEVAR is then based on the initial aortogram. If the anatomy is not amenable to endovascular repair, the endovascular aortic control proves to be invaluable as an "aortic cross clamp" similar to supraceliac aortic control or thoracic aortic control without the added morbidity of a thoracotomy. See Fig. 2 with an aortogram showing amenability to rEVAR with the aortic occlusion balloon inflated.

TECHNIQUE OF REPAIR

A multidisciplinary team consisting of vascular surgeons, anesthesiologist, emergency department physicians, radiology technicians, and operating room staff knowledgeable of endovascular techniques and a standardized protocol to the treatment are essential to the performance of the procedure and therefore survival of the patient. The operating room should be capable of both open and endovascular techniques. Over the past 40 years we have managed more than 1000 rAAA. We have evolved from initially performing them via the transabdominal approach to the open extended paramedian retroperitoneal approach as described by Mel Williams, and now to EVAR in more than 75% of the cases. As previously reported by Wanhainen et al, we have set up a network for transfer of aortic emergencies. In that article, we demonstrated that transfer was feasible and lowered mortality rates for rAAA. This corroborated other reports that show that low volume hospitals had a higher mortality rate even if the same board certified vascular surgeons performed the repair in the low volume hospitals. Most patients have had preoperative imaging and, if transferred from other hospitals, can have CT scan images transferred electronically well before the patient arrives at the aortic center. This provides the receiving institution the ability to assess the suitability for EVAR and prepare the hybrid room. If deemed unsuitable for EVAR, the staff can prepare for an open procedure. In those instances when the patient is unstable and no images are available, one has to approach the procedure in the way the surgeon and staff are most comfortable. Historically, 50% of intraoperative deaths were from venous injuries obtaining aortic control. Thus, as surgeons become less familiar with open aortic exposure, most feel more comfortable obtaining femoral access, placing an occlusion balloon, and then proceeding with either EVAR or open repair depending on the interpretation of the angiogram obtained after aortic occlusion. Remember that this has to be done quickly, and progress made without delay to definitive treatment, thus reinforcing the need for institutional and surgeon experience in rAAA.

FIG. 2 Aortogram with aortic occlusion balloon inflated.

Technique of Repair: Endovascular Repair

The endovascular approach should have a variety of off the shelf devices with possible endograft already lined up in the room to allow for easy and rapid deployment. Adjuncts, such as sheaths, wires, and catheters, should be readily available, and an aortic occlusion balloon should be opened and on the operating room table. The contralateral setup for possible open repair must be in the actual operating room.

Local anesthesia should be used, as was shown with the mortality benefit from the IMPROVE trial. At minimum, the patient should be prepped and draped for rapid aortic occlusion balloon for control before induction of anesthesia. Percutaneous femoral access under ultrasound or fluoroscopic guidance is followed by the placement of a stiff wire into the descending thoracic aorta, closed with a 12Fr introducer sheath and an occlusion balloon. Place the supporting sheath as far as possible to prevent the distal migration of the aortic balloon when circulation is restored. In an unstable patient, there may not be time for placement of closure devices before sheath placement, and the femoral arteries can be exposed and primarily repaired at the end of the case. It is not uncommon for the access vessel anatomy to be challenging. The arteries can be navigated with a guidewire that is chased with a flush- or angle-tipped catheter and then exchanged for stiffer wire. The key is to get through the iliac arteries without creating a dissection flap or tearing the artery. The next step is creating a stable platform for sheath placement. A stiff wire can be used to straighten tortuous iliac arteries, which may need to be relined with covered stent grafts (crack and pave technique). This will allow the endograft to seal within the covered stent. Often access vessel injury is not identified until after the endograft is in place and the sheaths are being removed. If an injury occurs, the large sheath usually tears the external iliac artery off of the common iliac artery at the origin of hypogastric artery while going in but seals the defect when repositioned. The key is to maintain wire access so that an occlusion balloon can be placed while a stent graft is used to bridge the gap and seal the bleeding temporarily in preparation for a covered stent. The use of an exchange length wire such as Lunderquist wire (Cook Medical) is invaluable because it will support the balloon in the descending aorta and limit the need for wire exchanges.

Once the occlusion balloon is in the appropriate position, make sure the anesthesia team is aware to allow for aggressive resuscitation. Images can then be gathered to determine whether the AAA is amenable to rEVAR through contralateral groin access using percutaneous methods with a preclose technique. The contralateral access can be used for a second stiff wire and introduction of the stent graft main body. We have found that crossing of the limbs offers the best configuration for cannulation of the contralateral gate. Once the device is in the appropriate position, the occlusion balloon must be retracted into the sac to prevent impinging and entrapment with deployment of the main body. Anesthesia must be prepared to treat some degree of resultant hypotension. Communication is important during the conduct of the case to maximize outcomes. Two approaches exist with respect to deployment of the main body. One method is to fully deploy the main body and retract the occlusion balloon into the aortic neck from the main body side. A second option is to continue cannulating the gate and proceed in the traditional fashion. Gate cannulation is the most time consuming and in 10% will require greater than 30 minutes for cannulation. It is important to have a variety of

cadaveric shapes and tip conformation to assist with cannulation. If all else fails, the bifurcated device can be converted to aortomonoiliac configuration, with the contralateral common iliac artery then embolized and a cryogenic bypass performed.

Another important clinical issue is whether bifurcated or aortomonoiliac endografts are better. The ARAS randomized trial used only aortomonoiliac endovascular grafts with the advantage of an easy learning curve and rapid control of abdominal hemorrhage, but it added time for the femoral-femoral crossover and increased risk of infection. In the acute setting, aortomonoiliac grafts may require general anesthesia as do the bilateral groin cutdown and tunneling of the femoral-femoral crossover bypass.

Once the graft of choice is deployed and the proximal, distal and connecting segments are ballooned, a completion aortogram is performed. See Fig. 3, a final aortogram showing complete sealing. Specifically, attention must be paid to ensure that there are no type I endoleaks (leaks at the area of fixation of the graft). Other useful adjuncts such as aortic coils, staples, stented chimney grafts, or a giant Palmaz stent may be used for type Ia endoleaks. For type Ib endoleak, sacrificing the hypogastric artery may be necessary for cessation of a distal seal. As the technology improves, newer devices off the shelf, such as the branch and fenestrated devices, may offer more advanced options for repair. Conversion to open ranges from 1% to 2% in most series and also has a mortality disadvantage.

Technique of Repair: Open Repair

Open repair has the option of a transperitoneal (TP) versus retroperitoneal (RP) approach. The TP approach uses a generous midline incision from the xiphoid bone to the symphysis pubis. If the aortic occlusion balloon is not used, supraaortic control can be obtained rapidly by mobilizing the left lateral lobe of the liver and retracting it to the right. The gastrohepatic ligament is incised and placed under tension, retracting the stomach to the left and downward with care taken to protect the left gastric or a replaced left hepatic. The esophagus (identified with nasogastric or orogastric tube) is identified and retracted away to the left. The right crura that is in full view is then divided with electrocautery to expose the supraaortic aorta. Attention is then shifted to the distal control at the level of the common iliac arteries and the distinction of the type of repair necessary. The more expedient repair is preferred, even with extensive iliac disease. Once the supraaortic clamp is applied, expeditious efforts should be made to move the clamp distally to perfuse the viscera. The infrarenal aorta is exposed by retracting the transverse colon cephalad and sweeping the small bowel to the right. Incision of the peritoneum by release of the ligament of Treitz allows the mobilization of the duodenum to the right and the anterior wall surface of the aorta. In a ruptured state with a clamp in situ, this can be challenging and care is needed to prevent further injuries. The goal at this point is to locate the renal arteries and find a suitable clamping site. After proximal and distal control is established, the sac is opened and repair is conducted in the standard fashion. Aortic arterial fistula presents a challenge wherein the sac open is met with robust bleeding from the right side of the aneurysm sac. Large bites of a nonabsorbable suture from inside the aneurysm sac along with aggressive suctioning with sponge sticks applied proximal and distally to attempt control is the best strategy to offer a chance of survival in this situation.

The RP approach is feasible in the acute setting with a bump or small bag to allow the left chest to be elevated at 60 degrees with the pelvis at 45 degrees. It is the standard for the authors to manage ruptures in this fashion because we have performed more than 600 rAAA repairs using this technique. Incision is made from the margin of the rectus (mid distance between the pubis and umbilicus to the tenth intercostal space). Dissection is performed through the three muscle layers with gentle care taken to prevent entry into the peritoneum. As the retroperitoneum is entered, the hematoma has usually done the dissection for you, and the bowel and ureter are swept toward the right, and the kidney is retracted toward the left shoulder. The surgeon's left hand can be slipped into the lateral gutter as the kidney and peritoneum can be retracted medial and cephalad. When moving each hand along the diaphragm, one will encounter the left crus. This allows excellent digital control of the supraaortic aorta. Once digital control is obtained and the patient is stabilized, one can incise the left crus and place an aortic clamp supraaortic, above or below the renal arteries.

FIG. 3 Final aortogram.

COMPLICATIONS

Ruptured aneurysms exponentially inflate the rate of complications compared with elective aneurysm repair. Keen attention to details to minimize preventable measures while limiting obstacles as much as possible is the key to survival. The postoperative period poses a significant challenge. Complications can generally be divided into systemic or specific organ systems. The generalized state of shock impacts on the all the tissues and is the major obstacle of the postoperative period. Myocardial infarction is reported to be as high as 25%, respiratory failure 40%, acute renal failure 40%, and sepsis 15%.

Bowel ischemia or infarction, colitis increases fivefold after ruptured aneurysm surgery. The risk factor for this is in part due to age and coverage of the inferior mesenteric artery, which are not controllable risk factors. Systemic hypotension alone is enough to cause colonic ischemia, coupled with the occasional need for coverage of one or both internal iliac arteries. The watershed area of the inferior mesenteric artery (i.e., the sigmoid colon) is logically affected first. The impact of bowel ischemia not only adds to the morbidity of the disease, but significantly increases mortality rates. Bowel movements during surgery, or even in the immediate perioperative time, should raise suspicions for colonic ischemia. Additionally, worsening of pain, bloody bowel movements, or both are important symptoms. A rapid rise in white blood cell count after surgery should also increase suspicion. It is routine practice at many centers that all ruptured aneurysms undergo sigmoidoscopy within the first 24 hours after repair. This can be performed with a bowel preparation enema and bedside sigmoidoscopy. Treatment for colonic ischemia is based on the degree of ischemic colon. Mild ischemia is usually treated with intravenous antibiotics, bowel rest, and close monitoring. Severe forms of colonic ischemia need rapid bowel resections.

Abdominal compartment syndrome in rAAA ranges up to 20%. A large retroperitoneal hematoma presents a space-occupying lesion coupled with large fluid volumes for resuscitation, leading to intestinal edema with resultant increased pressure on the renal vein and inferior vena cava, subsequently impeding venous drainage leading to

renal dysfunction and hypovolemic shock. Pressure on the diaphragm reduces lung volumes. Massive transfusion, coagulopathy, and use of aortic occlusion balloons have all been linked to abdominal compartment syndrome. Open transperitoneal repair offers removal of a large portion of retroperitoneal hematoma, direct assessment of abdominal wall laxity, and the opportunity to leave the fascia open as damage control. The retroperitoneal approach is unique in that it must be closed primarily. In that situation, a transperitoneal laparotomy is necessary, leaving the fascia open. Usually this diagnosis is based on clinical suspicion, because overt signs of compartment syndrome signify a delayed diagnosis, which exponentially increases mortality risk. Adjuncts such as bladder pressure and peak airway pressure monitoring can be used to detect early rising toward compartment syndrome.

Access-related complications are frequent and mitigated with an armamentarium of endovascular and open techniques. Chronically occluded iliac arteries can be difficult to navigate, but the more worrisome and dreaded is the ruptured external iliac artery as the previously placed sheath, which tamponaded the tear, is removed from the patient. Having several sized covered stent grafts and maintaining wire access usually solves this issue. An occlusion balloon is inflated, followed by rapid deployment of a covered conduit, which can typically treat the tear. Thrombosis and acute occlusion of the stent graft limbs or native iliac arteries is not unusual. This is effectively treated by use of an embolectomy catheter after cutdown on the femoral artery or arteries or, in the worst case, by femorofemoral crossover bypass. Always be suspicious of a kinked or stenotic stent graft limb in acute occlusion. Distal ischemia from emboli is also treated with embolectomy in the standard fashion. The use of heparin is based on individual practice patterns. There exists a combination of practices, ranging from heparin after aortic control, to half dosing, to no anticoagulation due to the inherent hypercoagulable state induced by shock.

Acute renal failure may occur due to a combination of hypotension and any form of aortic clamping/manipulation. Additionally, the contrast agent used in rEVAR is additive to the renal impairment.

CONCLUSION

rAAA is one of the most devastating disorders treated by surgeons. Despite many advances in the field since the endovascular revolution, survival remains poor. Active screening programs, multidisciplinary aortic care centers, and smoking cessation programs have shown a reduction of the rupture repairs. Nevertheless, it must be entertained in the differential diagnosis with abdominal pain and considered in unusual presentations. Once a diagnosis is made, transfer the patient to a center equipped to care for acute aortic emergence with capabilities for rapid delivery of endovascular and open repair. These centers must have specialized capabilities to handle the complications to enhance the possible outcomes.

Abdominal Aortic Aneurysm and Unexpected Abdominal Pathology

Aarona M. P[illegible], D, and Natal a "Ra [illegible] a, , D, ,h D

Abdominal aortic aneurysm (AAA) is a typically asymptomatic condition with potentially life-threatening complications if ruptured. The management of ruptured AAAs is an emergent setting is well understood, but the management of concomitant intraabdominal pathologies at the time of elective aneurysm surgery, a rarely encountered situation, is less well documented. Although endovascular aneurysm repair (EVAR) or retroperitoneal open approaches may be encouraged with concomitant intraabdominal pathology, these may not always be possible. This chapter aims to organize the two pathologies along two axes of decision-making, based on these axes, we propose management recommendations and raise questions that warrant further inquiry.

GENERAL MANAGEMENT OF AAA AND CONCOMITANT PATHOLOGY

We believe that AAA management with concomitant pathology should be organized along two axes. The first axis concerns whether the AAA repair is emergent. Along these lines, the concomitant pathology should be evaluated. Is it emergent, urgent, or nonurgent? This helps to clearly delineate the prioritization of pathologies present and direct management of each. The second important axis of management concerns the degree of contamination involved with the concomitant pathology organ system. For instance, biopsy of a retroperitoneal lesion may be considered a sterile concomitant procedure, whereas biopsy of an intestinal lesion would expose an aortic graft to contaminated flora.

EMERGENT AAA REPAIR AND COEXISTING PATHOLOGY

If emergent AAA repair is being attempted and resources allow for an endovascular repair, this should be attempted; however, certain

renal dysfunction and hypovolemic shock. Pressure on the diaphragm reduces lung volumes. Massive transfusion, coagulopathy, and use of aortic occlusion balloons have all been linked to abdominal compartment syndrome. Open transperitoneal repair offers removal of a large portion of retroperitoneal hematoma, direct assessment of abdominal wall laxity, and the opportunity to leave the fascia open as damage control. The retroperitoneal approach is unique in that it must be closed primarily. In that situation, a transperitoneal laparotomy is necessary, leaving the fascia open. Usually this diagnosis is based on clinical suspicion, because overt signs of compartment syndrome signify a delayed diagnosis, which exponentially increases mortality risk. Adjuncts such as bladder pressure and peak airway pressure monitoring can be used to detect the early trending toward compartment syndrome.

Access-related complications are frequent and mitigated with an armamentarium of endovascular and open techniques. Chronically occluded iliac arteries can be difficult to navigate, but the more worrisome and dangerous is the ruptured external iliac artery at the previously placed sheath, which compounded the scar, is removed from the patient. Having several sized covered stent grafts and maintaining wire access usually solves this issue. An occlusion balloon is inflated, followed by rapid deployment of a covered conduit, which can typically treat the tear. Thrombosis and acute occlusion of the stent graft limbs or native iliac arteries is not unusual. This is effectively treated by use of an embolectomy catheter after cutdown on the femoral artery or arteries or, in the worst case, by femorofemoral crossover bypass. Always be suspicious of a kinked or stenotic stent graft limb in acute occlusion. Distal ischemia from emboli is also treated with embolectomy in the standard fashion. The use of heparin is based on individual practice patterns. There exists a combination of practices, ranging from heparin after aortic control, to half dosing, to no anticoagulation due to the inherent hypercoagulable state induced by shock.

Acute renal failure may occur due to a combination of hypotension and any form of aortic clamping/manipulation. Additionally, the contrast agent used in rEVAR is additive to the renal impairment.

CONCLUSION

rAAA is one of the most devastating disorders treated by surgeons. Despite many advances in the field since the endovascular revolution, survival remains poor. Active screening programs, multidisciplinary aortic care centers, and smoking cessation programs have shown a reduction of the rupture repairs. Nevertheless, it must be entertained in the differential diagnosis with abdominal pain and considered in unusual presentations. Once a diagnosis is made, transfer the patient to a center equipped to care for acute aortic emergence with capabilities for rapid delivery of endovascular and open repair. These centers must have specialized capabilities to handle the complications to enhance the possible outcomes.

Abdominal Aortic Aneurysm and Unexpected Abdominal Pathology

Aarona M. Ali, MD, and Natalia Glebova, MD, PhD

Abdominal aortic aneurysm (AAA) is a typically asymptomatic condition with potentially life-threatening complications if ruptured. The management of ruptured AAAs is an emergent setting is well understood, but the management of concomitant intraabdominal pathologies at the time of elective aneurysm surgery, a rarely encountered situation, is less well documented. Although endovascular aneurysm repair (EVAR) or retroperitoneal open approaches may be encouraged with concomitant intraabdominal pathology, these may not always be possible. This chapter aims to organize the two pathologies along two axes of decision-making, based on these axes, we propose management recommendations and raise questions that warrant further inquiry.

GENERAL MANAGEMENT OF AAA AND CONCOMITANT PATHOLOGY

We believe that AAA management with concomitant pathology should be organized along two axes. The first axis concerns whether the AAA repair is emergent. Along these lines, the concomitant pathology should be evaluated: Is it emergent, urgent, or nonurgent? This helps to clearly delineate the prioritization of pathologies present and direct management of each. The second important axis of management concerns the degree of contamination involved with the concomitant pathology organ system. For instance, biopsy of a retroperitoneal lesion may be considered a sterile concomitant procedure, whereas biopsy of an intestinal lesion would expose an aortic graft to contaminated flora.

EMERGENT AAA REPAIR AND COEXISTING PATHOLOGY

If emergent AAA repair is being attempted and resources allow for an endovascular repair, this should be attempted; however, certain

aneurysm anatomy require open repair. In this circumstance, the following pathologies are explored.

EMERGENT COEXISTING INTRAABDOMINAL PATHOLOGY

Appendicitis

Acute appendicitis is considered an intraabdominal general surgical emergency. Although data regarding the use of antibiotics alone for treatment are controversial, especially in the setting of an appendicolith, there have been reports of post-EVAR appendiceal rupture causing erosion into aorta, endograft, and subsequent life-threatening infections. The potential risk of appendiceal rupture in acute non-perforated appendicitis, with subsequent intraperitoneal contamination and biofilm creation, in our opinion warrants concomitant laparoscopic appendectomy or open appendicectomy with meticulous attempts at control of intraperitoneal contamination. Stenting the AAA Dacron graft in rifampin should be considered. Additionally, closure of the aortic sac and retroperitoneum over the graft should be performed. Irrigation of any pus should be avoided because it may spread the contamination.

Ruptured Tubo-ovarian Abscess

Ruptured tubo-ovarian abscess can be a true emergency. Contamination may involve the entire pelvis and bilateral lower abdominal quadrants. This may present problems especially regarding the distal limbs of a tube graft placed for an emergent AAA repair. Once again, consideration for EVAR or retroperitoneal AAA repair should be given if possible. Frequently, a laparotomy for emergent AAA repair is performed and thus the previously mentioned alternatives are not possible. Laparoscopic suction, consideration of a pelvic drain, long-term antibiotics, and meticulous graft coverage should be undertaken. Though this circumstance has been reported rarely, it is even more uncommon than appendicitis given that it generally occurs in women of childbearing age, and ruptured AAA is more likely to present in an older population.

URGENT COEXISTING INTRA-ABDOMINAL PATHOLOGY

Cholecystitis

Although cholecystitis is not generally considered an emergency, it is a surgical urgency and can lead to gangrene or perforation, sepsis, or cholangitis if left untreated, especially in the diabetic population. The earliest signs of an infection should be investigated and antibiotics started to cover gram-negative flora; in addition, antibiotics such as a cholecystostomy tube should be considered in the immediate postoperative circumstance of cholecystitis arising after an open AAA repair. If cholecystitis is present at the time of open AAA repair, a large series of more than 600 patients from the Veterans Affairs experience has demonstrated that concomitant repair can be fraught with more complications than staged repair, and the authors recommended staged repair. In a much smaller series of mixed abdominal pathology including symptomatic cholelithiasis with AAA repair, the authors described concomitant repair with the cholecystectomy performed after the AAA repair had been done and the retroperitoneum closed tightly, with no subsequent complications. However, an argument may be made about bacterial contamination to acute cholecystitis that may preclude concomitant surgery if a cholecystostomy tube is possible.

Pancreatitis

Coexisting pancreatitis is rare, but clearly poses a dilemma because it can be both a peritoneal and retroperitoneal process causing significant inflammation, with the potential for pancreatic necrosis, further infection, and making dissection around the mesenteric plate difficult. As far as we know, there have been no reports of AAA repair with concomitant pancreatitis, but coexisting pathology would certainly make the operation more difficult and, if possible, endovascular repair should be attempted.

NONURGENT COEXISTING INTRA-ABDOMINAL PATHOLOGY

Diverticular Disease

Though there is a paucity of evidence-based support, we advise against resection of an incidentally found Meckel's diverticulum. An elective bowel operation should be avoided if possible in the face of an open AAA repair because of contamination; however, large bowel symptomatic diverticulitis is a different pathology. In one study, a combined retroperitoneal approach for AAA repair and laparotomy for diverticular disease was not associated with increased mortality nor did it increase incisional hernias. Moreover, in symptomatic disease, staging a colectomy and open AAA repair did not appear to increase aneurysm-related mortality. Notably, two colonic anastomotic leaks were managed nonoperatively in this study with paracutaneous drains, with no graft infection noted; however, the risks of possible graft infection should be seriously considered, with a low threshold for extraanatomic bypass because infected graft erosion and subsequent herald bleeds or rupture can be catastrophic.

URGENT AAA REPAIR AND URGENT/EMERGENT CONCOMITANT PATHOLOGY

Appendicitis

Although unusual, reports of a large symptomatic AAA causing acute back pain with concomitant appendicitis have been case described. In this case, the authors proceeded with appendicectomy followed by a second-stage AAA repair. We agree with the initial management of appendicitis, but intraoperative vascular surgical consultation for consideration of concomitant EVAR or retroperitoneal repair may be warranted because of evidence in the surgical literature of laparotomy-associated AAA rupture. The hemodynamic changes associated with sepsis from a coexisting intraabdominal pathology, which are usually supplemented with large volume resuscitation per most sepsis protocols, can lead to increased intraluminal pressure precipitating AAA rupture and has even been reported in elective colectomies. Although it may seem reasonable to undertake robotic or laparoscopic colectomy in this circumstance to prevent gross contamination and avoid violation of fascial planes, any prolonged anesthetic times associated with hemodynamic instability should be avoided with large AAA.

Colitis

Infectious colitis at the time of concomitant urgent AAA repair should be addressed. Although most diverticulitis will respond to antibiotic therapy, Hinchey III or IV diverticulitis should be expeditiously washed out, drains placed to discourage erosion and abscess formation around aortic grafts, and stentification should be given to an ostomy to prevent anastomotic leak associated complications, which would then be a significant threat to the aortic graft.

ASSOCIATION OF CONCOMITANT CONDITIONS

Inflammatory Bowel Disease

Lately, a link between Lynch/Peto syndrome and ulcerative colitis has been proposed; what has been known for some time is that up to one half of these patients do have associated colitis and inflammatory bowel disease manifestations. The idea that these patients could present a scenario with both pathologies in active disease state is not impossible, although the disease itself is rare. If there is no clinical suspicion for active infectious colitis, however, the colitis should be left for medical management and the vascular pathology should be addressed

to a prioritized fashion if the AAA meets size criteria for repair or is causing symptoms. Additionally, there is some evidence that a retroperitoneal approach to open AAA repair may be associated with less inflammatory markers and an earlier resolution to inflammation postoperatively. These data suggest that if there is known concomitant inflammatory bowel disease, preferential consideration should be given to retroperitoneal AAA repair over transperitoneal approach.

NONEMERGENT AAA REPAIR AND CONCOMITANT NONEMERGENT DISEASE

Colorectal Cancer and AAA

Multiple studies have examined concomitant management versus staged management of AAA and colorectal adenocarcinoma. A meta-analysis pooling several studies examined concomitant open AAA repair (or EVAR) with colectomy versus staged repair. Except for a few patients (n < 5) with graft-related complications (thrombosis) associated with EVAR, the long-term outcomes favored EVAR over open AAA repair. Only one graft infection was reported in more than 200 cases; most deaths were attributable to either cancer or cardiac complications and no deaths were attributed to aneurysm rehabilitation. This is a change from the traditional findings in the 1980s regarding risk of rupture of larger AAA after unrelated laparotomy for elective colorectal cases. This improvement in outcomes may be attributable to improved anesthesia, better understanding of hemodynamics associated with AAA, or shorter operative times for colorectal cases. It is important to be aware of the complication of sigmoid ischemia after EVAR following a prior colectomy resulting in inferior mesenteric artery coverage, and the dangers it could pose to a colorectal anastomosis.

Renal Neoplasm and AAA

Although renal neoplasms are not a type of malignancy that general surgeons routinely treat, the concomitant renal mass found during an elective, urgent, or emergent AAA repair poses questions regarding the prognosis, renal ischemia regarding juxtarenal repair, tumor staging, and the safety of any biopsies in case of a renal or perinephric mass that is suspicious. The largest series to date examining the question examined 27 patients undergoing either simultaneous or staged repair and found that the group undergoing simultaneous repair had better long-term survival. A smaller series concurred with this result, but also observed that concomitant open AAA repair and radical nephrectomy was associated with higher postoperative acute kidney injury, although it appeared to resolve without any long-term affect on renal function.

Other Solid Organ Systems and AAA

Other solid organ tumors such as gastric cancer, liver tumors, and peritoneal implants have been rarely described, but there is no clear precedent for their management with concomitant incidental AAA. The considerations once again center around the emergency or urgency of associated pathology, and the more life threatening of the two should take priority. Another important consideration, however, is regarding contamination. Most genitourinary masses or other solid organ masses can at least be safely biopsied since these systems are normally sterile by nature; gastrointestinal masses should not be routinely biopsied due to contamination risk. Additionally, in any situation of elective AAA repair and incidental intraabdominal pathology, consideration should be given to the benefit of AAA repair (namely, prevention of rupture and mortality) in the setting of a possible malignancy that may be the rate-limiting condition affecting the patient's life span. If obvious metastatic cancer is present during laparotomy for AAA repair, one should consider aborting the repair as its benefit for the patient's life span may not outweigh the risks of the operation.

CONTAMINATION AND ITS EFFECT ON INTRAOPERATIVE DECISIONS

An interesting question arises regarding existing stomas during open AAA repair. Historically, large bowel and even urinary stomas were considered a contraindication to elective open AAA repair. However, open transperitoneal AAA repair in presence of permanent ostomies has been described, without any graft infection or adverse outcomes on long-term follow-up. We encourage proceeding with the operation if necessary, especially with long-standing stomas that have not had any associated hernias, infection, or uncontrolled output. If open AAA repair is indicated, retroperitoneal approach should be considered to avoid the stoma if possible.

Management of Descending Thoracic and Thoracoabdominal Aortic Aneurysms

Roland Assi, MD, MHS, Toby Steinberg, MD, and Prashanth Vallabhajosyula, MD, MS

Descending thoracic aortic aneurysms (DTAAs) involve the thoracic aorta from the left subclavian artery (LSA) to the diaphragmatic hiatus. Thoracoabdominal aortic aneurysms (TAAAs) involve varying lengths of both the descending thoracic and the abdominal aorta. It is not uncommon for these aneurysms to be associated with aneurysms of the aortic root, ascending aorta, and aortic arch. The management of DTAA and TAAA is rather complex and historically has been plagued by significant morbidity and mortality. This has improved with better understanding of the disease natural history, improved technical skills and available technology, and the use of organ protection methods.

INDICATIONS FOR SURGERY

Different disease processes can lead to DTAAs and TAAAs. Atherosclerotic disease is the hallmark of the aneurysms of the abdominal aorta, whereas aortic dissection, degenerative disease, connective tissue disorders, inflammatory disease, and trauma are more commonly involved in thoracic aortic aneurysms. Clinical presentation is also variable, ranging from incidental findings on cross-sectional imaging

to a prioritized fashion if the AAA meets size criteria for repair or is causing symptoms. Additionally, there is some evidence that a retroperitoneal approach to open AAA repair may be associated with less inflammatory markers and an earlier resolution to inflammation postoperatively. These data suggest that if there is known concomitant inflammatory bowel disease, preferential consideration should be given to retroperitoneal AAA repair over transperitoneal approach.

NONEMERGENT AAA REPAIR AND CONCOMITANT NONEMERGENT DISEASE

Colorectal Cancer and AAA

Management of Descending Thoracic and Thoracoabdominal Aortic Aneurysms

Roland Assi, MD, MMS, Toby Steinberg, MD, and Prashanth Vallabhajosyula, MD, MS

Descending thoracic aortic aneurysms (DTAAs) involve the thoracic aorta from the left subclavian artery (LSA) to the diaphragmatic hiatus. Thoracoabdominal aortic aneurysms (TAAAs) involve varying lengths of both the descending thoracic and the abdominal aorta. It is not uncommon for these aneurysms to be associated with aneurysms of the aortic root, ascending aorta, and aortic arch. The management of DTAA and TAAA is rather complex and historically has been plagued by significant morbidity and mortality. This has improved with better understanding of the disease natural history, improved technical skills and available technology, and the use of organ protection methods.

INDICATIONS FOR SURGERY

Different disease processes can lead to DTAAs and TAAAs. Atherosclerotic disease is the hallmark of the aneurysms of the abdominal aorta, whereas aortic dissection, degenerative disease, connective tissue disorders, inflammatory disease, and trauma are more commonly involved in thoracic aortic aneurysms. Clinical presentation is also variable, ranging from incidental findings on cross sectional imaging

for other reasons, to compressive syndromes causing pain or obstruction, to embolization, and, not uncommonly, rupture.

The most common indication for surgery is the absolute size of the aneurysm or the growth rate per 6 months or 1 year. In general, aneurysms larger than 6 cm should be repaired as long as the operative risk is not prohibitive. In patients with connective tissue disorders or chronic dissections, it is reasonable to intervene at 5 or 5.5 cm. A growth rate more than 5 mm per 6 months or 10 mm per year is also considered an indication for repair. The patient's age, comorbidities, and symptoms should be taken into consideration. In particular, we tend to intervene at an earlier stage in patients with pain or compressive syndromes, women more urgently, and in patients with family history of aneurysm rupture.

PREOPERATIVE CONSIDERATIONS

Anatomy

Knowledge of the anatomy of the entire aorta and major branches is critical for surgical planning. This is best done using high resolution computed tomography angiography with three-dimensional reconstruction. The anatomy of the aneurysm will dictate the extent of the repair and the extent of the operative risk. The Crawford classification remains the most commonly used for these purposes (Fig. 1). In addition, exact knowledge of the aortic anatomy is critical for the use of endovascular stent grafts. This includes identification of proximal and distal landing zones, the degree of tortuosity, and the use of access vessels.

Risk Assessment

A comprehensive workup is mandatory to evaluate the physiologic reserve. All patients undergo cardiac echocardiography and exercise testing. This is crucial because of the significant hemodynamic stresses and fluctuations that result from repeated aortic clamping and blood loss intraoperatively. Cases requiring circulatory arrest mandate knowledge of the left ventricular and aortic valve function. Those patients with abnormal tests undergo left and right heart catheterization. Pulmonary function testing is used to determine whether single lung ventilation would be tolerated and to identify the presence of chronic lung disease, which is associated with significant perioperative morbidity. Smoking cessation is mandatory for at least 6 to 8 weeks preoperatively to optimize pulmonary function and clearance. Renal function is evaluated with a baseline serum creatinine level. An elevated creatinine level should be investigated, and any systemic vascular causes should be intervened on. Preoperative chronic kidney disease is a factor for postoperative acute renal failure, and dialysis imposes a significant increase in operative mortality and might constitute a relative contraindication to elective TAAA repair. Frailty in elderly patients is an important risk factor for poor outcomes; in general, patients older than 75 years with poor functional status should not be offered open surgery.

OPERATIVE STRATEGY

Anesthesia

General endotracheal anesthesia is used in all patients. Double lumen intubation used to allow for single lung ventilation, which is required in the majority of cases. A right jugular venous sheath is inserted and a pulmonary artery catheter is placed. Unless there is an anatomic esophagogastric contraindication, a transesophageal echocardiography (TEE) probe is placed and continuous imaging is used throughout the case. The information gathered from the pulmonary artery catheter and the TEE is highly valuable in the hemodynamic management intraoperatively. A urinary catheter with temperature probe is used for the monitoring of urine output and core temperature. Right radial and left femoral arterial lines are placed and allow for monitoring of blood pressure to the brain and to the lower body, respectively. In patients requiring cardiopulmonary bypass via left thoracotomy cannulation, a right femoral arterial line is mandatory. Prophylactic antibiotics are administered and redosed as indicated.

Neurologic Monitoring

Near infrared spectroscopy, somatosensory evoked potentials (SSEPs), and motor evoked potentials (MEPs) are used for neurologic monitoring. Near infrared spectroscopy is useful for monitoring brain oxygen consumption, particularly in extent 1, in which the distal aortic arch is clamped or when circulatory arrest is used. When circulatory arrest is planned, electroencephalogram leads are placed for monitoring. SSEPs and MEPs are very sensitive in detecting spinal cord injury, but MEPs alter the anesthetic management but may be more sensitive for spinal cord injury detection than SSEP. A lumbar drain is placed in all cases in which a significant portion of the thoracoabdominal aorta is replaced (i.e., extents I, II, III, and V) because it has been shown that lowering cerebrospinal fluid (CSF) pressure is the most important intervention to prevent spinal cord injury (SCI). Other factors to consider to decrease risk of SCI include maintaining a high perfusion pressure (mean arterial pressure [MAP] >80 mm Hg), a patent LSA, short

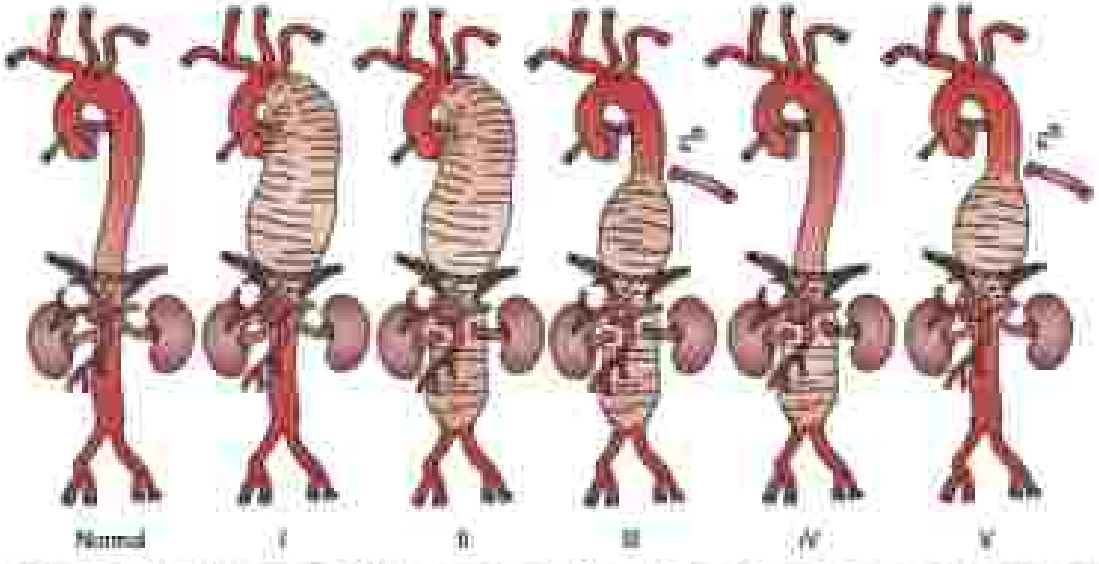

FIG. 1 Crawford classification of thoracoabdominal aortic aneurysms. Type I: distal from origin of left subclavian artery to above renal arteries. Type II: distal from the left subclavian artery to the infrarenal aorta. Type III: from the sixth intercostal space to the infrarenal aorta. Type IV: from the 12th intercostal space to the aortic bifurcation. Type V: below the sixth intercostal space to the renal arteries. (From Cronenwett JT, Johnston [illegible]. Rutherford's Vascular Surgery. 7th ed. Philadelphia: Saunders; 2007. Fig. 120.8.)

cross-clamp time, patent internal iliac arteries, and reimplantation of large intercostals with no back bleeding.

Positioning, Incision, and Exposure

The patient is positioned in a right lateral decubitus position over a beanbag with careful padding of all pressure points. The left arm is supported over an arm rest and the hips are rotated slightly to the left to allow for left groin access. The table is flexed at the hips about 40 to 45 degrees, allowing for complete exposure of the left chest and flank. The skin is prepped from the base of the skull to the mid thighs, from the spine to the sternum and from the spine to the right of the umbilicus (Fig. 2).

For DTAAs, a fourth intercostal space thoracotomy is used and allows an excellent exposure of the distal aortic arch. The fifth intercostal space is used for TAAAs extent I or II, and sixth or seventh intercostal spaces are used for extent III/IV (Fig. 2). The incision can be extended posteriorly and superiorly to improve exposure of the proximal descending thoracic aorta. In addition, the posterior ribs at the level of the incision are notched, which improves exposure significantly. The incision is then extended to the abdomen in a left paramedian fashion and the retroperitoneal space is exposed, avoiding violation of the peritoneum (Fig. 3). In retracting the peritoneal contents, extreme caution must be taken to avoid recoil or overt splenic injury.

In the chest, the left lung is isolated and the inferior pulmonary ligament is divided up to the level of the left inferior pulmonary vein. The lung is then retracted medially and anteriorly, allowing for excellent exposure of the thoracic aorta (Fig. 4). It is not uncommon to encounter some adhesions between the lung and the aorta or the chest wall; this is reflective of the inflammatory nature of the aortic disease. During dissection of the lung tissue off the aorta, care must be taken to visualize and preserve the vagus nerve that runs posteriorly to the pulmonary hilum, the phrenic nerve that runs anteriorly to the pulmonary hilum, and the left recurrent laryngeal nerve that drapes around the isthmus and is usually concealed by lymphatic tissue. It can usually be bluntly dissected and gently pushed out of the way to the right to allow aortic cross clamping or anastomosis. The diaphragm is divided circularly off the chest wall leaving a 3- to 4-cm rim to allow for reapproximation at the end. We typically place sutures of alternating color on either side of the diaphragm to help approximation during closure. The left crus of the diaphragm is then bluntly divided, exposing the aorta. In the abdomen, the incision is extended along a left paramedian line and the peritoneum is swept to the right, exposing the left psoas muscle and the left iliac artery. A table-mounted retractor system is deployed, allowing a complete exposure of the thoracoabdominal aorta as dictated by aneurysm anatomy.

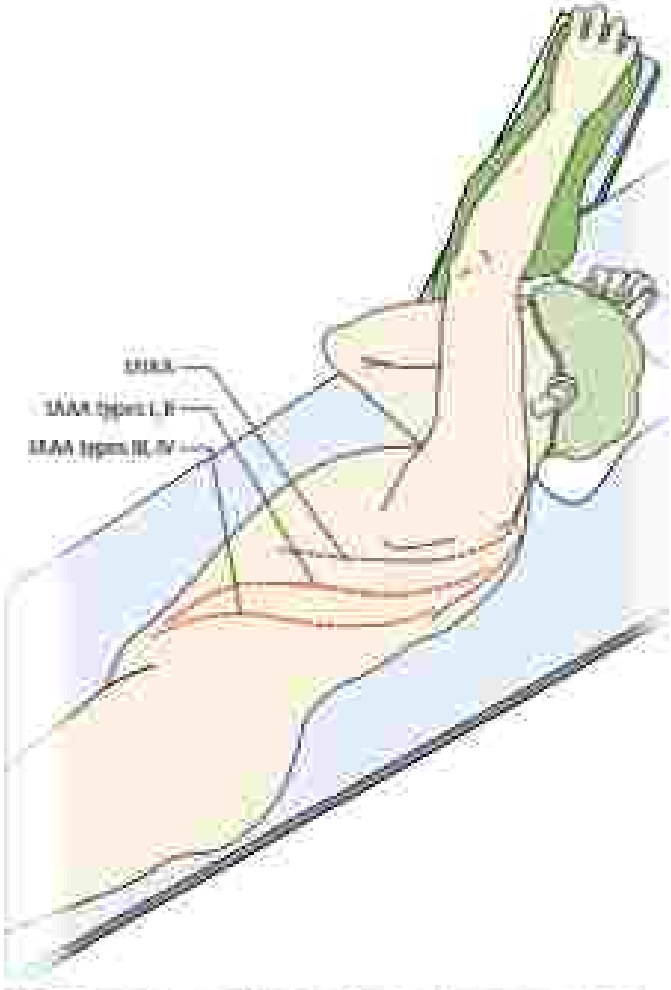

FIG. 2 Patient positioning in the right lateral decubitus position with hip rotation to the left to facilitate access to the femoral vessels. The level of the skin incision varies with the extent type of the aneurysm. DTA, Descending thoracic aortic aneurysm; TAA, thoracoabdominal aortic aneurysm.

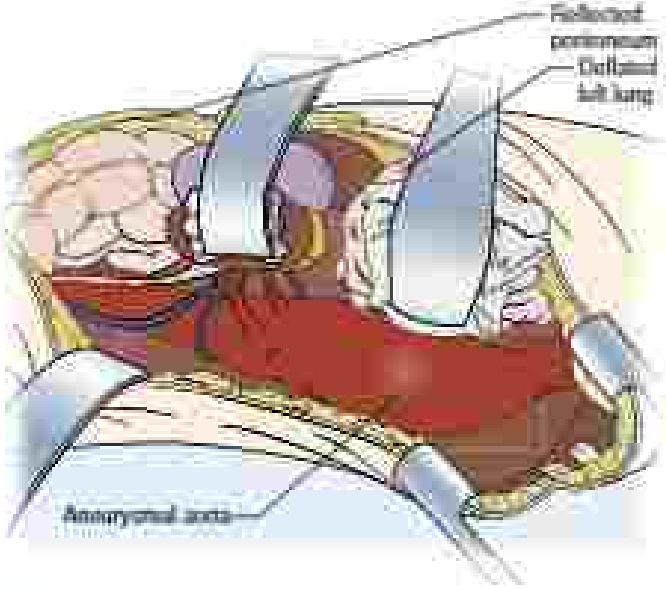

FIG. 4 Exposure of the aorta. The peritoneum is reflected medially to expose the abdominal aorta. The left lung is deflated to allow complete mobilization of the left lung.

P ...f ... Strategy

...

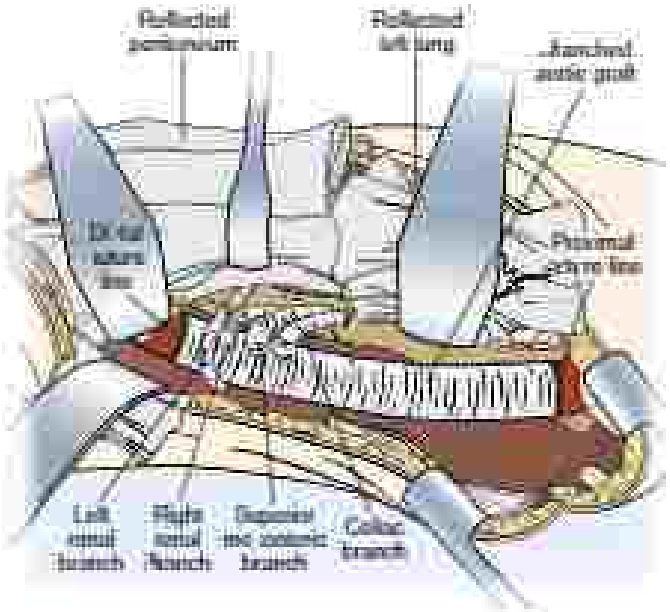

FIG. 1. ...

Organ Protection Strategy

During cross-clamp and visceral ischemic time, the renal, celiac, and superior mesenteric arteries are selectively cannulated with flexible balloon tip cannulas and perfused with cold blood at 8°C, but other groups have shown excellent results with cold crystalloid perfusate to the renal arteries. We usually ligate the inferior mesenteric artery.

For spinal cord protection, ischemic time is minimized as much as possible, MAP to the spine is maintained at 70 mm Hg or higher, SCP is drained to maintain a pressure of 8 to 10 mm Hg, hemoglobin is maintained at a physiologic level, and intercostal arteries are selectively reimplanted. It is our practice to reimplant only large intercostals that do not backbleed when the aorta is open. Other intercostals with good backbleeding are ligated to achieve hemostasis and prevent shunting of the spinal blood away from the spinal cord.

...hoice of Grafts and Technical Aspects

We use Dacron grafts that are sized based on the preoperative imaging and intraoperative findings. Graft diameters will fall between 28 and 32 mm for the thoracic aorta. For the abdominal aorta, we most commonly use 24-mm multibranched Dacron grafts. For reimplantation of the visceral vessels in extent type I, the distal aspect of the graft is beveled to create a patch that includes the celiac, SMA, and renal arteries. For extents II, III, IV, and V, we prefer to use branched aortic grafts instead of reimplantation in a patch configuration. This allows for complete resection of all aortic tissue around the visceral ostia and eliminates the risk of enlargement of residual aortic tissue. In many instances in which there is significant size discrepancy between the proximal and distal aorta, and when bifurcated grafts to the iliac arteries are used, we prefer to use separate grafts for the proximal and distal anastomosis. A graft to graft anastomosis is then completed after tailoring of the length and lay of the grafts. Aortic anastomoses are usually completed with 3-0 polypropylene and visceral branches with 4-0 or 5-0 polypropylene, depending on the vessel size and quality.

Closure and Transition to the Intensive Care Unit

After all reconstruction is completed, heparin is reversed with protamine, meticulous hemostasis is achieved, the surgical field is copiously

tonguard, and the peritoneal cavity is allowed to rest back in position with careful attention to [illegible]

[illegible]

circumferential calcifications, usually accommodates most device sheaths. Rarely, when femoral access is not adequate, iliac or distal aortic access can be achieved through a retroperitoneal incision. An aortogram is performed and measurements are confirmed against the preoperative computed tomography scan. For aneurysms, we use covered stents with 10% to 20% oversizing at the landing zones. For chronic dissecting aneurysms, we aim to cover the whole length of the DTA from the LSA to just above the celiac artery. This extent of coverage is associated with the best chances of aortic remodeling and obliteration of the false lumen. Besides anatomic considerations (access, tortuosity, length of landing zones), we avoid endovascular repair in patients with connective tissue disorders unless the landing zones are in graft material or as part of a staged hybrid procedure.

For TAAAs, we reserve endovascular repair for patients who have a prohibitive open surgical risk or as part of a hybrid staged procedure. Access to the visceral arteries is obtained through a sheath placed in the left brachial artery. Multiple variations in techniques and devices are available, but in general fenestrated grafts, snorkel, chimney and "sandwich" TEVAR techniques are used. Currently, clinical trials are under way for the use of endovascular branched stent grafts.

OUTCOMES

Risk factors for poor outcomes include advanced age, acute aortic syndrome, extensive repair, and history of stroke, cardiac, or pulmonary diseases. The expected operative mortality for DTAAs and TAAAs in experienced centers ranges between 2% and 10%, renal failure in 3% and 8%, and paraplegia in 1% and 8%. These numbers vary significantly depending on the extent of the repair, with extents II and III being the most morbid. Although in general the stroke risk is low, it has been reported around 2%, but up to 7% when circulatory arrest for arch reconstruction is used. Pulmonary complications remain the most common operative morbidity (up to 50% of patients) related to single volume ventilation, the retraction of a heparinized lung, the long duration of the surgery and mechanical ventilation, and adult respiratory distress-like syndrome related to acute blood loss, massive transfusion, fluid shifts, and ischemic and hypothermic injuries.

TEVAR for DTAAs is associated with significantly better operative mortality and adverse outcomes including SCI when compared with open repair at the cost of increased secondary reintervention rates to seal endoleaks.

Paraplegia resulting from SCI is probably the most devastating complication specific to aortic repair. Risk factors for SCI include advanced age, renal dysfunction, emergency surgery, aortic dissection or rupture, prior abdominal surgery, occluded internal iliac arteries, and the extent of repair. Many strategies have been proposed to mitigate this risk, including routine reimplantation of the intercostal arteries and intrathecal infusion of cold perfusate, but the most significant intervention to date remains the insertion of lumbar drain for CSF drainage, which we use on all DTAA and TAAA repairs. CSF drainage can also be used as a salvage strategy for patients who develop signs of SCI in the perioperative setting.

Management of Acute Aortic Dissection

Robert J. Bu[illegible] M.D., M[illegible] H. [illegible] M.D., F.A.C.C.

Acute aortic dissection is a distinct entity within the group of aortic pathologies known as acute aortic syndromes. It represents a true medical emergency that should prompt the early involvement of the surgical team. Its incidence is estimated to account for 400... to 1000... hospital admissions within the United States annually, though this likely is an underrepresentation that does not account for aortic dissection causing death before reaching the hospital. Because of its varied presentations and potential for rapid clinical deterioration, early diagnosis and treatment requires a high index of suspicion and a thorough understanding of pathophysiology and associated treatments. Even with this, aortic dissection can prove a challenging clinical entity even to practiced physicians. As Sir William Osler quipped, no disease is more "conducive to clinical humility."

PATHOPHYSIOLOGY AND RISK FACTORS

Aortic dissection results from a tear in the intimal layer of the aortic wall. Following this disruption, blood will quickly infiltrate the layer between the intima and the media, resulting in a "false lumen." It is the extent of this false lumen, including initial location within the ascending or descending aorta, direction of propagation (retrograde or antegrade), and involvement of branch vessels, that will ultimately determine the clinical manifestations of aortic dissection. The causative event resulting in the initial tear that initiates the aortic dissection pathway is an area of ongoing research, but likely represents a mechanical failure in a diseased aorta. This hypothesis is supported by biomechanical testing demonstrating that the intima of normal aortas is able to tolerate pressures well beyond those experienced physiologically. As such, an understanding of the risk factors that may precondition an aorta to dissection warrant discussion.

Hypertension is present in over two-thirds of all patients with acute aortic dissection. The effect of hypertension is twofold. First, the increased wall shear stress caused by increased systolic blood pressure directly increases the mechanical stress on the intima. Additionally, aortic ectasia or aneurysm results in medial thinning and increased risk of dissection, and hypertension is a risk factor for both these conditions. Smoking, dyslipidemia, and drug (crack, cocaine or amphetamine) use are among the highly prevalent modifiable risk factors for patients with aortic dissection. Genetic risk factors, including mutations in genes controlling connective tissue expression such as *FBN1* (Marfan syndrome), *TGFBR1/2* (Loeys-Dietz syndrome), *COL3A1* (Ehlers-Danlos vascular type IV), and *MYH11* or *ACTA2* (familial thoracic aortic aneurysm syndrome), result in increased risk of aortic dissection. Further, a family history of aortic dissection, even without an identifiable genetic predisposition, places a patient at increased risk.

PRESENTATION AND DIAGNOSIS

The diagnosis of aortic dissection relies on a high index of clinical suspicion early in the patient's clinical presentation. Symptoms are often vague and varied, and the historical symptom of "tearing" chest pain is present in less than 50% of individuals with aortic dissection. The consequences of an aortic dissection in the ascending aorta include acute myocardial infarction, cardiac tamponade, and hemothorax rupture, with associated mortality of 1% per hour. Dissections in the descending aorta can be more extensive and therefore affect nearly any body system through disruption of the arterial blood supply. These so called "malperfusion" symptoms can include acute mesenteric ischemia, stroke, acute renal failure, and acute limb (both upper and lower) ischemia. Especially in the case of limb ischemia, absence of pulses or pulse deficits can help raise the suspicion of dissection. Therefore, the diagnosis of aortic dissection should be considered in any patients with a history of hypertension presenting with these symptoms.

Risk score calculators help to delineate important elements of the clinical presentation that can aid in the rapid diagnosis. In 2010, the American Heart Association/American College of Cardiology (AHA/ACC) released guidelines for the diagnosis of acute aortic dissection, outlining a three point scoring system, which has subsequently been validated, to assess the risk of aortic dissection. Within the Aortic Dissection Detection (ADD) risk calculation, there are three categories, for which the presence of any factor within a category earns the patient a point. These categories include high-risk predisposing conditions, high-risk pain features and high-risk clinical manifestations (including pulse deficit and systolic blood pressure differential). The ADD risk score has sensitivity rates up to 97.7% and has been recently coupled with a D-dimer test to effectively rule out patients who do not have aortic dissection.

In patients with ADD risk scores of 2 to 3, expedited aortic imaging is warranted with transesophageal echocardiography, computed tomographic angiography (CTA) and or magnetic resonance angiography (MRA). Among these, CTA has emerged as the gold standard due to its widespread availability and rapid diagnosis. The use of contrast aids in the identification of the true and false lumens, with the false lumen being larger than the true lumen in 80% of cases. Absent contrast cessation or asymmetric kidney enhancement are evidence of malperfusion and can help to dictate the need for revascularization. Additionally, CTA may reveal the presence of an intramural hematoma, though the clinical implications of this entity are unclear.

CLASSIFICATION

Traditionally, aortic dissection has been classified using the DeBakey or Stanford classification systems, according to the segment of aortic involvement (Fig. 1). Within this system, DeBakey I and II (Stanford A) dissections involve the ascending aorta and DeBakey III (Stanford B) dissections extend to the descending aorta only. This classification system has been used historically to dictate clinical management, though with the advent of improved endovascular repair, additional detail is often required to guide more contemporary management. To this end, the DISSECT classification system was developed to more accurately communicate specific details regarding the dissection between providers. The DISSECT classification consists of the following elements: duration (Acute: <2 weeks; Subacute: 2 weeks to 3 months; >3 months), intimal tear location (ascending, arch, or descending), size of the aorta, segmental extent of aortic involvement, clinical complications, and thrombosis of the false lumen. Through a more accurate description of both the dissection location and clinical features, the intent of the DISSECT mnemonic is to convey all the information of interest that could help drive disposition to medical or surgical management.

MANAGEMENT STRATEGIES

Through most of the history of aortic dissection, treatment has been largely relegated to medical management. However, with their report of surgical repair of six aortic dissections in 1955, DeBakey, Cooley, and Creech helped to establish the efficacy of surgical treatment for acute aortic dissection. Their reported perioperative mortality of 33% (two of the six) was a dramatic reduction from the estimated 75% to 90% mortality of nonsurgical management reported at the time.

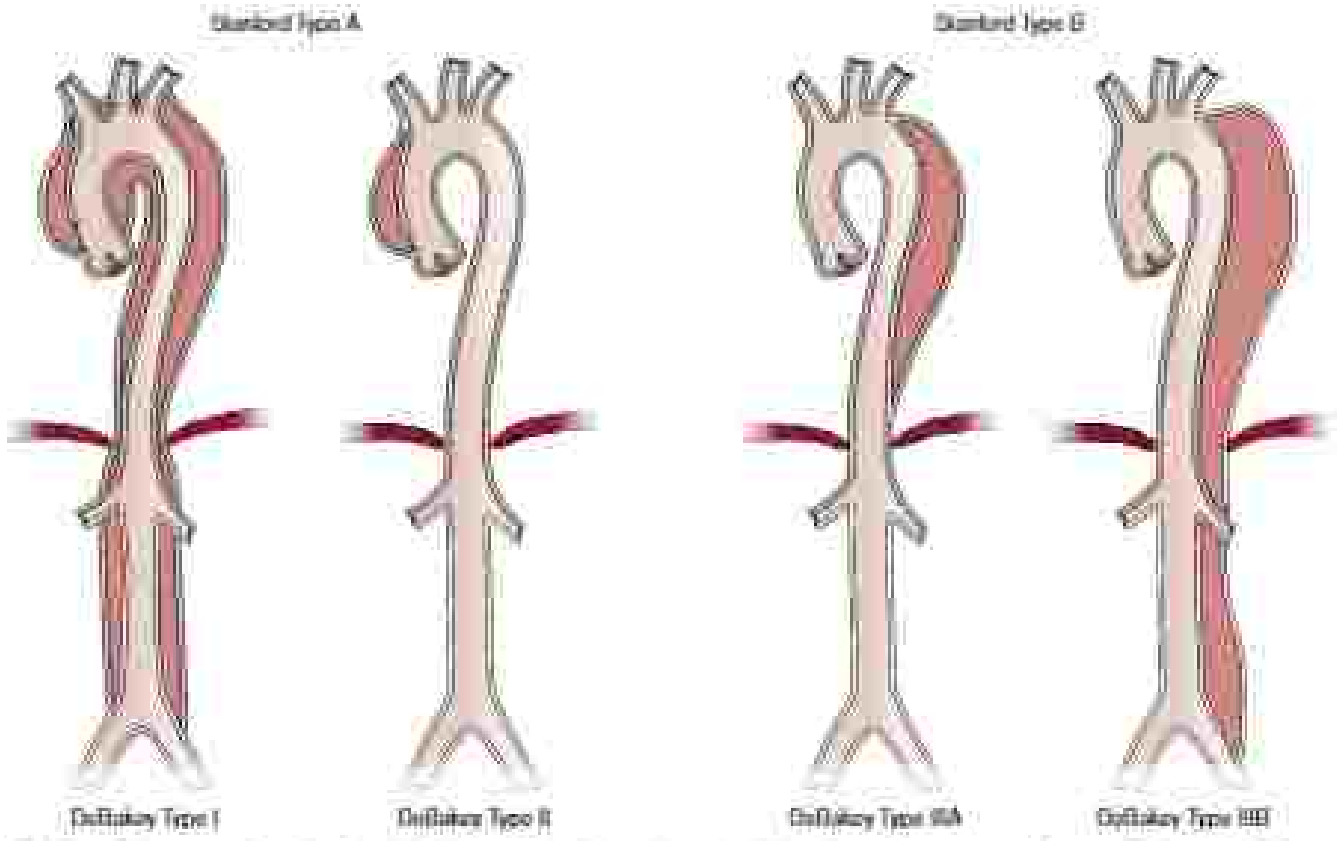

FIG. 1 Classification systems for aortic dissection. DeBakey I dissections involve a combination of ascending aortic, aortic arch, and descending aortic segments (Stanford type A). DeBakey II dissections are limited to the ascending aorta only (Stanford type A). DeBakey IIIA dissections involve the descending aorta only (Stanford type B). (Modified from Cooper MA, Ikonomidis JS, Hawkins AT, et al. Ann Thorac Surg. 2007;83(4):1546–1553; with permission.)

Through examination of the International Registry of Acute Aortic Dissection (IRAD), we have further delineated which patients will benefit from operative management. Initial management of patients with acute aortic dissection includes aggressive heart rate and blood pressure control, except in situations of hypotension and rupture. An important early distinction is the presence of a type A aortic dissection (TAAD) or type B aortic dissection (TBAD). Indeed, it is important to recognize that TAAD has high mortality that mandates early surgical therapy as opposed to TBAD, which are often treated medically.

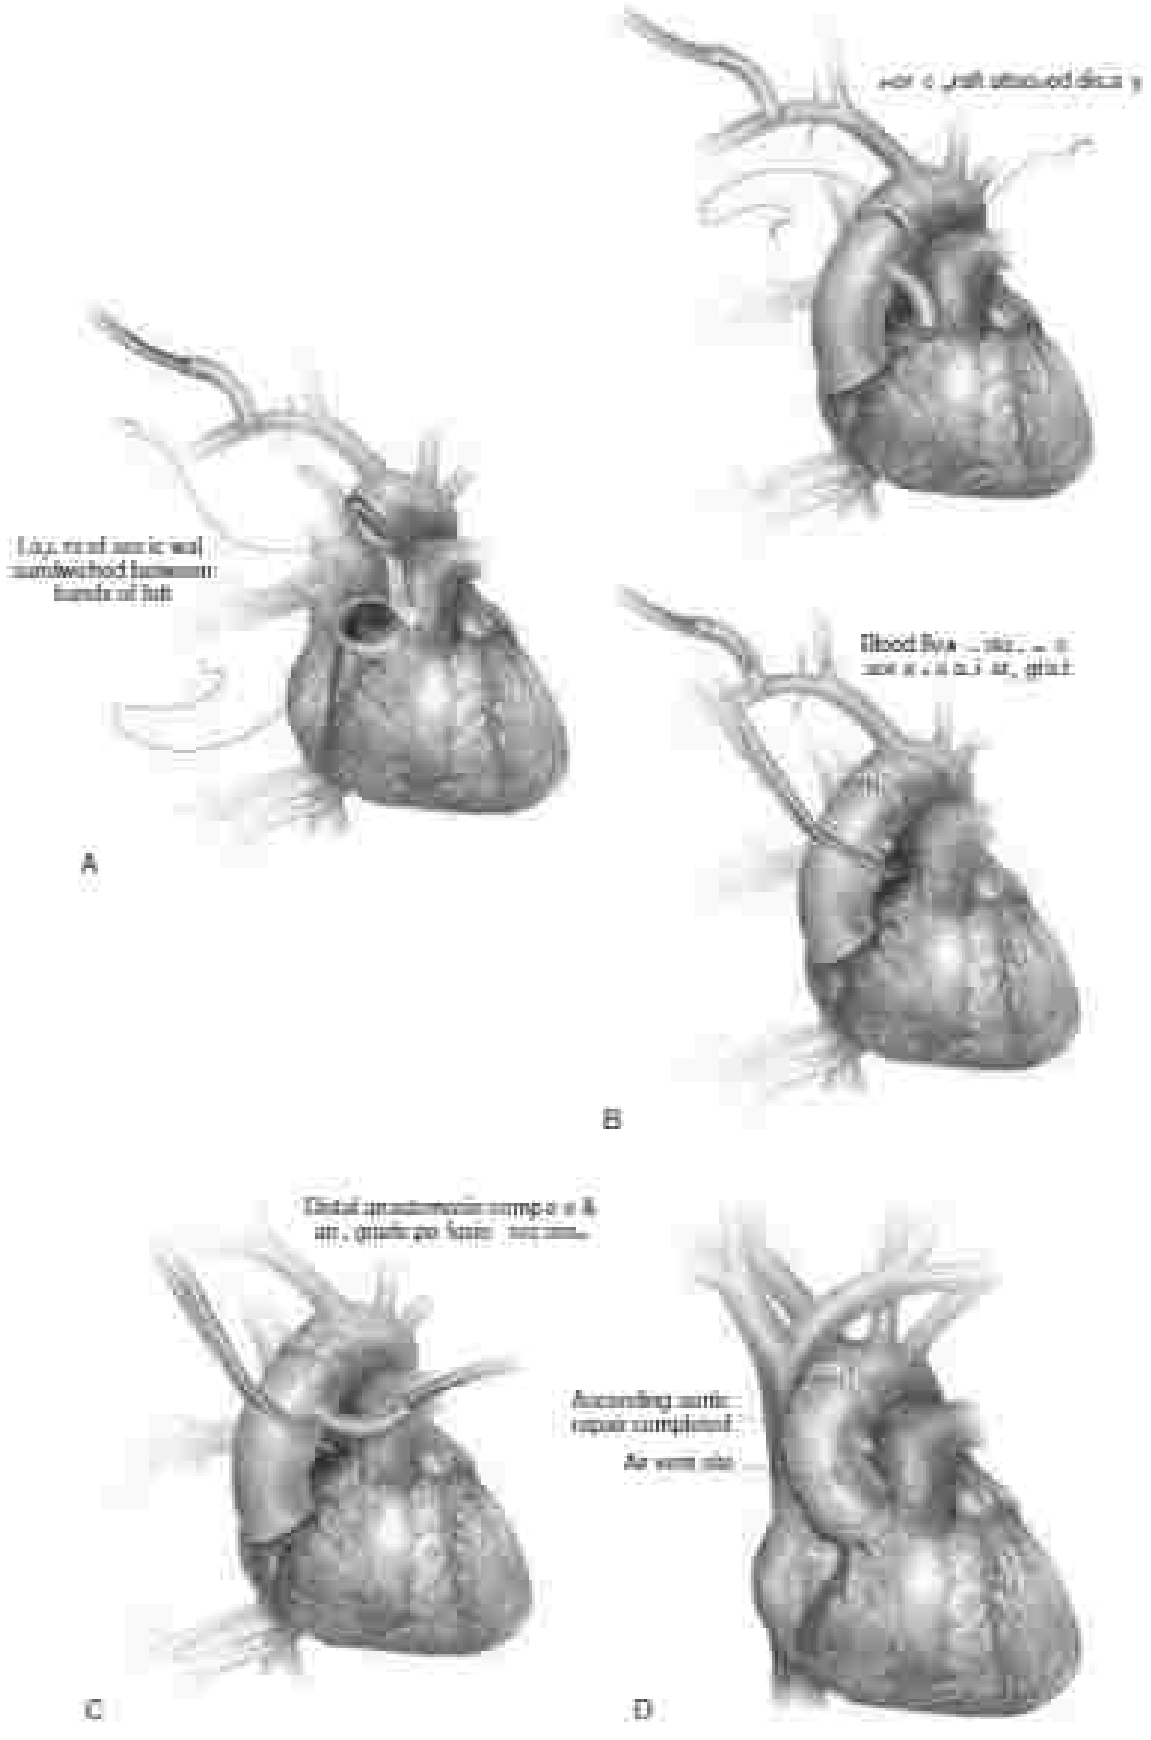
SURGICAL MANAGEMENT OF TYPE A AORTIC DISSECTION

Surgical management is the mainstay of therapy for treatment of acute TAAD. The rate of early mortality in this population has been cited as greater than 1% per hour. The majority of patients in initial report of the IRAD data in 2000 by Hagan et al. involved the ascending aorta, and in these patients, the operative mortality was only 16% compared to ~3% for medical management. These results are recapitulated in a recent Society of Thoracic Surgery database, in which operative mortality in the United States for TAAD was approximately 17% compared to contemporary estimates of greater than 50% in nonoperative management. These patients are at high risk for early postoperative complications including acute myocardial infarction, renal failure, stroke, and new visceral/limb malperfusion syndromes.

Approximately 80% of patients with TAAD progress to the operating room within 24 hours to an emergent fashion, the majority of which will require circulatory arrest. Strategies for cannulation for cardiopulmonary bypass are varied and include axillary, femoral, aortic, and combinations thereof, dependent on patient location. The femoral cannulation site has the longest history in ascending dissections and may facilitate the most rapid initiation of cardiopulmonary bypass, though evidence is emerging to suggest better outcomes with axillary cannulation. Approximately 50% of patients require a concomitant aortic valve procedure, with aortic valve resuspension being the most common valve procedure performed. In situations in which both the valve and the coronary stems can be spared, ascending aortic replacement can be completed with an interposition Dacron graft (Fig. 2). Postoperatively, TAAD patients are at high risk for continued bleeding, requiring ongoing transfusions, or possible reexploration.

MANAGEMENT OF TYPE B AORTIC DISSECTION

Early management of all acute TBAD should be directed at aggressive heart rate control to reduce the oscillatory shear stress exerted on the aortic wall. Patients should be closely monitored in an intensive care setting. The ACCF/AHA recommend a target heart rate of <60 beats/min, to be achieved with the use of intravenous beta blockers, with esmolol commonly being the agent of choice due to its rapid on/off profile and ease of titration. For patients who are unable to tolerate β-blockade, especially those with aortic regurgitation or at risk for a chronic obstructive pulmonary disease exacerbation, calcium channel blockers may be used. Once heart rate control has been achieved, blood pressure should be targeted for a systolic pressure of 120 mm Hg to reduce the risk of flap propagation and aortic rupture. This can be accomplished through a combination of ACE inhibitors and other antihypertensive agents if β-blockade is not sufficient. Blood pressure control should not be attempted prior to heart rate control, as compensatory tachycardia can lead to increased risk of rupture. Patients with persistent or refractory pain, aortic expansion, or evidence of malperfusion are deemed "complicated." There are two dominant mechanisms for malperfusion. Malperfusion may result from either



A
B
C
D

FIG. 2 Static (A) and dynamic (B) dissection flaps for aortic dissection. Static flaps result in permanent occlusion of outflow vessel with resultant thrombus. Dynamic dissection flaps result in intermittent occlusion and can lead to thrombus formation if not treated promptly.

static or dynamic dissection flap obstructions, leading to possibly intermittent malperfusion (Fig. 2). Clinical parts after dynamic flaps can be difficult to diagnose based on static images. Computed tomography (CT) angiography and magnetic resonance angiography (MRA) are the most commonly used imaging modalities in patients with aortic dissection. These studies are typically performed in patients with stable vital signs. Although these studies can be very helpful in delineating the anatomy of acute dissection, they are limited in their ability to assess dynamic flow patterns. Intraoperative transesophageal echocardiography (TEE) can be very helpful in assessing dynamic flow patterns and can be used to help guide surgical decision making.

Open Surgical Repair

The traditional open surgical approach to acute aortic dissection is to resect the intimal tear. Contemporary surgical repair is much more conservative and includes resection of the proximal intimal tear as well as the distal intimal tear and hematoma. As the proximal aorta is the most frequent site of acute dissection, most surgical repairs involve replacement of the ascending aorta with or without hemiarch replacement. Cannulation for cardiopulmonary bypass is usually performed through the right axillary artery or femoral artery. Cannulation through the left axillary or femoral artery for partial cardiopulmonary bypass if needed. Historically the results of open surgical management of TBAD are poor, with high rates of paraplegia, stroke and acute kidney failure. As such, open surgical intervention for TBAD has largely been abandoned, except in the case of rupture.

Endovascular Management

Thoracic stent graft repair of acute TBAD has become a mainstay for management of complicated dissections. Successful repair of complicated TBAD requires thorough preoperative planning. CTA of the entire aorta, from the heart to the pelvis, should be obtained, outlining the aortic anatomy to include the great vessels through the femoral vessels (Fig. 4). This allows for identification of proximal entry tear, which will need to be covered during endograft deployment, as well as ensuring adequate femoral and iliac vessel size for catheter and sheath introduction. Additionally, this may help to identify the location of the ostia of the visceral vessels in relationship to the true and false lumens.

Bilateral femoral cannulation is the preferred approach; however, in cases in which tortuosity in the thoracic aorta will likely prevent safe navigation of the thoracic endograft, brachial artery cannulation can be employed. This allows for dissection into the true lumen, using a "through and through" approach. From the femoral cannulation site, intravascular ultrasound (IVUS) is often useful to determine positioning within the true lumen and should be available prior to the start of the procedure. More typically, the true lumen is the more anterior of the two lumens, giving rise to the superior mesenteric and right renal arteries. However, preoperative assessment of the relationship between the true and false lumen can be determined based on the CT acquisition (Fig. 4). After cannulation, the anterior aorta is located using the left renal vein identification with IVUS and the location of the wire within the true lumen can then be confirmed.

Static obstructions (see Fig. 2) of visceral segments often mandate stenting, while dynamic obstructions may resolve with aortic stent grafting. In rare cases in which aortic stent grafting does not resolve visceral or renal malperfusion, fenestration of the dissection flap and stenting should be performed near the ostia of the branch vessel and should be limited to one to prevent further true propagation. It is important to note, excessive fenestration in the proximal abdominal aorta may increase the risk of subsequent visceral segment malperfusion due to unpredictable flow dynamics.

Thoracic endograft placement in complicated TBAD should be targeted to cover the primary entry tear of the dissection (Fig. 4). Coverage of additional smaller entry tears or distal entry tears may require introduction of additional stent grafts. It is possible that additional stent graft coverage may increase the risk of spinal cord ischemia, which results from coverage of thoracic lumbar arteries responsible for spinal blood supply, in distinction to degenerative aneurysms. Acute thoracic endografts should be oversized 5% to 15% larger than preoperative aortic diameter, oversizing of thoracic endografts in the setting of dissection is minimal. It is theorized that aggressive oversizing on a freshly dissected aorta may increase the risk of acute stent graft associated rupture, tearing of the dissection septum, or retrograde aortic dissection into the arch. The endograft should be positioned just distal to the left subclavian artery and a standard 2- cm proximal landing zone is advocated. In instances in which the dissection flap includes the ostium of the left subclavian or anatomic characteristics preclude adequate landing zone, the left subclavian artery can be covered. It is not necessary to perform a subclavian revascularization (most commonly through a carotid subclavian bypass or subclavian transposition) at the time of thoracic endovascular aortic repair (TEVAR), although it may be preferred if technically feasible and patient hemodynamics allow.

After the endograft has been successfully deployed, balloon dilatation should be avoided to prevent rupture or further dissection. A completion angiogram and IVUS are then performed to document coverage of the intimal defect as well as appropriate flow to the visceral vessels (Fig. 5B). If IVUS demonstrates significant true lumen compression or persistent malperfusion of the visceral or renal vessels, then additional fenestration or stenting may be required. After determination of a good angiographic result, catheters, wires, and sheaths can be removed in the standard fashion. The artery is then repaired with interrupted prolene sutures. If a conduit was used, it can be oversewn and left in situ.

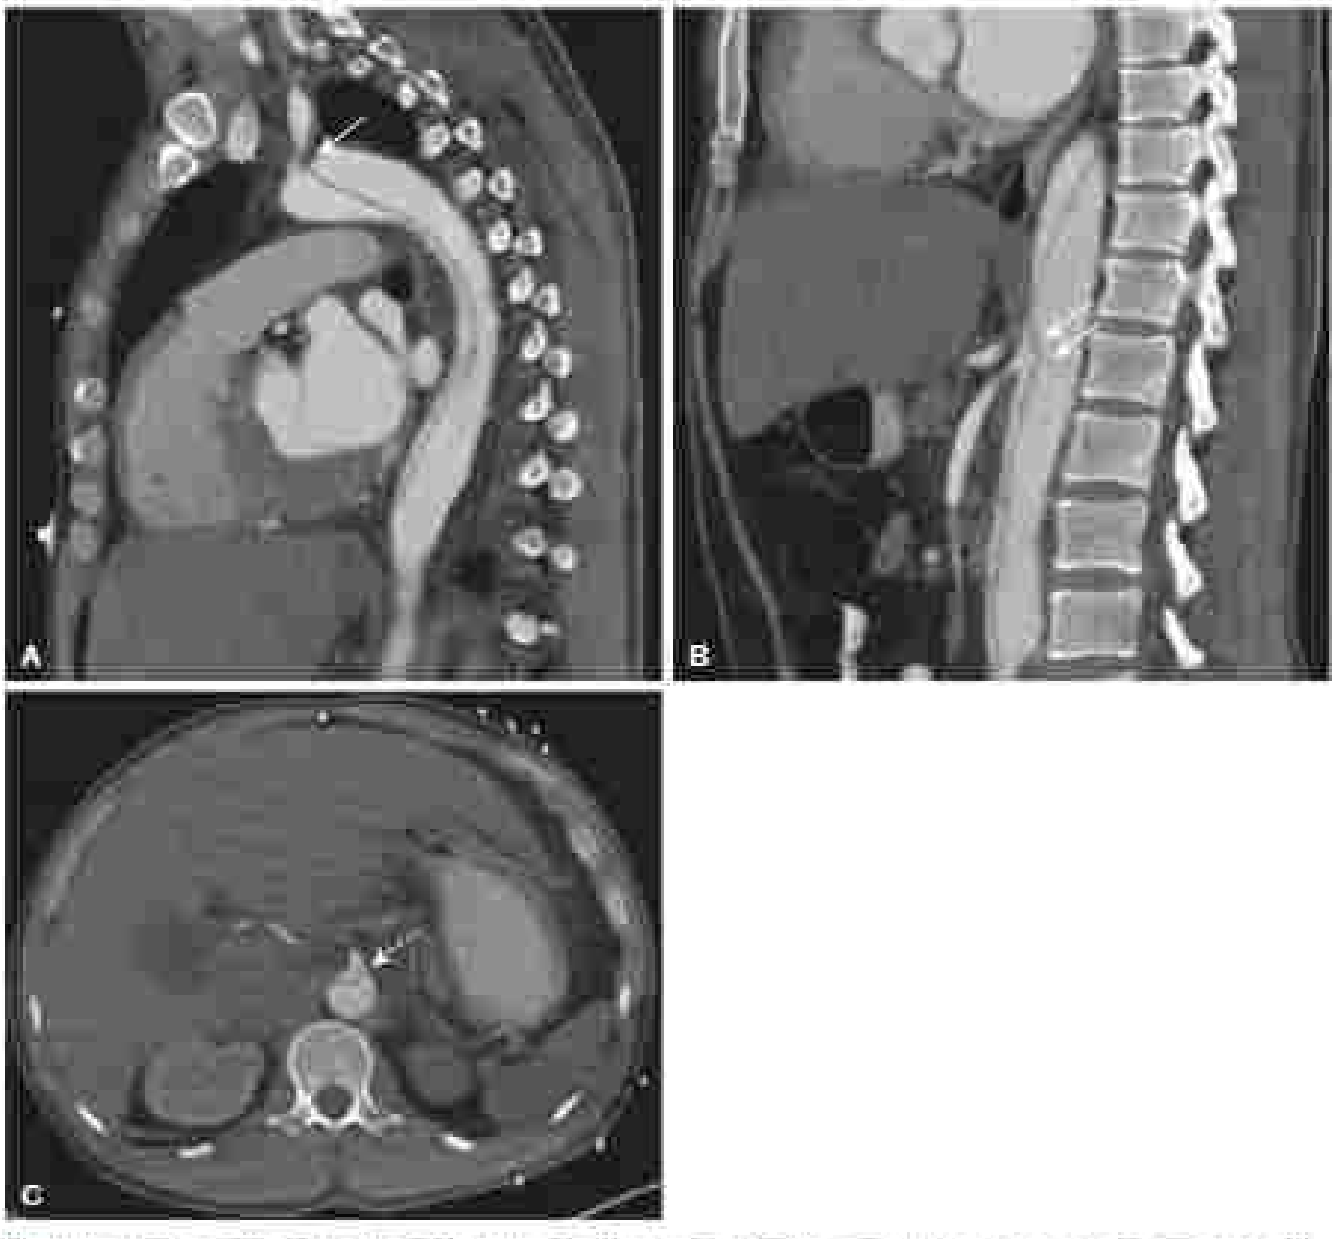


FIG. 4 (A) Preoperative sagittal computed tomography (CT) demonstrating luminal luminal starting immediately distal to left subclavian artery. (B) Sagittal CT demonstrating anterior true lumen from which the superior mesenteric artery (SMA) arises (arrow). (C) Axial CT demonstrating stable anterior true lumen with takeoff of the SMA (arrow).

The role for endovascular repair of uncomplicated TBAD is still an area of study. Investigators from the multicenter INSTEAD trial demonstrated equivalent 30 day mortality among patients undergoing endovascular repair (TEVAR) or maximal medical management. Additionally, the group undergoing surgical repair had a higher 1 year mortality. However, more recent evaluation has supported a lower "aorta related" mortality among patients undergoing early endovascular repair (6.9% vs 19.5%, $P = 0.2$), a result that is further supported by 5 year follow up studies in the IRAD database. Patients who undergo early TEVAR have higher rates of false lumen thrombosis and favorable aortic remodeling compared to maximal medical management.

COMPLICATIONS

Because of the tortuosity of the thoracic aorta, special care must be taken to limit "endoleaking" of the endograft. This occurs when the proximal edge of the graft pulls away from the tissue distortion of the aorta and provides a possible avenue through which blood may dissect between the aortic wall and the endograft. This can result in device migration and/or collapse and in rare instances, may result in aortic occlusion and subsequent cardiovascular collapse. Retrograde type A dissection has also been reported, in which the stress of the thoracic endograft cause an intimal tear that may propagate proximally and lead to stroke, myocardial infarction, or cardiac tamponade. This phenomenon is rare and is believed to be related to the noncompliant endografts, especially first generation and bare metal stent endografts. Additionally, the aneurysmal or heavily atherosclerotic thoracic vessels are also at risk for complications following device manipulation. Due to the large sheath size, these vessels may rupture on device removal. Any acute cardiovascular decompensation or loss of flow to the ipsilateral limb after device removal should immediately prompt concern for this vessel rupture or dissection. Provided the guidewire has not been removed, this can often be temporized with balloon inflation, followed by deployment of a covered stent.

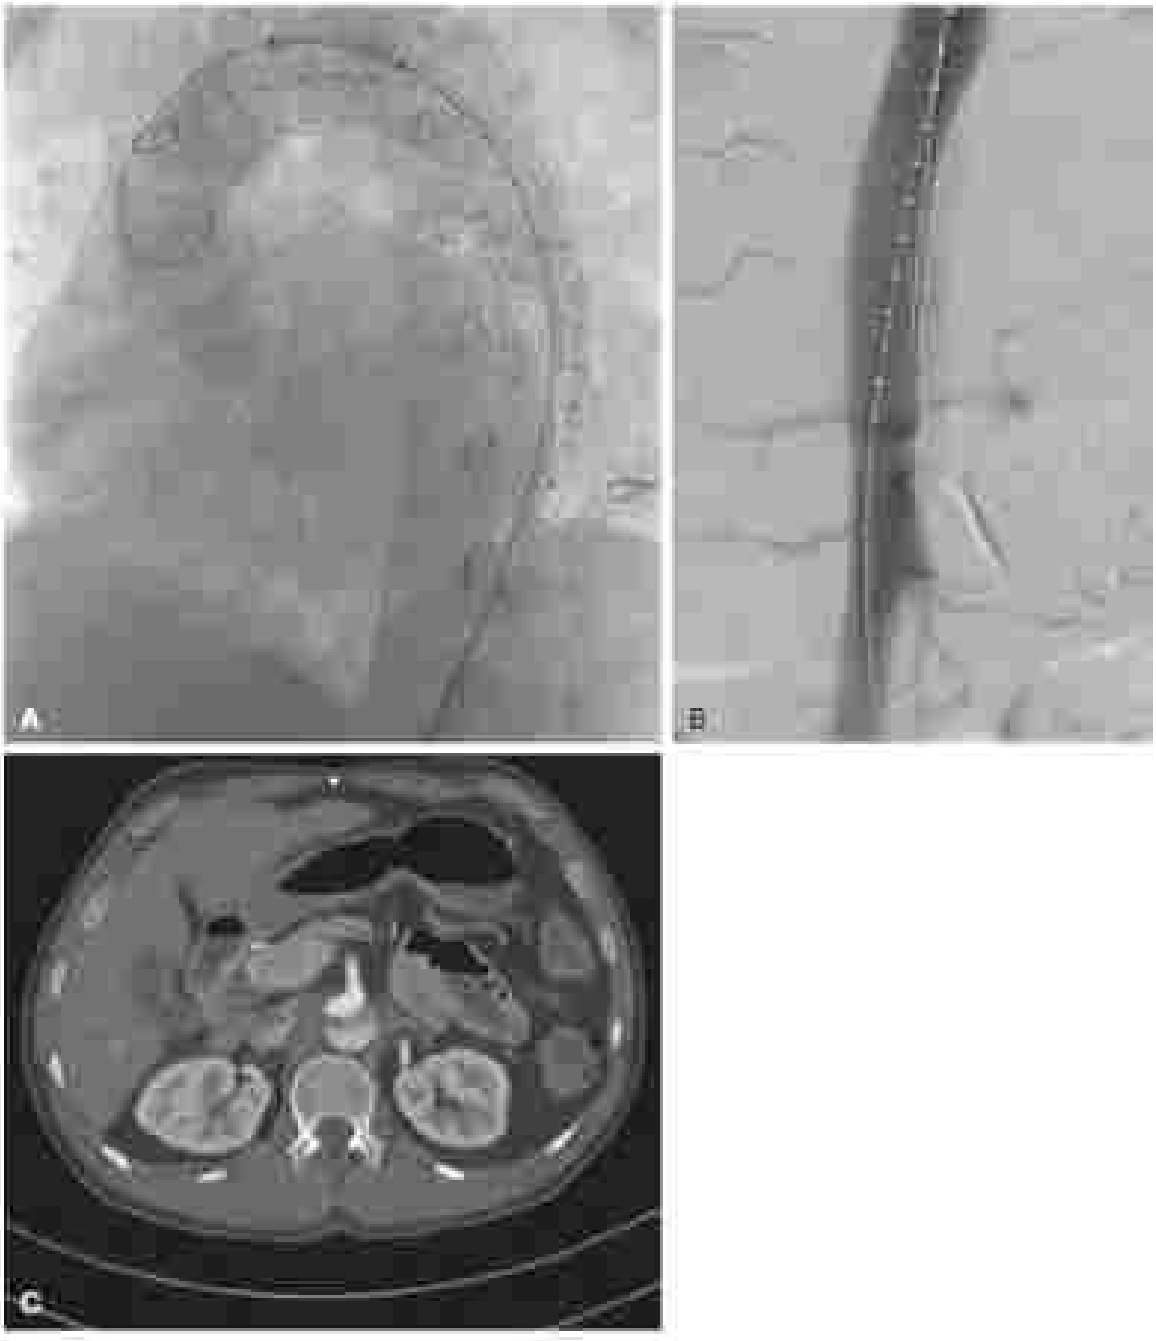

FIG 5. Operative and postoperative imaging for patient shown in Figure 4. (A) Deployment of thoracic endograft overlapping site of preoperative luminal tear. (B) Completion angiogram demonstrating adequate luminal result and visceral artery perfusion. Note enhancement of the thoracic false lumen is filling retrograde and likely resulting from a fenestration in the septum in the visceral segment of the aorta. (C) 3-month follow-up computed tomography scan demonstrating preferential filling of anterior true lumen, with continued visceral perfusion via patent superior mesenteric artery. The false lumen is appreciated to have decreased contrast density consistent with progressive thrombosis.

FOLLOW-UP

Long-term follow-up after acute aortic dissection is mandatory, as surveillance imaging may detect onset of degenerative aneurysms related to chronic aortic dissections. Patients should undergo CTA or MRA (if no indwelling thoracic stent). For surveillance of patients with chronic TBAD without indwelling stent graft, MRA may be preferred to monitor for degenerative changes and reduce the risk of repeated radiation exposure. For patients in whom an intervention has been performed, CTA surveillance should be started 1 month post procedurally (Fig 5C). In particular, the false lumen should be evaluated for luminal density appearance indicating progression to thrombosis. All dissection patients regardless of type or initial management strategy are recommended to undergo regular surveillance imaging at 1 month, 3 months, 6 months, 12 months and then annually thereafter.

For patients who underwent visceral segment angioplasty or stenting, postoperative evaluation with ultrasound may be a useful adjunct to limit overall radiation exposure. However, it should be noted that this requires a vascular lab facility to such an evaluation and

a patient with limited coronal obesity. All patients should be placed on statin and aspirin therapy and should have aggressive blood pressure control. These efforts are often best achieved through early coordination with the patient's primary care provider or cardiologist.

Carotid Endarterectomy

Courtenay M. Holscher, MD, and Che[illegible]
Rafa[illegible], MD, FACS

According to more than [illegible] million adults in the United States, stroke is a leading cause of death and disability. Stroke incidence increases with age, which must be considered in the context of an aging population. Approximately 80% of strokes are ischemic; of these, approximately 40% are caused by atherosclerotic disease of the carotid bifurcation. Carotid endarterectomy (CEA), originally performed by DeBakey in 1953, has become the definitive management of carotid artery stenosis to prevent death and disability due to stroke.

PRESENTATION

Clinical presentation

The management of carotid artery disease depends on whether patients present with neurologic symptoms referable to a carotid artery event or are found to have asymptomatic carotid artery disease either incidentally or on screening studies. Patients presenting with neurologic symptoms of carotid artery disease including stroke, transient ischemic attack (TIA), or other ischemic signs in the carotid distribution should undergo carotid artery imaging. This includes patients with amaurosis fugax, retinal artery emboli on funduscopic exam, and those with asymptomatic cerebral infarction found incidentally on imaging. It is important to note that if significant carotid artery stenosis is discovered on the contralateral side of a cerebral infarction or other ischemic sign, it would be considered asymptomatic. For example, should a patient with left sided weakness secondary to a right sided cerebral infarction have significant left carotid artery stenosis and no right carotid artery stenosis, this would be considered asymptomatic left carotid artery disease. In addition to evaluating for carotid artery disease, other causes of stroke should be ruled out, including cardiac thrombus, endocarditis, and intracranial cerebrovascular disease.

Screening of select asymptomatic patients should be considered only when patients are operative candidates and are willing to undergo a carotid intervention should a significant stenosis be found. These patients may include those with clinically significant peripheral vascular disease and patients aged [illegible] years or older who have another atherosclerotic risk factor such as tobacco smoking, hypercholesterolemia, or coronary artery disease.

Routine screening is not recommended in the general population due to the low prevalence of carotid artery disease. A neck bruit without other atherosclerotic risk factors is not an indication for screening. A bruit is neither a sensitive test a specific sign of carotid artery stenosis among those with a bruit, no more than 50% to [illegible]% will be found to have significant stenosis in the internal carotid artery (ICA).

[illegible]

Among those with high grade ICA stenosis, no more than 20% to 50% will have an ipsilateral bruit.

Imaging Studies

Duplex ultrasonography (DUS) by an accredited vascular laboratory is the imaging modality of choice for evaluation of carotid artery disease. DUS provides both anatomic information (B-mode) as well as flow velocity information (spectral Doppler), which can be used to determine the degree of stenosis. Multiple studies have correlated velocities with degree of anatomic stenosis based on catheter angiography, with increasing peak systolic (PSV) and end diastolic velocity corresponding to more significant narrowing. Many accredited vascular labs rely on the internal carotid to common carotid artery PSV ratio, as this controls for altered cardiac output and localized changes to carotid vessel flow dynamics due to collateralization and/or severe contralateral disease.

Beyond determination of the degree of stenosis, DUS can characterize the morphology of a carotid plaque, including calcification, lumen irregularity, ulceration, and the pattern of echogenicity that may indicate plaque instability caused by intraplaque hemorrhage or degeneration. Findings suggestive of an unstable plaque further support timely intervention in a patient with a significant carotid artery stenosis. DUS does have limitations to the setting of carotid artery disease, shadowing from calcific plaques creates artifacts that can limit ability to measure vessel anatomy and velocity. Additionally, DUS is not able to evaluate intracranial carotid disease or more proximal vessel disease in the chest.

Computed tomographic angiography (CTA), magnetic resonance angiography (MRA), or catheter based digital subtraction angiography (DSA) can be useful, whereas DUS is nondiagnostic or the vessels proximal or distal to the carotid bifurcation must be evaluated. It should be noted that there are several ways to measure carotid artery stenosis. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST) used different measurements to describe the degree of stenosis (Fig. 1); the NASCET measurement, which is commonly used in the United States, is less likely to classify stenosis as severe compared with the ECST measurement.

While time of flight MRA tends to overestimate stenosis, it spares contrast administration needed for gadolinium-enhanced MRA or CTA. Gadolinium enhanced MRA better defines the degree of carotid artery stenosis; however, gadolinium is associated with a risk, albeit low, of nephrogenic systemic fibrosis to patients with renal impairment. Although MRA can identify lipid core plaque morphology through black blood image sequences, CTA has replaced MRA as the axial imaging technique of choice. CTA can be performed quickly and provides anatomic information about the aortic arch, degree of carotid bifurcation calcification, tortuosity of the cervical carotid, and intracranial carotid arteries. Catheter based DSA, while previously the diagnostic gold standard, is associated with a 1% to 2% stroke risk and is, therefore, reserved for those cases where noninvasive imaging is indeterminate.

a patient with limited cranial density. All patients should be placed on statin and aspirin therapy and should have aggressive blood pressure control. These efforts are often best achieved through early coordination with the patient's primary care provider or cardiologist.

Imaging Studies

Duplex ultrasonography (DUS) by an accredited vascular laboratory is the imaging modality of choice for evaluation of carotid artery disease. DUS provides both anatomic information (B-mode) as well as flow velocity information (spectral Doppler), which can be used to determine the degree of stenosis. Multiple studies have correlated velocities with degree of anatomic stenosis based on catheter angiography, with increasing peak systolic (PSV) and end diastolic velocity corresponding to more significant narrowing. Many accredited vascular labs rely on the internal carotid to common carotid artery PSV ratio, as this controls for altered cardiac output and localized changes to carotid vessel flow dynamics due to collateralization and/or severe contralateral disease.

Beyond determination of the degree of stenosis, DUS can characterize the morphology of a carotid plaque, including calcification, lumen irregularity, ulceration, and the pattern of echogenicity that may indicate plaque instability caused by intraplaque hemorrhage or degeneration. Findings suggestive of an unstable plaque further support timely intervention in a patient with a significant carotid artery stenosis. DUS does have limitations in the setting of carotid artery disease, shadowing from calcific plaques creates artifacts that can limit ability to measure vessel anatomy and velocity. Additionally, DUS is not able to evaluate intracranial carotid disease or more proximal vessel disease in the chest.

Computed tomographic angiography (CTA), magnetic resonance angiography (MRA), or catheter based digital subtraction angiography (DSA) can be useful, whereas DUS is nondiagnostic or the vessels proximal or distal to the carotid bifurcation must be evaluated. It should be noted that there are several ways to measure carotid artery stenosis. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST) used different measurements to describe the degree of stenosis (Fig. 1); the NASCET measurement, which is commonly used in the United States, is less likely to classify stenosis as severe compared with the ECST measurement.

While time of flight MRA tends to overestimate stenosis, it requires contrast administration needed for gadolinium-enhanced MRA or CTA. Gadolinium enhanced MRA better defines the degree of carotid artery stenosis; however, gadolinium is associated with a risk, albeit low, of nephrogenic systemic fibrosis in patients with renal impairment. Although MRA can identify lipid core plaque morphology through black blood image sequences, CTA has replaced MRA as the axial imaging technique of choice. CTA can be performed quickly and provides anatomic information about the aortic arch, degree of carotid bifurcation calcification, tortuosity of the cervical carotid, and intracranial carotid arteries. Catheter based DSA, while previously the diagnostic gold standard, is associated with a 1% to 2% stroke risk and is, therefore, reserved for those cases where noninvasive imaging is indeterminate.

MEDICAL MANAGEMENT OF CAROTID ARTERY STENOSIS

Regardless of plans for procedural intervention, patients with carotid artery stenosis should be treated for hypertension, hypercholesterolemia, and provided counseling and resources for smoking cessation. However, aggressive treatment of hypertension is not recommended in the setting of an acute stroke. While diabetes should be medically managed, there is no evidence to support tight glucose control for reduction of stroke risk or reduction of perioperative risks of CEA. Patients should be counseled that smoking cessation both lowers their risk of stroke as well as their operative risks if CEA is indicated.

Antiplatelet and statin therapy is indicated for all patients with carotid stenosis. There is no evidence to support management with dual antiplatelet agents, nor evidence to support a particular aspirin dose. P2Y12 inhibitors, such as clopidogrel or ticagrelor, should be prescribed for patients with an aspirin allergy or sensitivity. Anticoagulation is not recommended but may be used if there is another indication, such as cardioembolic stroke. Statin therapy is associated both with decreased perioperative stroke and death risk and with decreased long-term stroke risk. Additional perioperative management is described below.

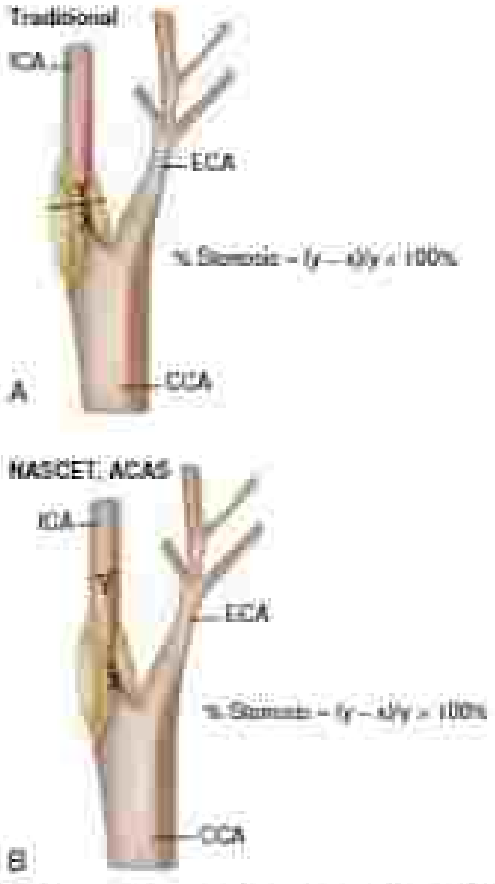

FIG. 1 Three methods of measuring carotid artery stenosis on an angiogram when the stenosis is within the bulb. CCA, Common carotid artery; ECA, external carotid artery; ICA, internal carotid artery. [illegible]

INDICATIONS FOR CAROTID ENDARTERECTOMY

Interestingly, there were five independent international guidelines with recommendations for management of carotid artery stenosis that were published in 2011: the Society for Vascular Surgery, the American College of Cardiology/American Heart Association, the European Society of Cardiology, the United Kingdom National Institute of Health and Clinical Excellence, and the Australasian guidelines. While these committees based their recommendations on the same literature, there are some differences between them. I.e report the Society for Vascular Surgery recommendations as they best follow the published evidence.

Symptomatic Disease

The Society for Vascular Surgery 2011 guidelines for management of extracranial carotid disease recommend CEA for a symptomatic carotid artery stenosis of 50% or greater. This recommendation is based on evidence from prospective randomized trials summarized in Table 1. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) collaborators, in their landmark 1991 paper, reported a 17% reduction in stroke risk over 2 years for stenosis >70% with CEA as compared to best medical treatment, which at that time was aspirin 1300 mg daily. The same year, the European Carotid Surgery Trial (ECST) collaborators reported a 13.9% risk reduction over 5 years for stenosis of 70% or greater. Subsequent analysis of NASCET participants with symptomatic 50% to 69% stenosis demonstrated a 4.5% reduction in stroke risk over 5 years.

Ideally, CEA should be performed within 2 weeks of the index event to prevent additional ischemic insult, based on the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST).

TABLE 1 Randomized Trials Comparing Carotid Endarterectomy with Medical Management of Ca...rtid Ste...osis

Trial	Stenosis Indication	Medical Stroke Risk	Surgical Stroke Risk	Risk Reduction
SYMPTOMATIC				
NASCET	70%–99%	26%	9%	17% over 2 years
	50%–69%	22.2%	15.7%	6.5% over 5 years
ECST	70%–99%	20.6%	6.8%	13.8% over 5 years
ASYMPTOMATIC				
ACAS	60%–99%	11.8%	5.1%	5.9% over 5 years
ACST	60%–99%	12.8%	6.8%	6.8% over 5 years

NASCET, North American Symptomatic Carotid Endarterectomy Trial; ECST, European Carotid Surgery Trial; ACAS, Asymptomatic Carotid Atherosclerosis Study; ACST, Asymptomatic Carotid Surgery Trial.

CEA is preferred over carotid artery stenting (CAS) for reduction of stroke and mortality risk in the majority of patients. While CEA was associated with a slightly increased risk of perioperative myocardial infarction, it was associated with both a lower risk of stroke and an improved long-term quality of life.

Asymptomatic Disease

Intervention for asymptomatic carotid artery stenosis depends both on the individual patient's life expectancy, as well as on the surgeon's perioperative stroke and death rates. If a patient has a life expectancy greater than 3 to 5 years and a surgeon's perioperative risk of stroke or death is less than 3%, the Society for Vascular Surgery 2011 guidelines recommend that asymptomatic patients with carotid artery stenosis of ≥60% or greater be considered for CEA. This is based on evidence summarized in Table 1. The Asymptomatic Carotid Atherosclerosis Study (ACAS) found a 5.9% reduction in risk of stroke over 5 years with CEA compared to medical management with aspirin 325 mg daily. Similarly, the Asymptomatic Carotid Surgery Trial (ACST) found a 5.4% risk reduction over 5 years with CEA compared to medical management.

It is important to note that alongside improved perioperative outcomes of CEA and CAS, there have been significant advances in medical treatment available including the introduction of statins in 1987. This has led to some clinical equipoise in the management of asymptomatic carotid artery stenosis, which should be addressed by the Carotid Revascularization and Medical Management for Asymptomatic Carotid Stenosis Trial (CREST-2) that began in 2014.

SPECIAL CONSIDERATIONS

Coronary Artery Bypass Grafting

Patients in need of coronary artery bypass grafting (CABG) should be screened for carotid artery stenosis prior to undergoing CABG given the high prevalence of carotid artery stenosis in this population. Patients with symptomatic carotid artery stenosis or severe bilateral asymptomatic carotid artery stenosis who are in need of CABG should undergo CEA prior to or concomitant with CABG. The surgical timing of carotid endarterectomy and CABG in patients with asymptomatic disease is controversial and may be performed based on surgeon and patient preference.

Prior Head and Neck Irradiation

Carotid screening is not recommended for asymptomatic patients who have had prior head and neck irradiation, but is recommended for patients with neurologic symptoms including stroke or TIA. For symptomatic patients with prior head and neck irradiation found to have a high grade stenosis, CAS is preferred over CEA.

OPERATIVE TECHNIQUE

Preoperative Medical Management

Perioperative management of patients undergoing CEA should include control of hypertension targeting a blood pressure less than 140/90 mmHg, β-blockade targeting a heart rate of 60 to 80 beats/min, and statin therapy targeting a low density lipoprotein level less than 100 mg/dL. Statin use decreases perioperative stroke risk and mortality as well as recurrent carotid stenosis; the evidence favors all patients undergoing CEA to be treated perioperatively and long-term with statins. Antiplatelet therapy with aspirin or P2Y12 inhibitors is also indicated.

Some surgeons use a dextran infusion for its antiplatelet effects intraoperatively and while the patient recovers in hospital. While previous studies have shown a reduction in embolic transcranial Doppler signals and perioperative stroke, more recent population based evidence suggests that it does not decrease perioperative stroke risk and may increase the risk of perioperative myocardial infarction and congestive heart failure.

Anesthesia

CEA can be performed under local anesthesia, regional anesthesia with a cervical block, or general anesthesia. Comparable lengths of hospital stay are seen with each anesthetic modality. The advantage of local or regional anesthesia, as compared to general anesthesia, is improved perioperative cardiac stability; however, this must be weighed against patient discomfort and anxiety. Our institutional practice is to perform CEA with general anesthesia unless the patient has prohibitive cardiac risks.

Positioning

Appropriate patient positioning is the first step in gaining adequate operative exposure, and is critical to preventing hyperextension injury to the patient. The patient is positioned supine and a roll is placed behind the scapula to extend the neck. The patient's head is turned to the contralateral side and a padded ring is placed to prevent extreme neck hyperextension (Fig. 2). The endotracheal tube and electroencephalogram electrodes and wires should be directed away from the operative field. The operating table should be adjusted to a beach chair with reverse Trendelenburg position to decompress the venous system. The field should be prepped from the base of the earlobe and mastoid to the sternal notch. If local or regional anesthesia is used, drapes should be suspended away from the patient's face for comfort and to prevent claustrophobia.

Incision

The standard incision for CEA is a longitudinal incision along the medial border of the sternocleidomastoid (Fig. 3). The upper portion of the incision can be angled posteriorly toward the earlobe to avoid the parotid gland if exposure above the angle of the mandible is needed. Alternatively, a transverse incision or an existing skin crease can provide excellent cosmesis, but there may be difficulty with exposure if the transverse incision is not directly superficial to the carotid bifurcation. A transverse incision does not easily allow cephalic or caudal extension. As such, intraoperative US can be helpful to guide placement of a transverse incision.

Exposure

Meticulous surgical technique to minimize manipulation of the carotid artery is critical to avoid nerve injury and intraoperative

FIG. 2 Appropriate patient positioning includes a roll under the patient's scapula to extend the neck and a padded ring under the patient's head, with the endotracheal tube, electroencephalogram electrodes, and wires directed away from the operative field.

embolization. The platysma is divided and the medial border of the sternocleidomastoid muscle is mobilized. The external jugular vein and the greater auricular nerve are located deep to the platysma and should be preserved, particularly as the external jugular vein can be used as a vein patch if needed. The sternocleidomastoid is retracted laterally, exposing the carotid sheath. The carotid sheath is entered. The internal jugular vein is dissected free along its medial border, facilitated by division of the facial vein, and retracted laterally. The vagus nerve should be identified and preserved (Fig. 4). Dissection continues to free the distal CCA where the ansa cervicalis should be identified, as well as the bifurcation into the ICA and external carotid artery (ECA). The ansa cervicalis can be followed superiorly to its junction with the hypoglossal nerve, which should be preserved. The superior thyroid artery is identified at its origin from the ECA and

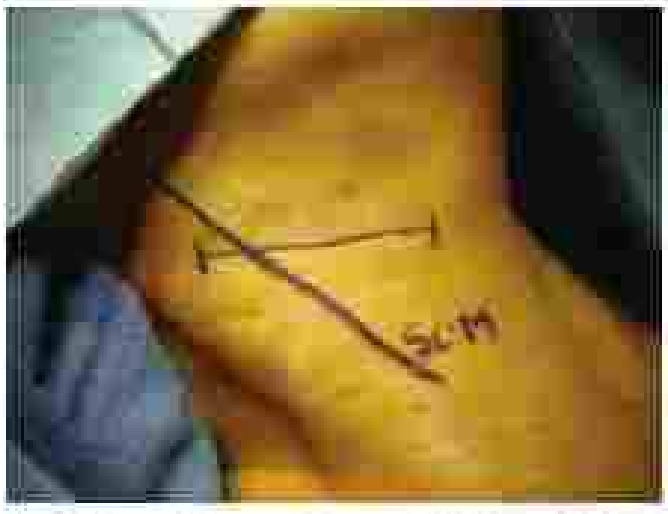

FIG. 3 Longitudinal and transverse incision options for carotid endarterectomy. A longitudinal incision is made along the medial border of the sternocleidomastoid (SCM). A transverse incision can provide improved cosmesis; however there may be difficulty with exposure of the carotid bifurcation should a transverse incision be made in a suboptimal location. (From Veith, F. et al. Rutherford's Vascular Surgery 7th ed. Elsevier, 2010.)

FIG. 4 Intraoperative exposure of the carotid bifurcation. The common carotid is encircled with an umbilical tape while the internal carotid, external carotid, and superior thyroid arteries are controlled with vessel loops. The vagus nerve (*small arrow*) and hypoglossal nerve (*big arrow*) should be identified and avoided.

controlled with a 3-0 or vessel loop. Dissection of the ICA should continue to a portion of the artery that is above the plaque and free of disease. During dissection of the carotid bifurcation, extreme care should be taken to avoid injuring the carotid body, located in the crotch of the carotid bifurcation. Injury to the carotid body can result in bleeding and hemodynamic instability. The carotid body can be injected with 0% lidocaine to prevent hemodynamic instability.

The carotid bifurcation ranges in location from the level of the second to the seventh cervical vertebrae. A bifurcation located high in the neck should ideally be noted on preoperative imaging. CTA can be useful to delineate bony anatomy in the setting of a high bifurcation. There are several methods to improve exposure for high carotid bifurcations. Nasotracheal intubation allows the patient's mouth to be closed during the operation, displacing the mandible 1 to 2 cm anteriorly. Next, the posterior belly of the digastric muscle can be divided. After the posterior belly of the digastric is divided, the muscular insertions of the styloid process can be divided and the styloid process can be resected for further exposure if necessary. Finally, if additional exposure is still needed, the mandible can be subluxed anteriorly with the assistance of an oral or plastic surgeon.

At this point, the CCA and its main branches are exposed and controlled (see Fig. 4). 70 to 100 U/kg heparin should be given and allowed to circulate for 3 minutes prior to any clamping, and a decision must be made regarding cerebral protection and monitoring.

Shunts and Cerebral Monitoring

There are three approaches to maintaining cerebral perfusion during carotid clamping: (1) performing CEA without a shunt, (2) routine use of shunts for all CEAs, and (3) selective use of shunts. In the case of CEA without a shunt, there is a small incidence of perioperative stroke and, therefore, this technique is considered outside the standard of care. Many surgeons routinely use shunts for all CEAs as it maintains antegrade perfusion of the ipsilateral cerebral hemisphere. This is especially important in those patients with contralateral disease, although technical issues related to shunt placement may rarely cause distal embolism or dissection. In the case of selective use of shunts, which aims to balance these risks, there are several techniques used to determine whether a shunt is needed. If local anesthesia or intraoperative electroencephalography is being used, a test clamp should be applied to the distal ICA for at least 3 minutes to assess for neurologic changes. If such changes occur, the ICA should be unclamped and reperfused before the bifurcation is opened and a shunt placed. If carotid stump pressure is being used, clamps are placed on the CCA and ECA and a needle connected to a pressure line is placed in the distal CCA superior to the clamp and inferior to the carotid bifurcation. A stump pressure higher than 50 mm Hg generally indicates adequate perfusion. Transcranial Doppler measurement of middle cerebral artery flow and measurement of cerebral oximetry can also be used to guide selective use of shunts following artery clamping. It must be noted that any clamping or placement of a needle into the vessels is associated with a risk of embolization.

Endarterectomy

Conventional Endarterectomy

Conventional endarterectomy uses a longitudinal arteriotomy and a patch closure. The ICA is clamped first to prevent any embolization that might result from CCA or ECA clamping. The longitudinal arteriotomy begins in the CCA with an 11 or 15 blade and continues through the carotid bifurcation into the ICA using Potts scissors. If a shunt is used, it is placed in the ICA and backbled before the proximal end is placed into the CCA. A number of commercial shunts are available including Argyle, eSAT, and Pruitt-Inahara shunts, and all have excellent results.

The endarterectomy is started mid plaque with a Freer or Penfield elevator in the plane between the media and adventitia (Fig. 5).

The plaque is freed inferiorly to an endpoint in the distal CCA where the plaque is transected. It is freed superiorly toward an endpoint in the ICA where it is either transversely pulled off the artery or transected. A smooth transition from endarterectomized surface to normal intima is critical to prevent embolization or dissection with reperfusion. Gentle saline injection into the endarterectomized surface can reveal intimal flaps that can be tacked down with 7-0 polypropylene or further endarterectomized. Tacking sutures are associated with increased perioperative stroke risk and should be avoided if possible. The plaque is then freed to the ECA where it is endarterectomized with eversion after the ECA clamp is removed. The endarterectomized surface should be carefully inspected and all residual fragments of intima and media removed.

Closure of the arteriotomy is accomplished with a patch (Fig. 4); primary closure is associated with a higher rate of restenosis. Materials used for patch closure include autologous vein, bovine pericardium, polytetrafluoroethylene, and woven polyester (Dacron), and all have excellent results. If a shunt was used, it should be removed and the ICA should be back bled to clear debris associated with shunt use. The arteriotomy is closed and the ICA clamp is briefly released to fill the vessel, then replaced. The CCA and ECA clamps are released to flush any remaining debris or air through the ECA before ICA reperfusion. The ICA clamp is removed last.

Eversion Endarterectomy

Eversion endarterectomy is an alternative technique used by many surgeons (Fig. 7). In this technique, the ICA is transected from the carotid bifurcation and the plaque is excised from the ICA. The plaque is endarterectomized from the CCA and ECA through the ICA origin transection. The ICA is then reanastomosed to the carotid bifurcation. Advantages of eversion endarterectomy include its rapid performance, lack of patch requirement, and low restenosis rate. However, eversion endarterectomy does not easily allow use of shunts and it can be difficult to visualize the endpoint of ICA endarterectomy because the artery wraps once the plaque has been endarterectomized.

Completion Studies

Perioperative thromboembolism and carotid artery thrombosis due to technical errors should be considered preventable. Technical defects that might lead to these etiologies of perioperative stroke can be assessed using intraoperative Doppler evaluation, DUS, or angiography. Doppler scan evaluation can identify areas of turbulence and

high velocity, but is highly operator dependent. Intraoperative completion DUS provides detailed anatomic information about the CEA clamp site that otherwise is difficult to assess. Catheter-based angiography has similar sensitivity in detecting major technical defects of the endarterectomy. However, there is not consensus as to which criteria merit re-exploration. Most agree that minor defects should be left alone while major technical defects should be addressed. Additionally, a postoperative DUS is indicated within 30 days to assess the status of the endarterectomized vessel.

RESULTS

Recent reported perioperative mortality after CEA ranges from 0.4% to 1.9% and is mainly due to myocardial infarction (Table 2),

TABLE 2 Perioperative Morbidity and Mortality Associated with Carotid Endarterectomy

	Reported Incidence
Death	0.4%–1.9%
Stroke	0.3%–2.9%
Myocardial infarction	0.2%–1.5%
Cranial nerve injury	
Hypoglossal	4.4%–17.5%
Recurrent laryngeal	0.3%–1.5%
Superior laryngeal	1.8%–4.5%
Marginal mandibular	1.1%–2.1%
Glossopharyngeal	0.2%–1.5%
Spinal accessory	1.0%
Cerebral hyperperfusion syndrome	0.4%–7.7%
Infection	0.09%–0.5%
Bleeding	0.7%–3.0%
Recurrent carotid stenosis	5.0%–22.0%

although mortality has declined over time. This reflects the systemic nature of atherosclerotic disease. Rates of perioperative stroke range from 0.3% to 2.9% and have also decreased over time. The most frequent complication of CEA is cranial nerve injury or dysfunction. Patients with high carotid bifurcation are at higher risk of cranial nerve injury. The majority of these nerve injuries are due to traction and resolve within a few days to weeks. While perioperative hemodynamic instability due to manipulation of the carotid sinus baroreceptors is not uncommon, it typically resolves within a few hours of CEA. A more severe loss of autoregulation in cerebral hyperperfusion syndrome, which occurs days after CEA. This is an acute neurologic deficit that is often preceded by a severe headache and is associated with hypertension. Cerebral hyperperfusion syndrome can result in intracerebral hemorrhage. Perioperative blood pressure control with a goal of less than 140/80 mm Hg to 0 might be preventive. While infection and bleeding are rare complications of CEA, recurrent carotid stenosis is seen on follow-up imaging in 5% to 22% of patients. However, only 3% of recurrent stenoses are symptomatic.

MANAGEMENT OF RECURRENT CAROTID STENOSIS

Roopanshu Tiwari, MD, and Ying "Bei" Lum, MD

The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the Asymptomatic Carotid Atherosclerosis Study (ACAS) are prospective randomized trials that have established carotid endarterectomy (CEA) as the gold standard treatment for high-grade symptomatic and asymptomatic carotid stenosis respectively. CEA significantly reduces the risk of stroke and death compared to best medical therapy. It is a safe and durable procedure with minimal morbidity and mortality when performed by qualified practitioners on appropriate surgical candidates. More recently, the evolution of endovascular therapy has introduced carotid angioplasty and stenting (CAS) as an alternative to CEA in patients who are considered at high risk. However, both CEA and CAS are not full-proof procedures. Timely carotid artery surveillance imaging post CEA and CAS have shown that a minority of patients will develop a narrowing of the carotid artery at or adjacent to the site of revascularization. A luminal diameter narrowing of 50% or greater on duplex ultrasonography (DUS), which corresponds to a 75% or greater narrowing in the cross-sectional area, is the most commonly used criteria to define carotid restenosis. Restenosis after CEA and CAS has been reported to range from 5% to 20% depending on the definition used to characterize restenosis and the duration of follow-up. This chapter aims to discuss the risk factors, morbidity, pathogenesis, the timing of surveillance and management of carotid artery restenosis after both CEA and CAS.

INCIDENCE, RISK FACTORS, AND IMPLICATION OF RECURRENT CAROTID STENOSIS

Patients who develop recurrent carotid stenosis post CEA are more likely to be asymptomatic. About 8% to 23% will present with

high velocity, but is highly operator dependent. Intraoperative completion DUS provides detailed anatomic information about the CEA clamp site that otherwise is difficult to assess. Catheter-based angiography has similar sensitivity in detecting major technical defects of the endarterectomy. However, there is not consensus as to which criteria merit re-exploration. Most agree that minor defects should be left alone while major technical defects should be addressed. Additionally, a postoperative DUS is indicated within 30 days to assess the status of the endarterectomized vessel.

RESULTS

Recent reported perioperative mortality after CEA ranges from 0.4% to 1.9% and is mainly due to myocardial infarction (Table 2).

Management of Recurrent Carotid Stenosis

Rengarajan Sooppan, MD, and Ying Wei Lum, MD

The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the Asymptomatic Carotid Atherosclerosis Study (ACAS) are prospective randomized trials that have established carotid endarterectomy (CEA) as the gold standard treatment for high-grade symptomatic and asymptomatic carotid stenosis respectively. CEA significantly reduces the risk of stroke and death compared to best medical therapy. It is a safe and durable procedure with minimal morbidity and mortality when performed by qualified practitioners on appropriate surgical candidates. More recently, the evolution of endovascular therapy has introduced carotid angioplasty and stenting (CAS) as an alternative to CEA in patients who are considered at high risk. However, both CEA and CAS are not fail-proof procedures. Timely carotid artery surveillance imaging post CEA and CAS have shown that a minority of patients will develop a narrowing of the carotid artery at or adjacent to the site of revascularization. A luminal diameter narrowing of 50% or greater on duplex ultrasonography (DUS), which corresponds to a 75% or greater decrease in the cross sectional area, is the most commonly used criteria to define carotid restenosis. Restenosis after CEA and CAS has been reported to range from 5% to 20% depending on the definition used to characterize restenosis and the duration of follow up. This chapter aims to discuss the risk factors, morbidity, pathogenesis, the timing of surveillance and management of carotid artery restenosis after both CEA and CAS.

INCIDENCE, RISK FACTORS, AND IMPLICATION OF RECURRENT CAROTID STENOSIS

Patients who develop recurrent carotid stenosis post-CEA are more likely to be asymptomatic. About 9% to 25% will present with

symptomatic neurologic events (i.e., transient ischemic attack [TIA], stroke). The incidence of recurrent carotid stenosis varies widely in the literature based on the method and time interval of surveillance. Follow-up prospective data collection from the ACAS trial using Doppler ultrasound surveillance has shown that the incidence of recurrent carotid stenosis post CEA is 4.1% in the early postoperative period (<3 months), 7.6% from 3 to 18 months and 1.9% from 18 to 60 months. Data from other studies have also shown that the average rates of recurrent carotid stenosis after CEA can be estimated to be 10% at 1 year, 3% in the second year, 2% after 3 years, and 1% after 5 years.

Several risk factors have been associated with recurrent carotid stenosis after CEA, namely continued smoking, hyperlipidemia, diabetes, hypertension, primary closure without patch angioplasty, and end-stage renal disease (Box 1). In-stent restenosis (ISR) after CAS has been attributed to similar risk factors as recurrent stenosis after CEA and to residual stenosis, use of balloon-expandable stent, stent undersizing, and deployment of multiple stents (Box 2).

Recurrent carotid stenosis post CEA increases the risk of cerebrovascular ischemia secondary to flow obstruction and thromboembolism. The risk of ipsilateral stroke after CEA is at its highest within the first 2 years after the operation and the risk decreases over time after 2 years. This can be explained by the relatively higher incidence of recurrent carotid restenosis during that time frame, which increases the risk of ipsilateral stroke. In fact, up to 50% of ipsilateral symptomatic strokes can be attributed to recurrent carotid stenosis after CEA. Not surprisingly, as the incidence of recurrent carotid stenosis decreases over time, so does the risk of developing symptomatic ipsilateral strokes after 2 years post CEA.

The real incidence of ISR after CAS is unclear, with reports ranging from 5% to 21%. The incidence of 80% or greater ISR after CAS has been reported to occur in up to 42.2% of patients and ISR of 80% or greater in as 8% at 5 years. Although ISR puts patients at increased risk of cerebrovascular events, the neointimal hyperplastic reaction seems to be associated with a reduced risk of distal embolization as compared to the initial native lesion. Several clinical trials have looked into the risk of stroke secondary to ISR. The Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) showed an increased risk of stroke at 5 years in patients who develop severe (>70%) carotid artery ISR. The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) also showed similar results, with more than 70% ISR after CAS placing patients at increased risk of stroke. However, multiple other studies including the Stent Protected Angioplasty versus Carotid Endarterectomy Trial (SPACE) showed that there was no associated increased risk of cerebrovascular ischemia in patients who develop ISR at 2 years.

BOX 1 Risk Factors Associated With Recurrent Carotid Stenosis After Carotid Endarterectomy

- Smoking
- Female sex
- Diabetes
- Hypertension
- Hyperlipidemia
- [illegible] stage renal disease [illegible] dialysis
- [illegible] [illegible] [illegible] carotid artery [illegible] at [illegible] to [illegible]
- Small internal carotid artery diameter
- Prior [illegible] carotid artery injury

BOX 2 Risk Factors Associated With In-Stent Restenosis After Carotid Angioplasty and Stenting

- Female sex
- Smoking
- Diabetes
- Hypertension
- Hyperlipidemia
- End-stage renal disease
- Residual stenosis after index procedure
- Use of balloon-expandable stents
- Stent under-expansion
- Deployment of multiple stents

PATHOGENESIS OF RECURRENT CAROTID STENOSIS

Intimal hyperplasia is the primary cause of recurrent carotid stenosis in the first 2 years after CEA. The endarterectomy bed undergoes a hyperplastic reaction, which accounts for the decrease in luminal diameter in the first 2 years after carotid endarterectomy. After 2 years, luminal narrowing is secondary to atherosclerotic lesions, which are deposited throughout the artery and not necessarily confined to the endarterectomy bed. Interestingly, patients who undergo CEA for asymptomatic carotid stenosis have been observed to have a higher risk of developing carotid restenosis at 1 year compared to patients who underwent CEA for symptomatic disease (i.e., TIA). This observation can be explained by the difference in atherosclerotic plaque content in asymptomatic compared to symptomatic patients. Asymptomatic patients tend to have stable plaques that have low macrophage levels, small or absent lipid core, and low levels of matrix metalloproteinase. On the other hand, inflamed plaques with high levels of macrophages, leukocytes, and lipid rich cores have high levels of matrix metalloproteinase activity, which leads to expansive remodeling of the media and adventitia and less restenosis.

Restenosis can also be secondary to a focal reactive process such as in cases where there are iatrogenic injuries to the blood vessels (i.e., trauma from forceps, vascular clamps, and intravascular shunts). Improper surgical technique can also contribute to recurrent stenosis (i.e., residual atheroma post endarterectomy, intimal flap, patch irregularities, residual thrombus, and irregular bends and kinks in the blood vessel after reconstruction).

ISR after CAS is the likely result of neointimal hyperplasia caused by chronic inflammation secondary to endothelial dysfunction and traumatic irritation of the intima. It occurs within 2 years after the index procedure or as de novo atherosclerotic lesions after 2 years. Interestingly, patients who develop recurrent carotid stenosis after CEA have a higher risk of developing ISR if their restenosis are treated with carotid artery balloon angioplasty or stenting; thus, suggesting that some patients have an above average aggressive hyperplastic response and unfavorable biology that places them at higher risk to develop early restenosis. Carotid ISR is often detected on surveillance DUS and is categorized in a classification pattern that is similar to the one used for the coronary circulation. There are five types of ISR summarized in Table 1 and Fig. 1. Notably, type 1 lesion (focal end-mid) are the most common after CAS and type IV lesions are very often found in the diabetic population and are predictive of subsequent stent failure that will require further intervention.

METHOD OF RECONSTRUCTION AND INFLUENCE ON RESTENOSIS AFTER CAROTID ENDARTERECTOMY

The carotid artery can be reconstructed by primary closure or with patch angioplasty. Comparison of outcomes between the two has been extensively studied and there is clear and overwhelming evidence that patch angioplasty is superior to primary closure in reducing the rate of carotid artery restenosis, especially when patients continue postoperative aspirin and statin therapy. The ACAS study showed a restenosis rate of 4.6% with patch angioplasty versus 16.9% with primary closure. The CREST trial also showed a reduction in restenosis rate with patch angioplasty but no difference in stroke

TABLE 1 Different Patterns of Carotid In-Stent Restenosis

Type	Description and Characteristics of ISR Lesion
I (Focal end-stent group)	Lesions are <10 mm long and are positioned at the proximal or distal margin (but not both) of the stent. Lesions >10 mm long at both ends of the stent are defined as type I, multifocal end-stent.
II (Focal intra-stent group)	Lesions are <10 mm long and are confined to within the stent(s) without extending outside the margins. Two or more discrete lesions <10 mm long located within the stent are defined as type II, multifocal intra-stent.
III (Diffuse intra-stent group)	Lesions are >10 mm long and are confined to within the stent(s) without extending outside the margins.
IV (Diffuse proliferative group)	Lesions are >10 mm long and extend beyond the margin(s) of the stent(s).
V (Occlusion group)	Lesion have no prograde flow and no lumen is identified.

ISR, in-stent restenosis.

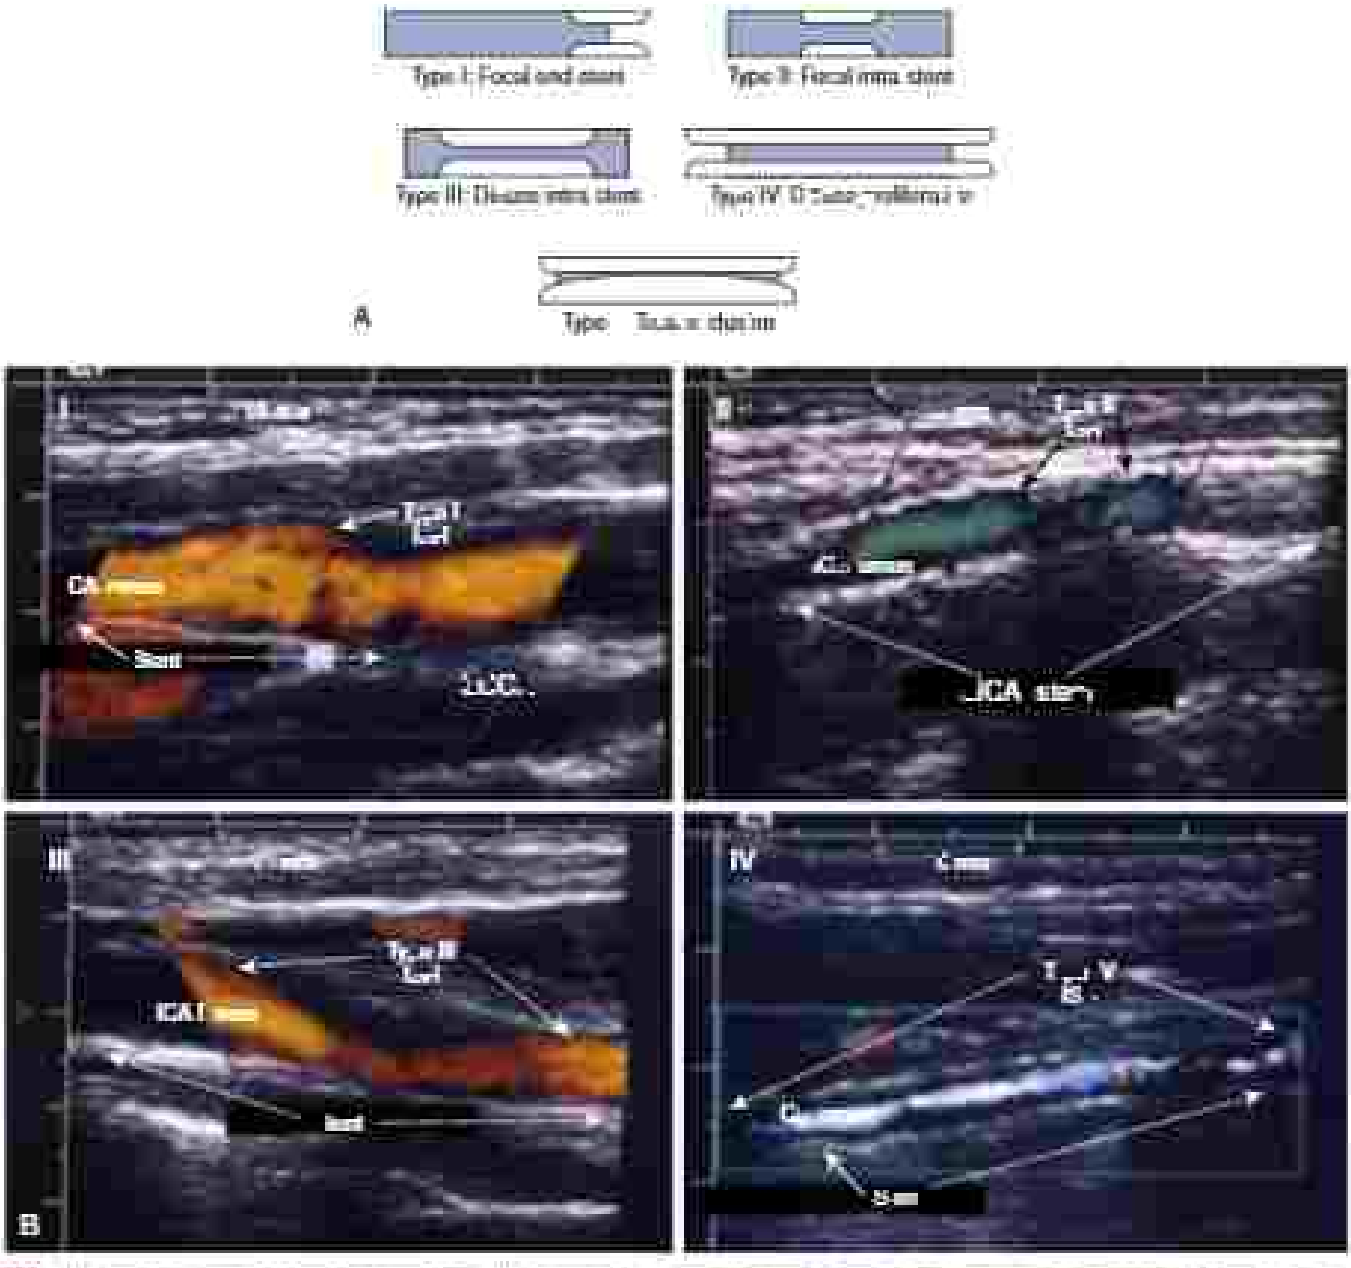

FIG. 1 (A) Type I to V carotid in-stent restenosis (ISR). (B) Representative B-mode ultrasound images of ISR corresponding to types I to IV of post-carotid angioplasty and stenting ISR. C, internal carotid artery; CCA, left common carotid artery; I, A, left internal carotid artery (Modified from [illegible] Patterns of in-stent restenosis after carotid artery stenting: classification and long-term outcomes [Chin Surg 2007;82:420–425])

rate. A Cochrane Systematic Review of the literature examined 1307 CEA operations in 1137 patients and found that patch angioplasty was superior to primary closure because there was a more than 50% reduction in occlusion and stroke rate at 1 year in the patch angioplasty group. Moreover, that study also showed that there was also a reduction in perioperative arterial occlusion and return to the operating room. Similarly, a retrospective review of 2017 CEA performed at The Massachusetts General Hospital identified primary closure as an independent risk factor for the development of restenosis. The Vascular Study Group of New England (VSGNE) review of CEA from their database from 2003 to 2008 also showed evidence that patch angioplasty significantly reduces the rate of restenosis post CEA compared to primary closure.

Some surgeons preferentially use the eversion endarterectomy technique when performing carotid endarterectomy. In this technique, the internal carotid artery is transected at the level of the carotid bulb and the distal segment of the internal carotid artery is everted and the plaque pealed away, leaving the endarterectomy bed behind. The Eversion Carotid Endarterectomy Versus the Standard Trial compared restenosis rates between standard CEA with patch angioplasty and the eversion technique. The study showed that the restenosis rates were similar in both techniques. In light of such convincing evidence from multiple studies that are in favor of conventional CEA with patch angioplasty or eversion endarterectomy over primary closure alone, the Society for Vascular Surgery (SVS) recommends patch angioplasty after conventional CEA or eversion endarterectomy in its practice management guidelines for CEA in order to decrease restenosis rate.

TYPE OF STENT AND INFLUENCE ON RESTENOSIS AFTER CAROTID ANGIOPLASTY AND STENTING

Carotid stents come in two main categories: open cell stent and closed cell stent. Open cell stents are designed to keep adjacent segments of the stent detached from one another. This design allows for better conformational change and adaptability to the vessel anatomy, but with less plaque coverage and more tissue prolapse. Closed cell stents, on the other hand, are designed with a higher density of interconnections due to more bridging of the adjacent segments. Closed cell stents offer more plaque coverage but have reduced conformability and apposition to the vessel wall. No long-term study, up to now, has shown a difference in restenosis rate between the two types of stents.

SURVEILLANCE OF RECURRENT CAROTID STENOSIS

After Carotid Endarterectomy

It is crucial to have a methodical and timely surveillance imaging schedule after CEA to assess for ipsilateral restenosis and contralateral progression of preexisting stenosis. In fact, the progression of contralateral stenosis is more common than ipsilateral recurrent stenosis. DUS is the imaging modality of choice for surveillance after CEA because it is noninvasive, cost effective, and has a sensitivity of 91% and specificity of 82% for detecting a ≥50% restenosis of the carotid artery. In its best practice guidelines, the SVS recommends surveillance imaging within 30 days postoperatively after CEA. The SVS guidelines also recommend continued surveillance in patients with 50% or greater ipsilateral restenosis or contralateral stenosis, in those who underwent primary closure of the artery after endarterectomy and in patients with high risk factors for atherosclerotic disease progression. However, there is no consensus on the timeline and the frequency of surveillance beyond the postoperative period, and this has been the subject of many debates. Since patients are more likely to develop an ipsilateral restenosis within the first 2 years after CEA, it is essential to have more frequent duplex surveillance in the early postoperative period. Most patients who develop atherosclerotic disease of the carotid artery have underlying risk factors such as smoking, diabetes, hyperlipidemia, and hypertension that inherently places them in the high risk patient category. In our practice, we surveil our patients at the 1 month, 6 month, and 1 year marks postoperatively after CEA. The subsequent surveillance schedule is then tailored to the patient's specific needs depending on their risk factors and the data from previous duplex about the progression of their disease.

After Carotid Angioplasty and Stenting

Surveillance for ISR in patients who underwent CAS is particularly important because the rate of developing restenosis after CAS is higher than after CEA, albeit most ISR are mild to moderate and require no intervention and only a minority of patients will develop high grade ISR that will require reintervention. Unlike restenosis after CEA, ISR after CAS can develop many years after the index procedure. A timely surveillance schedule is very important to identify hemodynamically significant lesions that need reintervention; however, there is no consensus on the time intervals and duration of surveillance after the procedure. As with CEA, the imaging modality of choice for surveillance after CAS is DUS. Other modalities such as computer tomographic angiography and magnetic resonance angiography can also be used to detect ISR. However, these imaging modalities tend to overestimate the degree of ISR and the results are often affected by stent artifacts. Whenever a hemodynamically significant ISR is suspected on noninvasive imaging, it is best to assess the suspected lesion with digital subtraction angiography to get a more accurate estimate of the degree of restenosis.

In our practice, patients who underwent CAS are surveilled in a similar fashion as our patients who underwent CEA. We obtain a DUS at the 1 month, 6 month and 1 year mark. Subsequent surveillance is then tailored according to DUS findings and progression of the disease. It is important to note that the velocity criteria for duplex surveillance post CAS are different from the velocity criteria used for surveillance post CEA. A summary of the velocities and corresponding degrees of restenosis post CEA versus CAS adopted by our vascular laboratory is shown in Table 2. The peak systolic velocity threshold used to correlate with the degree of restenosis is higher in CAS. The goal of duplex surveillance imaging is to identify patients who are at risk of hemodynamically significant (>70%–80%) restenosis that may result in a cerebrovascular event if not detected and intervened upon in a timely fashion. Patients found to have less than 50% stenosis do not need a rigorous surveillance schedule. Those who have 50% to 69% stenosis need closer surveillance as there are limited data available on the natural progression of such lesions. Patients with 50% to 70% restenosis need duplex surveillance every 6 months to monitor the disease progression into the severe ISR category. When 70% to 80% restenosis is identified, patients should undergo digital subtraction catheter angiography.

MANAGEMENT OF RECURRENT CAROTID STENOSIS

After Carotid Endarterectomy

In the ACAS and NASCET trials, patients who underwent CEA were concurrently treated with best medical therapy. The results established by these trials reflect the combination of CEA and best medical management. Therefore, it is imperative that all patients be placed on an antiplatelet agent (e.g., aspirin), lipid lowering therapy (e.g., statin) and their modifiable risk factors are reduced or controlled post CEA to reduce their risk of recurrent carotid stenosis. Despite best medical management post CEA, a subset of patients still develop high grade restenosis requiring surgical intervention. Reoperative CEA has a higher morbidity rate compared to primary CEA. The post procedural stroke rate is 7% and the cranial nerve injury rate is as high as 19%. Although some recent studies have shown that reoperative CEA with similar morbidity perioperative morbidity rates to primary CEA can be achieved, the risk of death, stroke, and myocardial

TABLE 2 Duplex Ultrasonography Velocity Criteria to Establish the Presence of Recurrent Carotid Stenosis in the Native Carotid Artery Post-Carotid Endarterectomy Compared With Established Velocity Criteria to Establish the Presence of In-Stent Stenosis Post-Carotid Angioplasty and Stenting

Degree of Stenosis	Native Carotid Artery	Stented Carotid Artery
0%–19%	PSV <130 cm/s	PSV <150 cm/s and ICA/CCA ratio <2.5
20%–49%	PSV 130–199 cm/s	PSV 150–219 cm/s
50%–79%	PSV 200–299 cm/s and EDV <120 cm/s	PSV 220–339 cm/s and ICA/CCA ratio >2.5
80%–99%	PSV >300 cm/s and EDV >120 cm/s, or ICA/CCA ratio >4.0	PSV >340 cm/s and ICA/CCA ratio >4.5

EDV, end-diastolic velocity; ICA/CCA, internal carotid artery/common carotid artery; PSV, peak systolic velocity.

infarction (MI) are all significantly increased in reoperative CEA compared to the primary procedure. In fact, analysis of the VISCAT registry showed a 3.9% death and stroke rate with reoperative CEA compared to 1.2% rate of stroke and death with primary CEA.

Symptomatic patients after CEA need a reoperation if their degree of restenosis is 50% or greater. The decision to operate on asymptomatic patients is more complex and requires weighing the risk of operative morbidity against the morbidity of stroke with medical management alone. To justify a reoperation in the asymptomatic population, the benefits of the operation must outweigh the risks of the operation (i.e., MI and stroke) and the risks of observation alone. The SVS and European Society for Vascular Surgery (ESVS) recommend against a reoperative intervention when the combined stroke and death rate exceeds 6% for patients with symptomatic carotid restenosis and 3% for those with asymptomatic carotid stenosis. In our practice, we initially treat asymptomatic carotid restenosis with a maximal statin and antiplatelet therapy. Surgical intervention is considered in patients who progress to high-grade restenosis despite maximal medical management.

SURGICAL TECHNIQUES FOR MANAGEMENT OF RECURRENT STENOSIS

Reoperative CEA is a high-risk operation and no specific technique has been described to offer superior results over another. Some of the techniques described include endarterectomy alone, patch angioplasty alone without endarterectomy (the patch can be saphenous vein, Dacron, or polytetrafluoroethylene [PTFE]), endarterectomy with patch angioplasty (the patch can be saphenous vein, Dacron, or PTFE), and resection of the artery with interposition graft (saphenous vein, Dacron, or PTFE; Fig. 1). In our practice, we attempt excising the previous patch, repeat an endarterectomy, and replace the old patch with Dacron or bovine pericardium. If the repeat endarterectomy is technically not feasible or leaves the artery severely compromised, our approach is to resect the artery and perform an interposition repair with translocated reversed greater saphenous vein graft preferentially. In patients who do not have suitable veins, we use PTFE for an interposition conduit. In patients who develop recurrent stenosis for the second time after a reoperation, we follow a similar algorithm to a first-time restenosis. Patients who are symptomatic with a 50% or greater restenosis and asymptomatic patients with a 70%–80% restenosis are offered an operation. However, for tertiary carotid interventions, we prefer resection of the involved segment of the artery with interposition graft with translocated reverse greater saphenous vein or PTFE.

Some surgeons prefer CAS as first-line management for secondary carotid interventions to avoid dissecting into a reoperative field hence reducing the risk of cranial nerve injury. CAS is an acceptable alternative to reoperative CEA. Both techniques have been studied retrospectively and have comparable outcomes in the endpoints of death, stroke, and MI. However, some studies have shown that CAS has a higher rate of restenosis compared to reoperative CEA. One study showed that reoperative CEA had a 50% restenosis rate of 5.9% compared to 20% for CAS, but the difference in restenosis rate was not associated with increased risk of death, stroke, or MI. A recent meta-analysis showed that patients who developed restenosis after CEA had a lower rate of tertiary restenosis when treated with CAS (4.2%) instead of repeat CEA (8.0%). Overall, current evidence appears conflicting and does not favor one technique over the other. Instead, the decision should be made on a case-by-case basis, especially taking into account the perioperative risk of MI if reoperative CEA is being considered. In anatomically suitable patients, our practice is to offer the patients CAS. However, we favor and perform reoperative CEA if the patient has a type III or severely calcified aortic arch, excessively

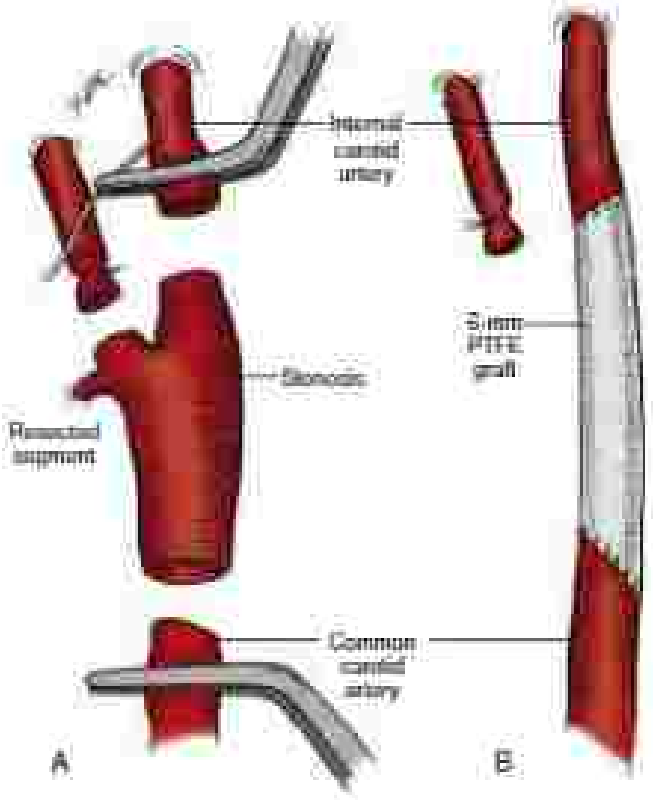

FIG. 1 (A) Resection of a diseased segment of the common and internal carotid arteries with ligation of the external carotid artery. (B) Placement of an interposition graft for reconstruction of the internal carotid artery circulation, in this case using polytetrafluoroethylene (PTFE). Reverse saphenous vein graft or Dacron additionally may be utilized. This is our preferred technique for management of tertiary recurrent carotid stenosis and for management of recurrent in-stent stenosis when endovascular options are not technically feasible.

tortuous, severely calcified and/or long segment stenosis of the internal and/or common carotid artery.

After Carotid Angioplasty and Stenting

The management of ISR after CAS is a subject of many debates, especially for the asymptomatic patient population. There are no prospective trials that have established time tested practice guidelines for the management of ISR after CAS. The consensus among most surgeons is that patients who are symptomatic and have an ISR of 50% or more require a reintervention. Patients who are asymptomatic with high-grade ISR of 70% or more on surveillance duplex should be considered on a case by case basis, taking into account the anatomy of their stenosis, lesions and their perioperative risk of stroke and death.

Endovascular techniques described to treat ISR after CAS include balloon angioplasty alone, repeat CAS alone, or a combination of repeat CAS and balloon angioplasty. Balloon angioplasty can be achieved by using a regular angioplasty balloon, a drug coated balloon, or a cutting balloon. Repeat stenting can be done with either a drug eluting or a regular stent. There are no prospective data that have established one technique to be superior to another. However, because ISR is caused by intimal hyperplasia many surgeons favor the use of balloon angioplasty with a cutting balloon over regular balloon angioplasty alone because of the reduced rate of recurrent stenosis of 4.2% with a cutting balloon as compared to 15% to 23% with a regular balloon. Fig. 3 shows an example of a type II carotid artery in-stent stenosis treated with angioplasty and stenting that showed improvement on both the completion digital subtraction angiography study and noninvasive duplex study 1 month postoperatively.

Open surgical techniques (i.e., CEA or carotid artery bypass/interposition grafting with translocated and reversed great saphenous vein or PTFE) can also be used for management of ISR after CAS, especially in cases where there are primary stent thrombosis, technical failure during stent deployment, heavily calcified lesions that precluded optimal stent apposition to the vessel wall resulting in an inadequate technical result, and pericarotid lesions that cannot be traversed using endovascular methods. In our practice, we prefer to manage ISR after CAS using angioplasty or repeat CAS if the lesion is anatomically amenable to endovascular intervention. Open repair is reserved for cases where the patient has a type III or severely calcified aortic arch, excessively tortuous, severely calcified and/or long segment stenosis of the internal and/or common carotid artery. We preferentially attempt stent removal with CEA and patch angioplasty and reverse carotid bypass or interposition graft with greater saphenous vein or PTFE for cases where an endarterectomy endpoint cannot be safely achieved without compromising the integrity of the vessel wall proximal or distal to the endarterectomy bed.

SUMMARY

Symptomatic and asymptomatic carotid artery stenosis are routinely treated with either CEA or CAS. The majority of patients have excellent long term results. However, there is a small subset of the patient population who have an aggressive disease biology and tend to develop severe intimal hyperplasia that causes recurrent stenosis of the carotid artery after both CEA and CAS. Routinely scheduled surveillance DUS is the best imaging modality to detect these lesions, such that timely intervention can be offered to the patients to prevent cerebrovascular events. Symptomatic patients who are found to have 50% or greater stenosis on duplex or asymptomatic patients with 70% or greater stenosis after both CEA and CAS are candidates for reintervention. The procedure of choice for a secondary intervention depends on the

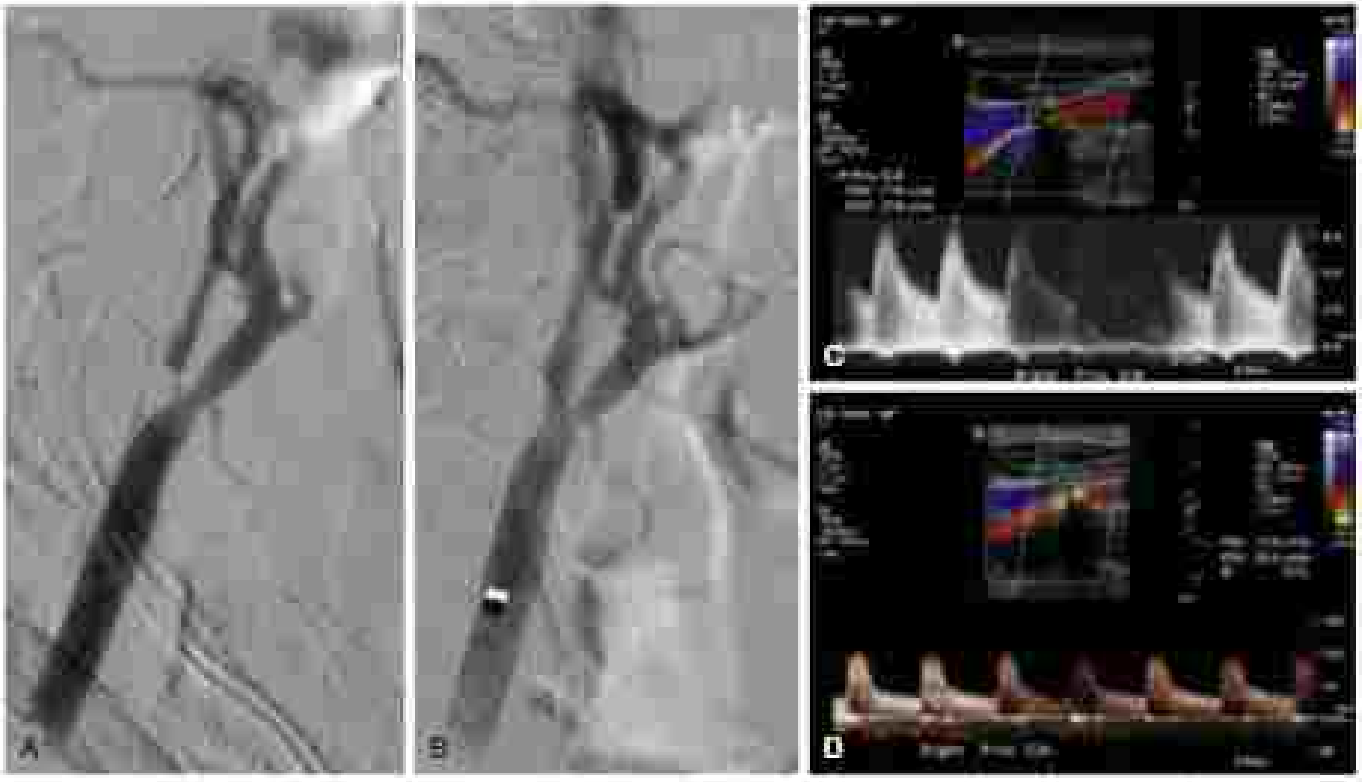

FIG. 3. Distal (type II) carotid in-stent restenosis (ISR) in a 78-year-old man with high-grade asymptomatic ISR a years after initial carotid angioplasty and stenting. (A) Carotid angiography demonstrated a string sign of the proximal internal carotid artery (ICA) with approximately 99% stenosis. (B) The restenosis was managed with carotid angioplasty with embolic protection followed by placement of a self-expanding 7 × 30 mm nitinol nonpreferential angiogram is demonstrated. (C) Preoperative duplex ultrasound demonstrated severe ISR with peak systolic velocity (PSV) of 710 and end-diastolic velocity (EDV) of 27 cm/s and ICA/common carotid artery (CCA) ratio of 12.3. (D) Duplex ultrasound obtained 1 month postoperatively demonstrated PSV of 136, EDV of 33 and ICA/CCA ratio of 2.5.

patient functional status, comorbidities, and anatomy of the tandem lesion. All patients should be on maximal medical treatment with an antiplatelet agent and a lipid lowering agent, preferably a statin.

Balloon Angioplasty and Stents in Carotid Artery Occlusive Disease

Dawn J. Garrido, MD, Daniel E. [illegible], MD, and Charles S. [illegible], MD, MCA

Nearly 800,000 people have a stroke each year in the United States, making it the third leading cause of death in people of years of age and older and the leading overall cause of serious, long-term disability. The total cost nationally for stroke-related illnesses is approximately $34 billion per year. The majority of strokes (about 87%) are ischemic in nature. Of these, an estimated 20% to 30% are related to an atherothrombotic or thrombotic event caused by carotid occlusive disease.

The first successful carotid endarterectomy (CEA) was done in 1953 by Dr. Michael DeBakey to prevent stroke. In the early 1900s, the efficacy of CEA came under intense scrutiny, largely due to highly variable perioperative stroke and mortality rates coupled with increasing frequency of the procedure being done. In response, the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and Asymptomatic Carotid Atherosclerosis Study (ACAS) were undertaken, and they established the efficacy of carotid endarterectomy over medical management for both symptomatic and asymptomatic carotid stenosis.

With the advent of endovascular interventions for other arterial occlusive lesions, carotid artery balloon angioplasty and stenting (CAS) was advocated as an alternative to CEA for treatment of carotid atherosclerosis. The first percutaneous transluminal carotid angioplasty was performed by Kerber in 1980. Although both CAS and CEA can be performed using local anesthesia with similar operative and hospitalization times, CAS offers the advantage of percutaneous groin arterial access rather than a neck incision for carotid artery exposure, which carries risk of mechanical pain, cranial nerve injury, wound infection, and neck hematoma.

In 2010, the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST 1) compared the outcomes of CAS with those of CEA for patients with symptomatic or asymptomatic extracranial carotid stenosis. The trial demonstrated the relative safety of CAS in both symptomatic and asymptomatic patients. However, the data showed a periprocedural stroke rate for CAS of 4%, with the highest risk for periprocedural stroke being among patients of advanced age (>70 years) and with recent (within 2 weeks) neurologic ischemic symptoms. In the CEA arm, the stroke rate was 2.3%. Myocardial infarction (MI) was noted to be more frequent with CEA than with patients undergoing CAS (2.3% vs 1.1%). However, these are numbers that should be interpreted in light of the fact that patients with a stroke complication were documented to have a worse quality of life than those who had MI.

Interpretation of the results of CREST 1 have been intensely debated and influenced by biases for or against CAS or CEA. Stenting enthusiasts argue that statistical similarity in the primary composite endpoint establishes equipoise for the procedures. In contrast, others question the inclusion of MI as a component of the primary endpoint for procedures that have stroke prevention as their principal objective. They argue for the use of only stroke and death as a more appropriate composite endpoint, which significantly favors endarterectomy in CREST 1.

Suffice it to say, CREST 1 has produced valuable level I data comparing CAS with CEA, but the trial did not fulfill the expectation of some of proving undeniably that CAS is better than or even equal to CEA. At the time of publication, the CREST 2 trial is in progress. Briefly, it consists of two independent multicenter, randomized controlled trials of carotid revascularization and intensive medical management versus medical management alone in patients with asymptomatic high-grade carotid stenosis. One trial randomizes patients in a 1:1 ratio to endarterectomy versus endarterectomy and another randomizes patients in a 1:1 ratio to carotid stenting with embolic protection versus no stenting. Medical management is uniform for all randomized treatment groups and is centrally directed. Results of CREST 2 are anxiously awaited.

PREPROCEDURAL CONSIDERATIONS

Preprocedural assessment includes a complete history focused on cardiovascular elements and on symptoms of neurologic or ocular ischemic events related to the carotid circulation. A thorough physical examination with an emphasis on palpation of pulses, auscultation for bruits, and complete neurologic assessment is of utmost importance. The decision about advising for or against CAS is influenced by current CMS guidelines regarding indications for the procedure. These guidelines are listed in Boxes 1 and 2.

Preprocedural imaging should include carotid duplex scan, computed tomographic angiography (CTA), magnetic resonance imaging (MRI), and magnetic resonance angiography. These imaging modalities give important information about the presence and hemodynamic significance of carotid occlusive disease, the condition of the brain parenchyma, the presence of additional intracranial or extracranial vascular anomalies (e.g., vascular aneurysms, vascular malformations), and the anatomy of the aortic arch.

Prior to CAS, patients should begin dual antiplatelet therapy. Our regimen consists of clopidogrel 75 mg daily and aspirin 81 mg daily beginning 5 to 7 days before the procedure. In emergency circumstances, when antiplatelet therapy has not been started before the procedure, we use a loading regimen of clopidogrel 600 mg and aspirin 325 mg given at the time of the intervention. In addition, for patients who have been taking antiplatelet therapy on a chronic basis,

patient functional status, comorbidities, and anatomy of the tandem lesion. All patients should be on maximal medical treatment with an antiplatelet agent and a lipid lowering agent, preferably a statin.

Balloon Angioplasty and Stents in Carotid Artery Occlusive Disease

Dawn E. Garrido, MD, Daniel E. Ramirez, MD, and Charles S. O'Hara, MD, MBA

Nearly 800,000 people have a stroke each year in the United States, making it the third leading cause of death in people of years of age and older and the leading overall cause of serious, long-term disability. The total cost nationally for stroke-related illnesses is approximately $34 billion per year. The majority of strokes (about 87%) are ischemic in nature. Of these, an estimated 20% to 30% are related to an atherothrombotic or thrombotic event caused by carotid occlusive disease.

The first successful carotid endarterectomy (CEA) was done in 1953 by Dr. Michael DeBakey to prevent stroke. In the early 1900s, the efficacy of CEA came under intense scrutiny, largely due to highly variable perioperative stroke and mortality rates coupled with increasing frequency of the procedure being done. In response, the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and Asymptomatic Carotid Atherosclerosis Study (ACAS) were undertaken, and they established the efficacy of carotid endarterectomy over medical management for both symptomatic and asymptomatic carotid stenosis.

With the advent of endovascular interventions for other arterial occlusive lesions, carotid artery balloon angioplasty and stenting (CAS) was advocated as an alternative to CEA for treatment of carotid atherosclerosis. The first percutaneous transluminal carotid angioplasty was performed by Kerber in 1980. Although both CAS and CEA can be performed using local anesthesia with similar operative and hospitalization times, CAS offers the advantage of percutaneous groin arterial access rather than a neck incision for carotid artery exposure, which carries risk of mechanical pain, cranial nerve injury, wound infection, and neck hematoma.

In 2010, the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST 1) compared the outcomes of CAS with those of CEA for patients with symptomatic or asymptomatic extracranial carotid stenosis. The trial demonstrated the relative safety of CAS in both symptomatic and asymptomatic patients. However, the data showed a periprocedural stroke rate for CAS of 4%, with the highest risk for periprocedural stroke being among patients of advanced age (>70 years) and with recent (within 2 weeks) neurologic ischemic symptoms. In the CEA arm, the stroke rate was 2.3%. Myocardial infarction (MI) was noted to be more frequent with CEA than with patients undergoing CAS (2.3% vs 1.1%). However, these are numbers that should be interpreted in light of the fact that patients with a stroke complication were documented to have a worse quality of life than those who had MI.

Interpretation of the results of CREST 1 have been intensely debated and influenced by biases for or against CAS or CEA. Stenting enthusiasts argue that statistical similarity in the primary composite endpoint establishes equipoise for the procedures. In contrast, others question the inclusion of MI as a component of the primary endpoint for procedures that have stroke prevention as their principal objective. They argue for the use of only stroke and death as a more appropriate composite endpoint, which significantly favors endarterectomy in CREST 1.

Suffice it to say, CREST 1 has produced valuable level I data comparing CAS with CEA, but the trial did not fulfill the expectation of some of proving undeniably that CAS is better than or even equal to CEA. At the time of publication, the CREST 2 trial is in progress. Briefly, it consists of two independent multicenter, randomized controlled trials of carotid revascularization and intensive medical management versus medical management alone in patients with asymptomatic high-grade carotid stenosis. One trial randomizes patients in a 1:1 ratio to endarterectomy versus endarterectomy and another randomizes patients in a 1:1 ratio to carotid stenting with embolic protection versus no stenting. Medical management is uniform for all randomized treatment groups and is centrally directed. Results of CREST 2 are anxiously awaited.

PREPROCEDURAL CONSIDERATIONS

Preprocedural assessment includes a complete history focused on cardiovascular elements and on symptoms of neurologic or similar ischemic events related to the carotid circulation. A thorough physical examination with an emphasis on palpation of pulses, auscultation for bruits, and complete neurologic assessment is of utmost importance. The decision about selecting for or against CAS is influenced by current CMS guidelines regarding indications for the procedure. These guidelines are listed in Boxes 1 and 2.

Preprocedural imaging should include carotid duplex scan, computed tomographic angiography (CTA), magnetic resonance imaging (MRI), and magnetic resonance angiography. These imaging modalities give important information about the presence and hemodynamic significance of carotid occlusive disease, the condition of the brain parenchyma, the presence of additional intracranial or extracranial vascular anomalies (e.g., vascular aneurysms, vascular malformations), and the anatomy of the aortic arch.

Prior to CAS, patients should begin dual antiplatelet therapy. Our regimen consists of clopidogrel 75 mg daily and aspirin 81 mg daily beginning 5 to 7 days before the procedure. In emergency circumstances, when antiplatelet therapy has not been started before the procedure, we use a loading regimen of clopidogrel 600 mg and aspirin 325 mg given at the time of the intervention. In addition, for patients who have been taking antiplatelet therapy on a chronic basis,

BOX 1 Indications for Carotid Stenting According to the Centers for Medicaid and Medicare Services

- Patients who are at high risk for CEA and who also have symptomatic carotid artery stenosis >70%
- Patients who are at high risk for CEA and have symptomatic carotid artery stenosis between 50% and 70%
- Patients who are at high risk for CEA and have asymptomatic carotid artery stenosis >80%

Medicare coverage is limited to patients having these indications and to procedures performed using Food and Drug Administration–approved carotid artery stenting systems and cerebral protection devices.
CEA, Carotid endarterectomy.

BOX 2 Patients at High Risk for Carotid Endarterectomy According to Centers for Medicaid and Medicare Services

- Congestive heart failure class III/IV
- Left ventricular ejection fraction <30%
- Unstable angina
- Contralateral carotid occlusion
- Recent myocardial infarction
- Previous CEA with recurrent stenosis
- Prior radiation treatment to the neck
- Other conditions that were used to determine patients at high risk for CEA in the prior carotid artery stenting trials and studies, such as ARCTICR, CARESAGE, SAPPHIRE, BEACH, and MAVERIC II.

CEA, Carotid endarterectomy.

we typically give a smaller loading dose of clopidogrel (150 to 300 mg) immediately after the intervention. If oral administration is not possible, clopidogrel can be given via nasogastric tube, aspirin can be given similarly or per rectum (300 or 600 mg suppository).

There are two major decisions to consider in planning CAS. Since the procedure is traditionally performed percutaneously, the first decision is the choice of access vessel. The second decision is what cerebral protection device, if any, should be used. Of these decisions, the former must be thoroughly assessed to ensure the most suitable platform to safely deliver the interventional devices. The latter is highly dependent on operator preference, but we encourage using one of the commercially available cerebral protection devices.

Traditionally CAS is performed via a percutaneous transfemoral arterial approach. Assessment of the iliofemoral arterial system and evaluation of the arch anatomy via CTA will determine the suitability of this access as a successful platform to deliver the treatment. The presence of an easily palpable femoral pulse strongly suggests that femoral access is suitable. On the contrary, the absence of a femoral pulse should trigger exploring other access options. The presence of a type III or bovine aortic arch, or severe arch atheroma, or of prior aortic or cervical arterial procedures each complicate the use of the femoral arteries as the access vessel and can potentially increase the risk of cerebral embolization.

TRANSFEMORAL APPROACH FOR CAROTID ANGIOPLASTY

Provided that the patient has suitable iliofemoral and aortic arch anatomy, the transfemoral approach is usually chosen. The patient is placed supine on the angio table. Topographic fluoroscopic evaluation of the chest and the neck is performed prior to prepping to identify objects such as wires, leads, or other previously inserted devices that would interfere with imaging. The range of motion of the C-arm is also evaluated to make sure it will rotate freely and away from other equipment in the procedural room.

We use local anesthesia at the groin access site when performing a transfemoral approach to afford patient comfort while also being able to assess neurologic function during the procedure. At certain times during CAS, the patient is asked to intermittently squeeze a neurologic testing device held in the contralateral hand for motor function and to count verbally to assess cognitive function.

To facilitate accurate entry, the chosen femoral artery is accessed under ultrasound guidance with a micropuncture needle that is subsequently exchanged over a micro wire for a micropuncture sheath using the Seldinger technique. If this step goes smoothly, we do not perform an access arteriogram. If there is any question about the appropriateness of the vascular access, an arteriogram should be performed through the micropuncture sheath and any consequential iliofemoral lesion identified should be managed prior to continuing with the planned intervention.

Once the access is deemed satisfactory, systemic anticoagulation therapy is initiated either with intravenous heparin bolus administration at 100 U/kg wt. for those patients where heparin is contraindicated, bivalirudin (Angiomax) at 0.75 mg/kg intravenous bolus, followed by 1.75 mg/kg per hour intravenous infusion. During the procedure, activated clotting times are maintained between 250 and 300 seconds.

A standard 0.35 straight tip wire is advanced just distal to the aortic arch under fluoroscopic guidance. The micropuncture sheath is exchanged for a 90 cm 6 F sheath, and the tip is advanced to the proximal thoracic aorta. Over the same wire a 5 Fr or 6 Fr pigtail catheter is advanced retrograde through the arch into the proximal ascending aorta. The C-arm is positioned at 30 to 40 degrees in the left anterior oblique orientation and arch aortography is performed via the pigtail catheter using 15 to 20 mL of contrast by either power or hand injection. This imaging should provide sufficient anatomic detail for choosing an appropriate catheter to selectively cannulate the common carotid artery on the side of the pathology.

Typical aortic arch anatomy allows for use of a selective catheter with a simple curve, while increasingly complex and tortuous aortic arch anatomy requires the use of selective catheters that have either an intermediate curve or a complex curve. The pigtail catheter is then exchanged over a guidewire and the chosen catheter is advanced to the previously mapped area of interest. We use a floppy glide wire to select the common carotid with the aid of the catheter. The catheter is advanced to a reasonable purchase but kept proximal to the level of the carotid bulb. The guidewire is then exchanged for a stiffer wire and the 6Fr sheath is advanced either over the catheter or by exchanging the catheter for the sheath introducer to the distal common carotid artery.

If the purchase on the wire is not enough to advance the sheath, angiographic mapping and super selective cannulation of the external carotid artery (ECA) often provides the required strength to advance the sheath into the common carotid (Fig. 5). Extreme care is given to avoid introduction of microthrombi and tiny air bubbles by frequent wiping of guidewires with Telfa nonadherent strips moistened with heparinized saline and by meticulous flushing of catheters and sheaths with heparinized saline solution.

After successful cannulation of the common carotid artery, a distal filter typically is used for embolic protection. The distal filter, attached to a 0.014 inch wire, is passed through the sheath, carefully maneuvered through the carotid stenosis under fluoroscopic control, and placed in the distal cervical internal carotid artery (ICA), where it is deployed with removal of its covering sheath. Very tight carotid stenosis that cannot be safely negotiated with the tip of the embolic protection device may require use of a low profile microcatheter and steerable microwire. Occasionally, predilation of a tight stenosis with a low profile coronary angioplasty balloon may be necessary to allow subsequent crossing of the lesion with the distal filter. Also, problems imposed by vessel angulation and tortuosity can be resolved with use of a "buddy wire" to slightly straighten the anatomy and facilitate

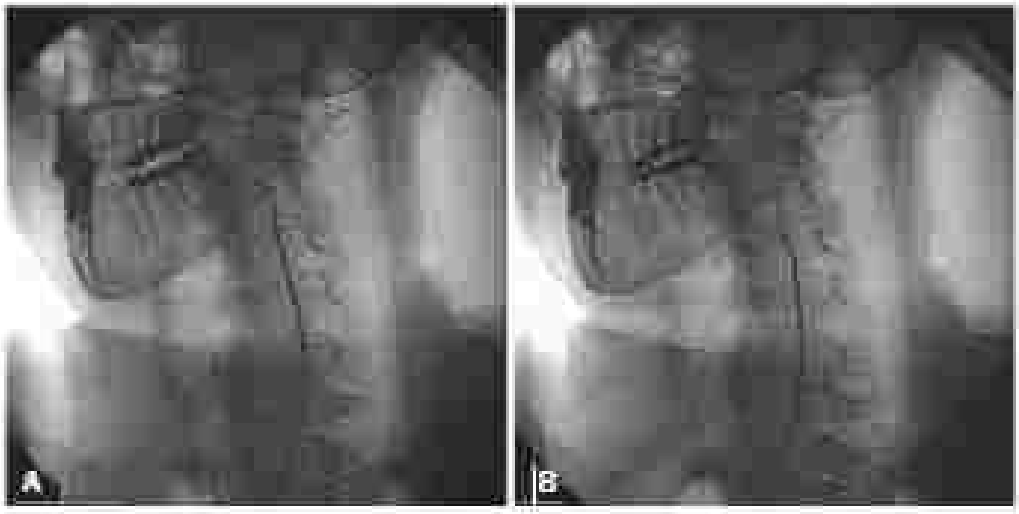

FIG. 1 (A) Selective injection to document catheter location in a posterior branch of the external carotid artery before placement of the exchange-length wire used for positioning of the long sheath into the distal common carotid artery. (B) Wire placement into the external carotid artery branch through the ascending catheter demonstrates vessel perforation by the wire; must be readily managed with manual compression against the posterior neck muscles.

crossing of a lesion by the distal filter, angioplasty catheter, or stent. Furthermore, for situations in which passage of the distal filter is difficult, maneuvers such as having the patient take deep breaths, having the patient turn the head far to one side or the other, or carotid manual pressure on the side of the patient's neck by an assistant can be helpful.

The stent is advanced over the wire to cover the carotid lesion. Because most lesions occur near the carotid bulb, tapered stents are better suited to accommodate any size mismatch of the common carotid and the internal carotid (Fig. 2). If a residual stenosis of more than 30% is present after stent placement alone, post deployment balloon angioplasty is typically done with a balloon that is 5, 5.5, or 6 mm in diameter and 20 mm in length within the confines of the stent. Post deployment balloon angioplasty is used to achieve an angiographically acceptable but not necessarily perfect result (Fig. 3).

The balloon angioplasty catheters and the carotid stent are passed into position over the wire attached to the distal filter. The same wire is used for passage of a retrieval sheath that captures the filter along with any microemboli that have been trapped during the procedure. After retrieval and removal of the filter and its wire, completion arteriograms are obtained of the treated carotid artery and of the cerebral territory that it supplies with injection of contrast through the long sheath. The long sheath is then removed over its dilator and a pushewire to avoid vessel trauma during exit. Systemic anticoagulation therapy is discontinued. After sheath removal, the femoral artery puncture site is sealed with either manual compression or use of a closure device.

TRANSCAROTID APPROACH FOR CAROTID ANGIOPLASTY

For patients with challenges of the aortic arch mentioned previously, femoral access may not provide a reliable or safe way to deliver the therapy. In such cases, transcarotid artery stenting (TCAR) approach offers an acceptable alternative. We perform this intervention using a superficial cervical plexus nerve block on the side of the procedure. Alternatively, general anesthesia with motor and sensory evoked potentials can be employed.

A transverse incision is made at the base of the neck, preferably in right territory. The sternocleidomastoid muscle is exposed and retracted laterally. The vagus nerve and internal jugular vein are identified and preserved. A 3- to 4-cm segment of the common carotid (CCA) artery is exposed, and the patient is systemically heparinized (Fig. 4). The CCA is accessed in the same manner as in the percutaneous sequence, including micropuncture, exchange for a 45-cm 6Fr sheath, systemic heparinization, crossing the lesion and deployment of the filter, delivery of the stent, and posttreatment dilation as needed.

Transcarotid artery stenting is still dependent on the presence of favorable neck anatomy. A short, thick neck can make access and control of the CCA challenging, and scarring from prior CEA can limit the space available for manipulation of endovascular devices. The exchange and manipulation of wires, sheaths, and stent devices are severely restricted when the distance from the plaque to the arterial puncture is short. Even with routine exchanges, the risk of embolization and dissection is increased. To overcome these challenges, we have modified the TCAR procedure by using a prosthetic arterial conduit. This technique has been used successfully in other endovascular procedures, such as iliac artery prosthetic conduits for aortic endograft delivery, and it requires no special training or devices. We believe this provides a stable access route for CAS with sufficient room to maneuver even in the setting of constrained neck anatomy.

When employing a conduit, the common carotid is exposed as mentioned above. After systemic heparinization, the CCA is controlled, and a longitudinal arteriotomy is performed. A 6-mm PTFE conduit is anastomosed to the CCA in end-to-side fashion (Fig. 5). In cases with a steep angle at the clavicle, the proximal end of the graft is tunneled and brought out through a counter incision on the anterior chest wall. The free end of the conduit is secured with Rumel's tourniquet and, with the patient in Trendelenburg position, the conduit is de-aired and flushed with heparin saline. A 45-cm sheath is advanced into the conduit to provide a stable platform for delivery of an embolic protection device and deployment of the stent as described previously (Fig. 6). At completion of the intervention, the conduit is transected close to the surface of the CCA and closed to prevent narrowing, effectively creating a patch angioplasty. The neck incision is closed routinely.

EMBOLIC PROTECTION DEVICES

Currently, the techniques to provide protection from embolic events during CAS are based on one of the following three principles: (1) distal balloon occlusion of the ICA, (2) filters in the distal ICA, and (3) flow reversal from the ICA by proximal and ECA balloon occlusion (Fig. 7).

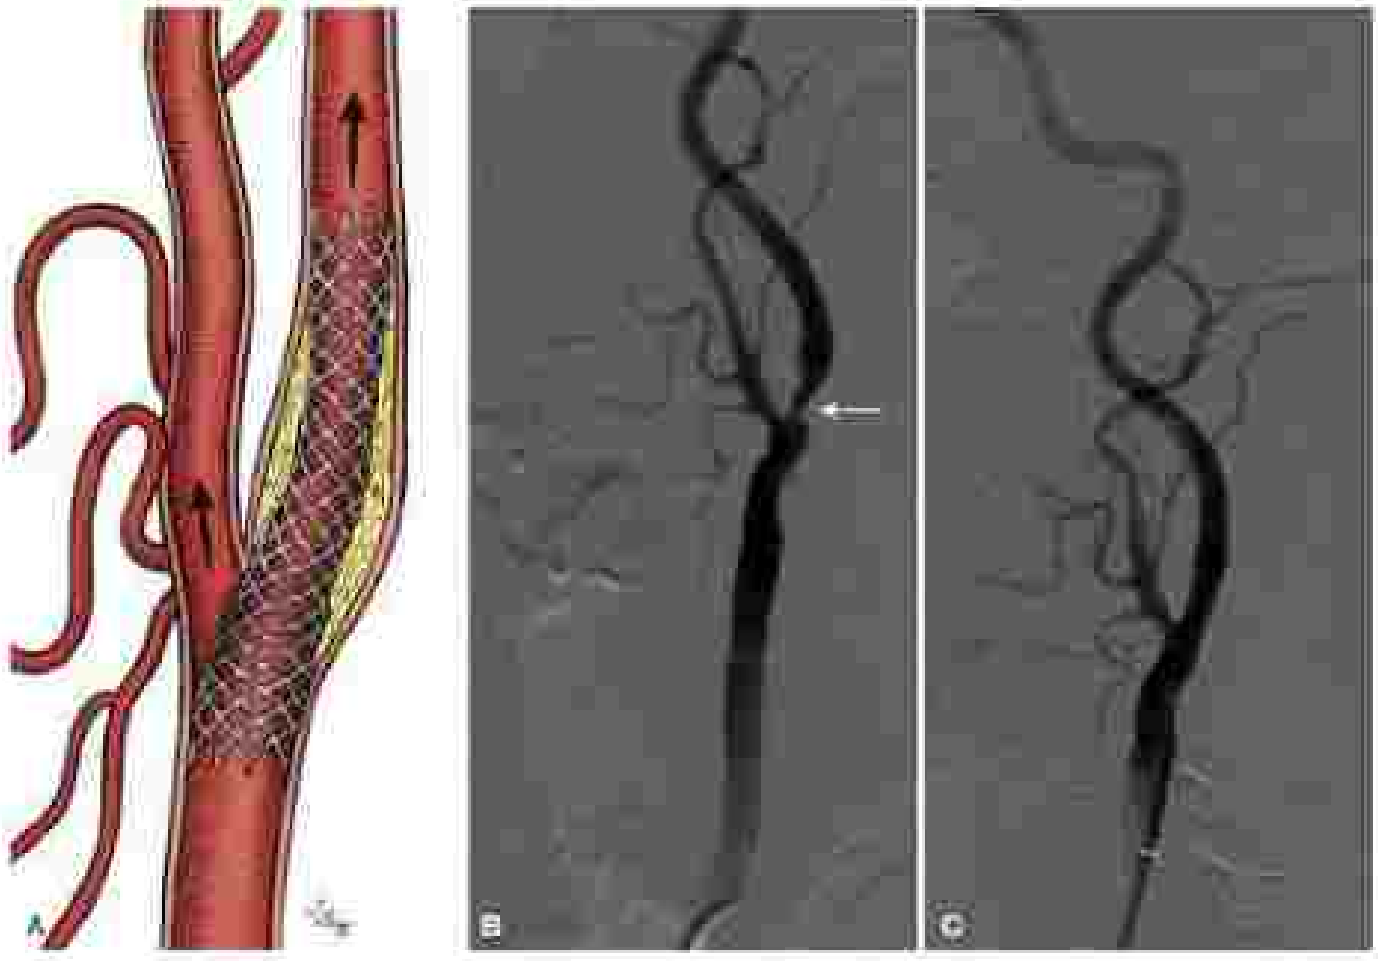

FIG. 2 (A) Schematic representation of a stent deployed across the carotid bifurcation to treat a proximal internal carotid artery lesion. Blood flow continues into the external carotid artery through the interstices of the stent. (B) Digital subtraction arteriogram (DSA) of a left common carotid injection, lateral oblique projection showing a severe stenosis in the proximal internal carotid artery (arrow). (C) Completion DSA after placement of a stent across the carotid bifurcation. Note correction of the internal carotid artery stenosis with continued perfusion of the external carotid artery and its branches. (A, courtesy Lynn Gregg, copyright 2018 Society of Interventional Radiology.)

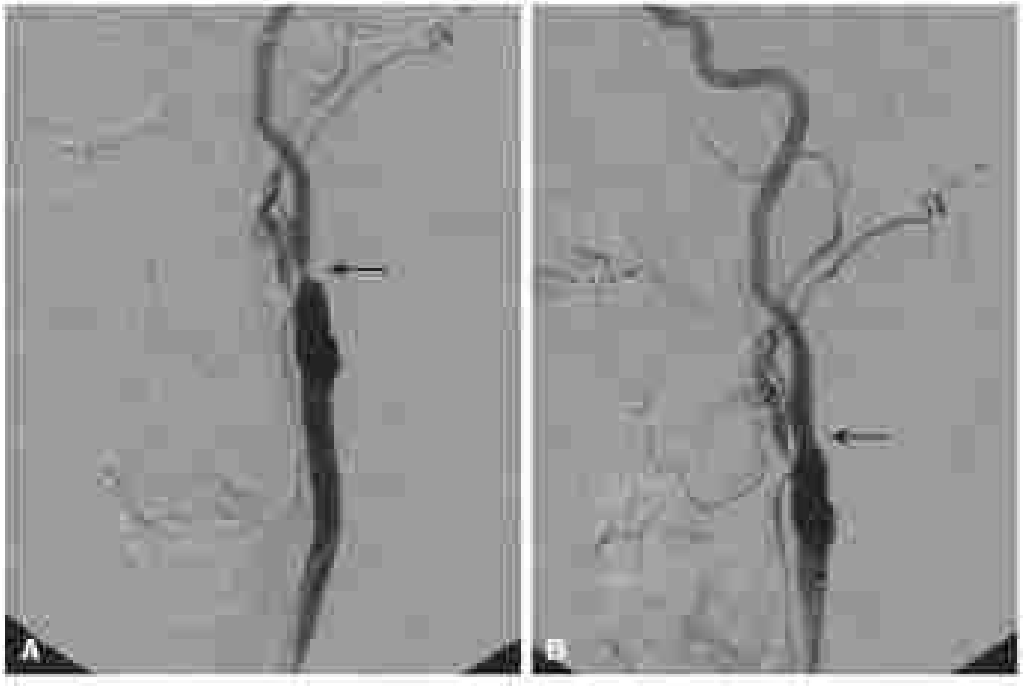

FIG. 3 (A) Digital subtraction arteriogram (DSA) of a left common carotid injection, lateral oblique projection showing severe stenosis in proximal internal carotid artery (arrow). (B) Completion DSA after carotid artery stenting. Note the residual mild stenosis (arrow) at the site of the lesion, which was judged acceptable even though not angioplastied further.

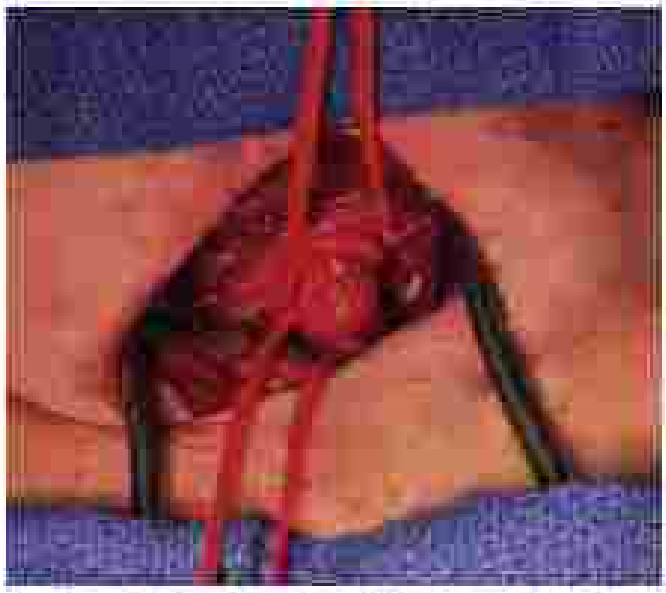

FIG. 4 Exposure of the common carotid through an oblique incision at the base of the neck in the right territory of the appropriate side. Dissection is then carried deep between the two heads of the sternocleidomastoid to expose a 3- to 4-cm segment of the common carotid artery (From Mesas IV, Khalifeh A, Jiménez CR, et al. Transcervical carotid artery stenting using a proximal carotid cardiac outflow occlusion balloon as a novel surgical technique. Ann Vasc Surg. 2018;51:1–7.)

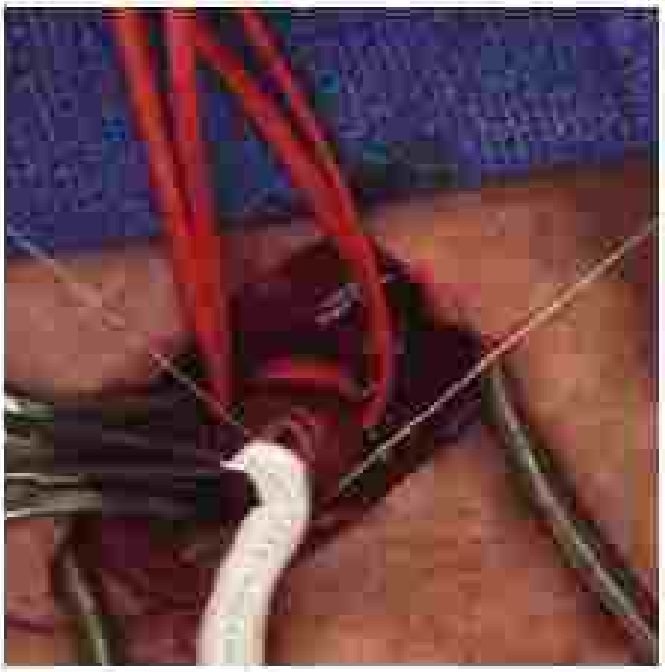

FIG. 5 Following systemic heparinization, the common carotid artery is controlled with vessel loops and clamped, and a longitudinal arteriotomy is performed. The 6-mm PTFE conduit is anastomosed to the vessel in end-to-side fashion and the proximal vessel is then unclamped, flushing the conduit with blood. (From Mesas IV, Khalifeh A, Jiménez CR, et al. Transcervical carotid artery stenting using a proximal carotid cardiac outflow occlusion balloon as a novel surgical technique. Ann Vasc Surg. 2018;51:1–7.)

FIG. 6 (A) Kassiotis Investigator is used to access the end of the conduit and the conduit is flushed with heparin saline solution. A 90° sheath is then advanced through the conduit to provide a stable platform for embolic protection device and stent deployment. (B) Digestic angiography is performed to visualize the lesion and establish a roadmap. The embolic protection device is deployed and a second guidewire is placed to guide placement of the self-expanding carotid stent. (C) Once the stent is deployed, flow is confirmed by completion angiogram. The embolic protection device is removed and the conduit is assessed and oversewn as a patch. (From Mesas IV, Khalifeh A, Jiménez CR, et al. Transcervical carotid artery stenting using a proximal carotid cardiac outflow occlusion balloon as a novel surgical technique. Ann Vasc Surg. 2018;51:1–7.)

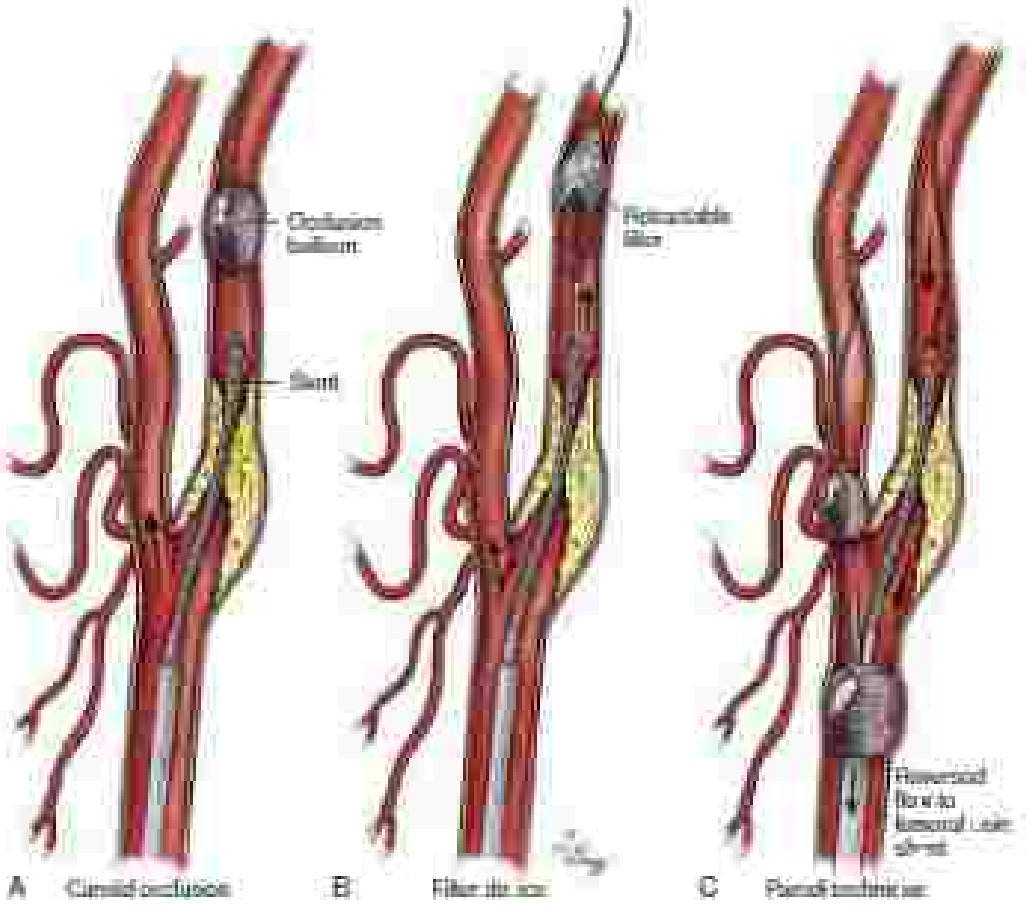

FIG. 7 Schematic representation of the different methods of embolic protection device. Arrows indicate the direction of blood flow. (A) Distal occlusion. Stenting is performed with internal carotid artery flow temporarily interrupted by inflating a balloon within the distal internal carotid artery. After stent deployment and after dilation, stagnant blood proximal to the balloon, which may contain plaque debris, is aspirated through the delivery catheter. After aspiration, the distal space below the balloon is flushed with saline solution to clean any remaining material from the internal carotid artery. The balloon is then deflated and removed. (B) Distal filtration. A filter is advanced through the stenosis and deployed in the distal internal carotid artery by withdrawing its constraining sheath. After stenting, a recovery catheter is used to retrieve the filter and its contents. (C) Proximal protection. During stenting, two occluding balloons are inflated, one in the common carotid artery and the other in the external carotid artery. Flow reversal is created either with active aspiration from the delivery catheter in the common carotid artery distal to the common carotid artery balloon or with directing flow from the catheter to a sheath in the femoral vein. With use of a system that returns blood to the femoral vein, a filter is used within the construction to trap debris from the carotid plaque. (Courtesy Cook Group, copyright 2005 John F. Eidem, commercial relationship.)

Distal protection with either balloon or filter has the disadvantage that the carotid lesion must be crossed before initiation of cerebral protection. Nevertheless, because of simplicity and ease of use, combined with avoidance of carotid flow interruption, distal protection with a filter has become the most commonly used method for embolic protection. However, transcranial Doppler scan studies have shown that particles smaller than the pore size of the filters (60–140 μm) can flow through the filter and evade capture. Such microemboli may be associated with new white lesions on the diffusion weighted MRI of the brain, but the clinical consequences of this "controlled embolization" are uncertain.

Embolization can also occur while crossing the lesion prior to deploying the device intended to prevent them in the first place. Incomplete apposition of the filter rim to the vessel wall may allow emboli of various sizes to pass around the filter. Furthermore, filters occasionally can be difficult to retrieve, and they may become occluded from obstructing debris captured during CAS.

The MoMa Ultra device (Medtronic) is the only available Food and Drug Administration approved flow reversal embolic protection device. It is a catheter with two balloons, one of which is placed in the ECA and other in the CCA, both mounted on a single sheath. A working channel allows delivery of the stent. After stenting, blood in the ICA is aspirated until clear of debris through the same working channel. The retrieved blood is then filtered and delivered back to the patient via a venous cannula placed percutaneously in the femoral vein. The concept of proximal protection is appealing because crossing the lesion with the protection device is not required.

Recent reports suggest that proximal protection, in experienced hands, is associated with low risk of microembolic events during CAS, acceptable 30 day stroke and death rates, low incidence of femoral access complications, and low (<1%) rate of patient intolerance to temporary proximal occlusion. In addition, proximal embolic protection provides an option when marked arterial tortuosity or a limited landing zone precludes use of distal protection. Nevertheless, clinicians have been slow to adopt proximal protection devices because they require larger sheath access (9Fr or 8.5Fr), are more complicated to use than distal filter devices, and may be poorly tolerated by patients with inadequate intracranial collateral circulation. Also, this method of embolic protection has the disadvantage of limiting the ability of the operator to visualize angiographically the precise location of the lesion during stent deployment.

PERIPROCEDURAL MANAGEMENT

Distal embolization is a principal concern with CAS, but the consequences of cerebral embolic events vary widely. Microemboli may produce white lesions on diffusion-weighted MRI scan without apparent neurologic sequelae. Larger emboli may produce a small stroke by MRI criteria yet remain clinically silent, or they may cause devastating neurologic deficit, depending on the function of the cerebral tissue that has been damaged. Therefore, operators who perform CAS must be familiar with the anatomy of the brain and its vasculature so that intracranial cerebral branch vessel occlusion can be readily identified. It is equally important that operators be thoroughly familiar with normal neurologic function and the clinical manifestations of stroke. In addition, dedicated expert neurologic support is essential for a successful carotid stenting program.

Inflation of an angioplasty balloon in the proximal internal carotid artery sometimes provokes bradycardia and hypotension. This must be addressed with intravenous atropine 0.6 mg either preemptively before balloon postdilation or effectively when it occurs. Patients with severe aortic stenosis may be intolerant of even mild bradycardia and hypotension with balloon inflation, and consideration should be given in such patients to using monitored anesthesia and placing a temporary pacemaker prior to the procedure. Bradycardia and hypotension with carotid balloon angioplasty are rarely seen in patients who have previously undergone CEA, probably because of the denervating effect of surgical dissection near the carotid bulb.

Distal cervical ICA vasospasm is sometimes induced by catheter or wire manipulation or by distal filter or balloon placement. Avoidance of movement of the distal filter once deployed helps to minimize vasospasm at this site. Resolution of the vasospasm often occurs spontaneously but can be hastened with transcatheter administration of nitroglycerin (200 μg bolus) into the involved artery.

As mentioned previously, antiplatelet therapy is essential for success of CAS. Dual antiplatelet therapy with clopidogrel (75 mg daily) and aspirin (81 or 325 mg daily) is the current standard. The considerable individual variation in the degree of platelet inhibition provided by antiplatelet therapy is now well known. Also, the impact of clopidogrel or aspirin resistance on long-term stent patency and restenosis rates is being increasingly recognized. Testing for such resistance is commercially available and should be considered preoperatively in all patients when timing allows.

If a patient has less than 20% inhibition on the platelet assay, a higher dosage of antiplatelet medication is warranted. This increase in target level of inhibition does not translate to higher risk for bleeding, durning this increase safe. Ticlopidine (250 mg twice daily) can be used in patients who cannot tolerate clopidogrel. If a patient cannot take antiplatelet therapy, carotid stenting should be reconsidered, as the periprocedural stroke risk may thus be unacceptably high.

Dual antiplatelet therapy should be continued for at least 3 months after the stent procedure, and daily aspirin should be continued indefinitely thereafter. Glycoprotein IIb/IIIa inhibitors are associated with increased risk of intracranial hemorrhage after carotid stenting, and their use should be confined to the treatment of acute thrombus formation during or immediately after the procedure.

For management of acute in-stent thrombosis, alteplase is administered by giving half of the 0.25 mg/kg bolus dose intra-arterially near the clot and administering the second half of the bolus dose intravenously over 5 minutes, followed by an intravenous infusion of 0.125 μg/kg per minute for 12 to 24 hours.

Postprocedural hypotension may accompany periprocedural bradycardia and is usually managed with volume expansion. Moderate bradycardia and mild hypotension, similar to that seen occasionally after CEA related to carotid baroreceptor stimulation, are best treated with fluid supplementation, close observation for any neurologic dysfunction, and occasional use of low-dose vasopressor support.

Control of postprocedural hypertension is important to minimize risk of cerebral hyperperfusion syndrome (CHS). Severe headache associated with hypertension after CAS should heighten suspicion of CHS, which can also present with seizures and focal neurologic deficits. Proper management of CHS entails early diagnosis, rapid control of hypertension, anticonvulsant therapy, smooth diuresis, and neurologic consultation.

FOLLOW-UP

Patients are usually discharged from the hospital on the day after undergoing CAS. Follow-up office visit occurs 4 to 6 weeks after surgery, again 6 months later, and annually thereafter. Follow-up includes a complete neurologic assessment and carotid ultrasound scan examination. Each visit also includes a global cardiovascular evaluation with emphasis on possible coronary, renal, and peripheral arterial occlusive problems. Hypertension and hypercholesterolemia are managed aggressively. Because of antiinflammatory and plaque stabilization effects, statin therapy is advised for almost all patients, even in the absence of laboratory evidence of cholesterol abnormalities. Healthy lifestyle habits are encouraged, with emphasis on regular aerobic exercise, dietary discretion, and complete abstinence from tobacco use.

Hemodynamically significant restenosis of carotid stents is not frequent and has been quoted as less than 5%. By carotid ultrasonography, velocity criteria of native vessels may overestimate the degree of in-stent stenosis if used for CAS surveillance. We follow the criteria of Bruennle and colleagues, who use a peak systolic velocity of 350 cm/s or greater in the stent as a reliable indication of 70% or greater restenosis in a stented carotid artery. Although this approach requires prospective validation, consensus is building that routine native carotid duplex velocity criteria are likely to overestimate the incidence and severity of in-stent restenosis in the CAS patient.

SUMMARY AND PERSPECTIVE

Results of clinical trials have shown that both CAS and CEA are effective procedures for stroke prevention; each has an important place in carotid disease management. Currently, concerns about higher stroke risk with CAS, coupled with reimbursement restrictions and cost effectiveness issues for asymptomatic CAS, make CEA the standard, and much more commonly performed method of treating carotid occlusive disease when intervention is warranted. In our practice, CAS is reserved for patients with recurrent stenosis after CEA, a history of neck irradiation or radical neck dissection, lesions located high in the neck (above the level of the C2 cervical vertebra), contralateral vocal cord paralysis, and traumatic dissections with neurologic symptoms in the absence of significant atherosclerotic disease.

Most of our patients undergoing CEA are at high risk with traditional risk criteria, and only rarely are we compelled to use CAS because of extreme cardiopulmonary risk factors that make surgical treatment prohibitive. Carotid endarterectomy should be used with reservation in situations where the risk of periprocedural stroke is higher than usual.

These circumstances involve both clinical and anatomic factors. Clinical factors include age older than 80 years and recent (within 2 weeks) neurologic ischemic symptoms. Anatomic factors include vessel angulation greater than 60 degrees, and a severely diseased aortic arch, especially when combined with branch vessel configuration that is hostile for sheath access. More frequent use of proximal embolic protection, replacement of bare metal stents with covered stents, and selective use of transcervical access may lower the stroke risk of CAS.

In the meantime, skilled vascular surgeons who are trained and experienced in performing both CAS and CEA bring a unique perspective and ability to judge the multiple variables that must be weighed carefully in deciding which of these two good procedures is the better choice for an individual patient.

Management of Aneurysms of the Extracranial Carotid and Vertebral Arteries

Vikram S. Kashyap, MD, and Gabriel L. Rose, MD

Arterial aneurysms of the extracranial circulation of the carotid and vertebral arteries are a truly rare entity. Only 0.1% to 2% of all carotid interventions are performed for aneurysmal disease, and these lesions account for less than 1% of peripheral aneurysms overall. The available literature is notable for the predominance of small, single-center retrospective series, the single largest published experience with true extracranial carotid artery aneurysms (ECAA) was reported recently by Ni and colleagues who intervened on 34 such lesions over a 20-year period. This slight platform of evidence represents the bulk of guidance available to practitioners who see and treat these aneurysms.

Extracranial vertebral artery aneurysm (EVAA) is yet less common than ECAA, and the available published experience is confined largely to case reports, many of which come from the neurosurgical literature. These aneurysms too can be treated successfully, and the evidence base, however slim, does provide guidance for clinical decision-making and treatment.

EXTRACRANIAL CAROTID ARTERY ANEURYSMS

Etiology

True ECAA is most often attributable to arterial wall degeneration, with histologic features such as thinning of the media and weakening of the elastic lamina, which are typical to peripheral aneurysms in general. Although atherosclerosis is believed to be a co-existing, rather than inciting, factor, as many as 83% of patients with ECAA have a reported history of hypertension. Most of these aneurysms are fusiform. The most common site for aneurysmal degeneration is the common carotid artery at the carotid bifurcation, or at the proximal internal carotid artery (ICA). ECAA found outside these locations tend to be saccular. External carotid artery aneurysms are exceedingly rare.

Other causes of aneurysms include blunt and penetrating trauma. Blunt penetrating trauma resulting in ECAA involves the common carotid, although any artery is vulnerable depending on the pattern of injury. Aneurysmal degeneration occurs as the result of either direct arterial damage resulting in early pseudoaneurysm formation, or as a late consequence of a weakened or dissected arterial wall. The ICA near the skull base (zone III) is particularly prone to dissection in blunt trauma, with subsequent aneurysm formation. Fibromuscular dysplasia, collagen vascular disorders, cystic medial necrosis, granulomatous disease, and congenital defects have also been identified as causes of ECAA.

Aneurysms as a result of infection are now relatively unusual in the antibiotic era. When these are seen, they are most often the consequence of angioplasty patch infection following carotid endarterectomy (CEA). Pseudoaneurysm has also been reported as a late complication of CEA. No difference has ever been conclusively demonstrated between polyester (Dacron), expanded polytetrafluoroethylene) or autogenous patch material in the rates of post-CEA infection, possibly because the incidence of infection following this procedure is so low that any difference that actually exists would be statistically very difficult to demonstrate.

Natural History, Presentation, and Diagnosis

Neurologic symptoms are the hallmark of extracranial carotid aneurysmal disease. Perhaps half of patients present with amaurosis fugax, transient ischemic attack, or stroke, and these patients also represent the majority of interventions. These events are thought to be due to distal embolization from the lesion, but can also develop from slow arterial flow through the aneurysmal sac. Other symptoms that can lead to the diagnosis of ECAA are the results of mass effect from the enlarged artery. Nerve compression can lead to facial pain or cranial nerve palsies, hoarseness, or even Horner's syndrome (ipsilateral ptosis, miosis, pseudoenophthalmos, and anhidrosis) from compression of the sympathetic chain. Dysphagia can also occur. Rupture with associated hemorrhage or erosion either into the pharynx or via a sinus tract through the skin of the neck is uncommon, but has been reported. This is most often seen with mycotic aneurysms and pseudoaneurysms and is frequently fatal. Likewise, ipsilateral embolic changes in association with a palpable neck mass can suggest an infected aneurysm. Degenerative aneurysms are found in older patients with the usual risk factors for peripheral arterial disease. Aneurysms due to trauma, infection, or systemic conditions can be seen in patients of all ages.

On physical examination, the most common finding is the presence of a palpable lateral neck mass. A submandibular mass suggests common carotid artery disease, whereas a mass at the mandible ramus can be associated with an ICA lesion. Some aneurysms can resemble a deep peritonsillar abscess as they expand into the oropharyngeal space. The differential diagnosis also includes redundant carotid artery, tumors, lymphadenopathy, and congenital disorders such as cystic hygroma or branchial cleft cyst. One proposed algorithm for diagnosis and treatment is depicted in Fig. 1. Any suspicion for ECAA should be interrogated promptly with advanced imaging techniques such as duplex ultrasonography, computed tomographic angiography (CTA), or magnetic resonance angiography (MRA). These modalities are typically diagnostic and will assist with preoperative planning. Duplex ultrasound in particular is favored as the initial screening test of choice because of its ready availability, low cost, and noninvasive nature, although it is most useful when employed by a skilled operator for most ECA lesions. The sensitivity of ultrasound can

also be compromised by tortuous or heavily kinked arteries. The use of catheter based carotid angiography is now mainly limited to the operating room itself at the time of intervention, although unmatched in its resolution and utility as an arterial imaging technique, the fact that it essentially represents a "luminogram" makes it a poor initial screening test for aneurysmal disease.

Indications for Intervention

Whether symptomatic or asymptomatic, the presence of ECAA represents in and of itself an indication for intervention in suitable patients. Indeed, the natural history of these aneurysms is for most patients to present with symptoms, and those patients asymptomatic at presentation are likely to become symptomatic with time. Given that most symptomatic ECAA present with acute neurologic events, a strategy of aggressive invasive treatment is warranted. ECAA that are ruptured or appear near rupture (skin drainage, bronchial blood, pain, suspicious imaging findings) should be considered for urgent repair.

The generally accepted definition of aneurysmal disease in the carotid bed is similar to that identified for arteries in other distributions, in other words, 1.5 times larger than the adjacent normal artery or what would be expected from anatomic series. However, because the normal carotid bulb can be 100% larger than its associated ICA, some authors have proposed that a lower bound of 2 times the adjacent normal ICA diameter be used to avoid confusion with what might otherwise be simply a generously sized but normal carotid bulb.

Treatment

The options for treatment of ECAA are no different from those available for treatment of aneurysms generally. Medical management has been proposed in patients who represent prohibitive risk for invasive intervention, or for those asymptomatic patients who for unrelated reasons are not expected to survive long enough to benefit from a prophylactic repair. For these patients, various combinations of therapies consisting of antiplatelet and/or anticoagulation medications are available, some of which are well validated for this indication by anything other than expert opinion. The two options for intervention are open surgical repair and endovascular therapy, with the latter becoming increasingly common in medium series.

Preoperative Evaluation

The preoperative evaluation should for the most part be familiar to any interventionalist who performs carotid procedures for occlusive disease. A thorough history and physical examination is taken, paying particular attention to the pattern of symptoms if present, any prior neurologic events, and the baseline neurologic examination. An appropriate cardiovascular risk assessment should be performed in older patients and those patients presenting with atherosclerotic lesions. Capacity for neck extension and rotation, as well as neck size and distance from the clavicle to the angle of the mandible, are useful for preoperative planning. One consideration specific to open aneurysm resection is the potential need for conduit in the event of interposition bypass. Bilateral lower extremity vein mapping should be obtained. However, carotid reconstruction can be performed using prosthetic conduit with good results.

The use of advanced imaging modalities such as CTA or MRA is mandatory for preoperative planning. These techniques provide invaluable information about the location and morphology of the aneurysm. Imaging should be obtained of the entire neck, as well as the aorta, arch, head vessels, and the intracranial circulation.

If an infectious etiology is believed likely, soft tissue coverage of the carotid repair may be a concern, and assistance from a colleague experienced with oncologic reconstructions of head and neck cancers may be indicated. Decisions regarding anesthetic technique and intraoperative neurologic monitoring are best done when considering the strengths and preferences of the team in the operating room, although a general anesthetic may be preferred for open surgical repair because of the possibility of extended procedure time with difficult dissection and prolonged carotid clamp time as compared with standard CEA.

The decision for open versus endovascular treatment demands deliberation over multiple aspects of the patient presentation and must be tailored to each individual case. Although reported results limit endovascular intervention have the advantages of lower in-hospital mortality and morbidity rates, reduced risk of cranial nerve injury, potentially lighter anesthetic requirements, and greater utility for distal ICA lesions, it is important to remember that these results were achieved in carefully selected patients. An endovascular approach is believed to be particularly well suited to aneurysms

secondary to traumatic injuries, carotid dissection, or for pseudoaneurysm after CEA, provided infection can be ruled out. Endovascular intervention is also believed to be advantageous in patients with very distal or near III lesions, and in those patients with hostile necks (prior surgery, history of radiation) or who represent a prohibitive risk with a general anesthetic. However, endovascular treatment via transluminal access carries an increased risk of stroke as compared with open carotid interventions, especially in patients with heavy calcific disease or unfavorable aortic arch anatomy. In addition, the thrombus burden typically associated with these aneurysms is thought to represent a higher embolic risk during endovascular repair than does an occlusive lesion. Patients with tortuous carotid anatomy may not be suitable for endovascular treatment based on the limitations of current stent grafting technology. In particular, endovascular treatment of aneurysmal lesions in this bed, especially degenerative, carries with it the same concerns about durability and need for reintervention as it does for arterial aneurysms of the abdomen and the lower extremities.

Patients presenting with compressive symptoms have traditionally been believed to be best served with open surgery, however, good results have been reported with endovascular therapy. ECAA with infectious etiology is considered a strong relative, although not prohibitive, contraindication to endovascular repair.

Open Surgical Repair

Traditionally, the operation of choice and that with the longest history in the literature is aneurysm resection with either primary end-to-end anastomosis or interposition grafting. Frequently, ECAA is associated with a degree of redundancy in the artery, especially in the case of ICA aneurysm. This is often the scenario for which resection with primary anastomosis is the preferred approach. The external carotid artery can be ligated with impunity, however, any variation to that technique in the potential for distal external carotid artery dilation with end to end anastomosis of the proximal external carotid to the distal ICA to restore inflow. Common carotid aneurysms and those involving the carotid bulb are usually best treated with interposition grafting. Reversed great saphenous vein graft is an excellent option with a proven track record, and usually provides a good size match to the nondiseased native carotid arteries. The choice of graft material is between prosthetic and autologous vein, either can be used with good results in the absence of infection. Open reconstruction in the presence of infection mandates the use of autologous conduit; if no vein is available in any extremity, then the use of superficial femoral artery has been described, or external carotid transposition as described earlier.

Dissection of the aneurysm and the associated arteries can be difficult because of the dense inflammatory reaction these lesions commonly provoke (Fig. 2). Nevertheless, meticulous technique is necessary to ensure safe identification of all important structures, most notably the cranial nerves. The nerves most at risk will depend on the location of the aneurysm; in a recently published large series, the most commonly injured nerves were the recurrent laryngeal, hypoglossal, glossopharyngeal, and the motor branch of the facial nerve. An endoaneurysmorrhaphy technique can also be used, in which the aneurysm is identified and opened, and the interposition graft then placed in anatomic position and covered with the residual aneurysmal sac. This may minimize the chance of nerve injury as compared with radical sac resection.

As in CEA, the aneurysm should be manipulated as little as possible during dissection to minimize the chance for downstream athero-embolization. Systemic heparin is given once proximal and distal control of all arteries to achieved, in dose sufficient to double the baseline activated clotting time as measured serially in the operating room.

Exposure of distal ICA aneurysms can prove challenging. Some alternatives well known from the CEA literature can be used in this situation, albeit at the cost of increased morbidity and added potential for cranial nerve injury. Division of the styloid process or mandibulectomy is now rarely done. Conversely, division of the posterior belly of the digastric muscle or mandibular advancement can be employed with relatively little risk. Very high ICA aneurysms can be treated using balloon occlusion for distal control, usually in conjunction with intraarterial shunt placement. ICA ligation is an alternative, although this maneuver has been historically associated with unacceptably high rates of stroke exceeding 25%. However, the safety of ligation can be assessed in the operating room using carotid stump pressure measurement. A 20-gauge Angiocath is inserted into the ICA just distal to the intended endpoint of resection, following heparinization and control of the common and external carotid arteries but prior to opening the aneurysm. This is connected to a standard arterial line setup provided by the anesthesia team and the arterial pressure waveform is assessed. A mean ICA pressure of >50 mm Hg suggests adequate collateralization of the Circle of Willis without need for a shunt. We use this method routinely to determine the need for placement of a shunt in CEA with excellent results. If used, the shunt is placed into the open ends of the normal arteries distally and proximally immediately after opening the aneurysm. If stump pressure suggests that ICA ligation is not safe, and the lesion is too high for grafting to be technically feasible, extracranial to intracranial bypass has been proposed. Alternately, many would consider this type of lesion to be a strong relative indication for consideration of endovascular treatment. In any event, ligation is best reserved as a fallback technique for situations in which carotid reconstruction is believed to be difficult or impossible. In addition to stump pressure measurement, these patients undergoing ligation should be anticoagulated postoperatively for a minimum of 3 months to prevent embolization (carotid stump syndrome).

The principles for treatment of infected carotid aneurysm are concurrent with those of arterial infections in general. All these patients require expeditious evaluation and operative repair. Parenteral broad-spectrum antibiotics are administered perioperatively beginning prior to any operation, and subsequently narrowed on the basis of intraoperative culture results. The entire infected field and any prosthetic material must be aggressively debrided back to healthy tissue. Adequate soft tissue coverage is mandatory. The sternocleidomastoid muscle is often sufficient, although a myocutaneous flap may be the best option in the case of prior neck irradiation or radical neck dissection.

The approach to exposure is dependent on location of the aneurysm. The choice incision for all these exposures is along the anterior border of the sternocleidomastoid muscle, although some I common carotid aneurysms below the level of the clavicle may require mobility to achieve proximal control.

Endovascular Repair

Modern series of ECAA have demonstrated a definite trend toward endovascular techniques for treatment, representing as many as 70% of interventions in the later periods of hospital reported experiences. This technique generally mirrors the development of successful approaches to the treatment of disease in the treatment of abdominal aortic aneurysm, utilizing available stent graft technology (albeit off-label) in combination with coil embolization of the external carotid artery. Advantages of endovascular treatment are likewise similar to those found with this technique in other aneurysms, lower in-hospital mortality and morbidity rates, reduced risk of bleeding and damage to nearby structures, and greater flexibility in the treatment of lesions for which surgical exposure may come with increased risks. An endoluminal approach to ECAA is particularly appealing when considering treatment of high cervical lesions.

The consideration unique to endovascular repair of ECAA lies in maintaining cerebral blood flow while minimizing the risk of downstream athero-embolization to the brain without use of an ICA clamp. Indeed, although the risk of cranial nerve injury is lower

than with open repair, the operative stroke risk is believed by many authors to be higher with endovascular intervention. Here too, the risk of subsequent arterial degeneration and possible need for reintervention remain significant limitations common to all endovascular therapies.

The standard access for endovascular treatment is via the common femoral artery, but the common carotid artery can also be accessed by direct surgical cutdown. A general anesthetic is not necessary unless in cases of hemodynamic instability. Aortic arch aortography is performed using a pigtail flush catheter and a power contrast injector to delineate the anatomy of the head vessels. Systemic heparin is administered. A long sheath is advanced into the arch, and the common carotid artery is selected using a Glidewire and the operator's choice of appropriate catheter. Cerebral angiogram is then obtained, and a low profile system is positioned across the lesion for intervention. Identification of the proximal and distal extent of the aneurysm will not always be obvious based on angiogram alone, and knowledge of anatomic landmarks from preoperative imaging or the use of on table cone beam computed tomography (CT) may be helpful. Distal cerebral protection is mandatory in our view if technically feasible, positioned in the ICA distal to the aneurysm at the earliest possible time prior to stent deployment.

A broad variety of endovascular devices have been used for ECAA repair; an exhaustive list of every possibility and product is beyond the scope of this text. Use of both bare metal stents and covered stents have been described. A proximal and distal landing zone of healthy noncarotid arterial (a healthy to healthy bridge) is required for durable aneurysm exclusion, although little guidance exists for exactly how long these zones must be to achieve an adequate repair. Use of devices outside the indications for use is routine. Postdeployment balloon dilation should be undertaken for most cases but must be done judiciously given the attendant risk of dissection. Completion cerebral angiogram is then obtained to assess for any complication. Placement of a covered stent across the origin of the external carotid artery is often necessary and well tolerated by patients, representing the endovascular equivalent of a vessel ligation. When this is undertaken, coil embolization of the external carotid artery prior to stent deployment is advocated as protection against endoleak, the phenomenon whereby an aneurysmal sac continues to grow as a result of arterial flow from an open collateral vessel.

Covered stents are perhaps the strongest choice and most frequently used devices as they provide the most straightforward means of aneurysm exclusion, thus preventing aneurysm growth or rupture while isolating the embolic source posed by thrombus in the aneurysm wall. Some reports have emerged, however, associating covered

stents with an increased risk of early thrombosis, despite chronic oral anticoagulation. Bare metal stents are less commonly used but are sometimes needed in situations in which the additional radial force they exert against the arterial wall is required; they are the treatment of choice for dissections. In addition, some lesions are treated with bare metal stents in arteries with diameters too small to accommodate a covered stent or its associated larger introducer sheath. In vessels of this size, the placement of the stent alone may be sufficient to induce thrombosis of the sac.

Saccular aneurysms or large pseudoaneurysms can be excluded by inducing thrombosis of the aneurysm with coils, followed by reapposition of the flow lumen by stenting. Another technique places a closed-cell stent initially, followed by introduction of coils through the interstices of the stent using a microcatheter. Alternatively, complications of coil migration or embolization can be avoided entirely if coil embolization is delivered and performed as an interval procedure only if the sac fails to thrombose (Fig. 3).

Hybrid techniques represent an exciting new frontier in the treatment of ICAA, with variations that allow for near infinite variability in customization of the repair to the patient. Their presence in the literature is limited to case reports and extremely small subsets of reported series. In some cases, as with hybrid aneurysm repair in other arterial beds, an open procedure is used as a bridge for successful endovascular intervention, creating an acceptable landing zone for a stent where none was available. The applicability of this technique to challenging cases of ICA lesions is obvious. Another described use of a hybrid strategy involves the use of endovascular therapy to temporize an unstable patient, even in the case of rupture or infection, in anticipation of a definitive open repair at another time shortly thereafter.

Results of Treatment

The small number of overall reported patients over a decades of treatment in the modern era complicates any rigorous comparisons of therapy. No randomized controlled trials are available, nor are there ever likely to be any. The strongest published evidence consists of single-center retrospective consecutive series and literature reviews. Within these limitations, the modern literature supports that treatments for ICAA can be carried out safely. Moreover, there is little doubt that the results of surgery are superior to what is known about the natural history of the disease.

For true ICAA, surgical repair represents the standard of care in the present day. Contemporary results for open surgical resection with arterial reconstruction remain excellent. Recent data demonstrate 30-day stroke rates between 0.7% and 10%, and 30-day mortality less than 2%. Cranial nerve injury remains the feared complication, with rates approaching 30%. It should be noted, however, that most of these injuries are not permanent in the series so stratifying them. Long-term follow-up after open surgical repair again demonstrates good results with 85% to 95% survival, with similarly acceptable stroke-free survival rates greater than 85%. Freedom from reintervention is also excellent, with reported rates of more than 90%, and thrombotic graft occlusion was for the most part well tolerated.

Results of endovascular treatment continue to reinforce the efficacy of this strategy as an alternative to open reconstruction. Technical success is consistently greater than 90%. Perioperative stroke rates are comparable with open repair, ranging from zero to 6% in contemporary series. The rates of cranial nerve injury are frequently reported to be zero. Reintervention rates are reported to be as high as 30%, the most frequent indications for return to the angiographic suite were incomplete sac thrombosis and in-stent restenosis.

FIG. 3 Digital subtraction angiography of a left internal carotid aneurysm at the skull base with associated mild flow stenosis. (A) Before treatment by bare metal stent placement. (B) After treatment. Note the absence of residual aneurysm and presence of a small residual aneurysmal sac, which subsequently clotted completely.

Medical therapy alone without invasive intervention has not been embraced as an acceptable strategy, given that most ECAA present with symptoms and of those that do not, most are thought to be a significant threat to become so. Antiplatelet and/or anticoagulation medication can be given, in a manner informed by the existing carotid disease literature, without surgery in selected patients. The best support for a nonoperative strategy is suggested by a recent retrospective review by Lumsden and colleagues at the Mayo Clinic, who reported a series of 141 patients with ECAA, most of whom were managed medically. The lesions managed without surgery tended to be small, asymptomatic pseudoaneurysms, but it should be noted that none of these patients developed symptoms requiring intervention during a mean follow-up of 77 months. These results suggest that nonoperative management with medical therapy and close follow-up may be appropriate for highly selected patients, but confirmation of these outcomes by additional authors is required.

VERTEBRAL ARTERY ANEURYSMS

EVAA are very uncommon and are usually the late result of dissection or pseudoaneurysm. Trauma is often the incipient cause. True degenerative EVAA are quite rare, fewer than 1% of all vertebral artery lesions, and are most frequently associated with connective tissue disorders that predispose to aneurysm formation in other arterial beds. The scarcity of this entity has to date precluded any large cohort based studies on which to base natural history or treatment, the majority of the guidance must be derived from the larger literature on vertebral artery disease due to occlusion or embolism.

As with ECAA, trauma to the head and neck can result in damage to the vertebral arteries, resulting in dissection or pseudoaneurysm. Although pseudoaneurysm is often associated with penetrating trauma and dissection with blunt force injuries, it is important to remember that either type of injury is possible with any type of trauma. Either type of lesion can eventually lead to progressive aneurysmal dilatation. Even seemingly trivial mechanisms can result in injury, including a mere head rotation of the neck or other minor accidents, symptoms for which may not appear until the arterial source becomes apparent. These perhaps surprising presentations are especially common in the elderly although arterial injury has increasingly been recognized in younger patients with active lifestyles. Iatrogenic (manipulation) or rapid deceleration (whiplash) injuries are often implicated.

The vast majority of vertebral artery aneurysms are intracranial. Among EVAAs, the V2 segment of the artery is most susceptible to aneurysmal degeneration. Most patients are asymptomatic, and the aneurysm is detected as an incidental finding on CT or magnetic resonance (MR) imaging performed for some other purpose. Duplex ultrasound is an unreliable screening test, especially in the V3 segment approaching the skull base. Patients may present with persistent ipsilateral head and neck pain following trauma. Uncommonly, an EVAA may present as a cause of vertebrobasilar insufficiency or posterior stroke. The pathophysiology is either embolism from the aneurysm or slow arterial flow through the lesion. Pulsatile neck mass can be seen, but is probably less sensitive a finding than with ECAA. Reports of rupture are rare.

Traditionally, an aggressive treatment strategy has been favored by most published authors for EVAA. As noted previously the natural history is poorly defined, and there may well be a difference in the danger posed by EVAA that arise as a result of arterial trauma as opposed to those rarely seen aneurysms that are truly degenerative. It is now known that most vertebral artery dissections do heal spontaneously without sequelae, and no definitive treatment exists that has been shown to prevent onset of neurologic complications or progression to EVAA. Specific consensus indications for intervention are lacking. In our view, most EVAAs can be observed with antiplatelet therapy for 3 to 6 months and follow up imaging with CT or MR to assess for resolution. Surgical treatment is indicated for symptoms that can be reasonably attributed to the EVAA, or for aneurysms that are enlarging on serial imaging. A careful assessment of the suitability of the patient for elective aneurysm repair is however essential; higher-risk patients and those with limited potential to benefit from elective repair should prompt a higher threshold for recommendation of intervention.

Open surgical repair of EVAA is probably best attempted only by experts experienced in the field. Vertebral reconstruction surgery is marked by the many variations in anatomic exposure that may be necessary, via approaches that are rarely familiar to most surgeons. For this reason, preoperative imaging with MRA or CTA is essential for planning.

In general, the operative strategy is similar to that for ECAA, with resection of the offending lesion and interposition grafting with harvested vein or artery. Arterial transposition is another option for vertebral disease, and extraanatomic bypass with aneurysm ligation has also been described. The most straightforward exposure is probably to the V1 segment, which encompasses the portion of the artery from the usual origin at the subclavian to the vertebral foramen at C6. Proximal vertebral occlusive disease is frequently amenable to repair via a vertebral-common carotid artery transposition. This is accessible from a supraclavicular incision similar to that used for carotid subclavian bypass and involves ligation of the aneurysmal portion of the vertebral artery with reimplantation of the distal portion to the adjacent common carotid artery. The subclavian artery or the thyrocervical trunk is alternate source of inflow.

The V2 segment is found within the transverse foramina of the cervical vertebrae and represents much greater challenges to exposure because of the need for bone resection and the meticulous dissection required of the associated venous plexus. Exposure of the distal V3 segment is more appealing, especially from a posterior approach, but should probably only be attempted by those experienced in the field. Possibilities for distal reconstruction are transpositions of the vertebral to the external or internal carotid, or interposition grafting using saphenous vein to the vertebral from the common carotid, the external carotid, or the subclavian artery. These operations can be performed safely and demonstrate the same durability profile as with their counterparts in other areas of the peripheral circulation.

The last decade has seen increasing use of endovascular treatment for vertebral artery lesions. Despite questions about durability, starting with or without use of coil embolization is appealing considering the challenges of open vertebral reconstruction. In our view, endovascular treatment of EVAA should only be considered in the presence of a robust contralateral vertebral artery because of the relatively high incidence of in-stent restenosis reported for treatment of occlusive disease. The promise of endovascular therapy of EVAA has yet to meet the reference standard set by open repair.

Brachiocephalic Reconstruction

Rebecca Sorber, MD, and Caitlin W. Hicks, MD, MS

The brachiocephalic vessels, also known as the great vessels, supply the circulation of the upper extremities and head, including the entirety of intracranial blood flow. Given the intimate association of these vessels with the aortic arch and their proximity to the aortic root, it is rare that the general surgeon must intervene on pathology in this region. However, a basic understanding of the potential manifestations of brachiocephalic disease and options for repair or reconstruction will facilitate the care of these patients with respect to all procedures.

The embryologic origin of these vessels is complex, like the aortic root and transverse arch themselves, they arise as an intricate admixture of the embryonic aortic arches and often have considerable variability in their anatomic configuration. The most common configuration is to the form of three separate vessels arising from zones 0 to 2 of the transverse aortic arch (Fig. 1). The innominate artery arises from zone 0 and subsequently branches into the right common carotid and right subclavian arteries; the left common carotid arises from zone 1; and the left subclavian artery arises from zone 2 and gives off the left vertebral artery just distal to its origin (Fig. 2A). The most common variant to this configuration is a bovine arch, which has the innominate and the left common carotid arteries arising from a common trunk (8%, Fig. 2B) or variant (16%). Less common variants include a left vertebral artery, which arises from the arch at a separate origin proximal to the left subclavian (6%, Fig. 2C), or a right subclavian artery, which arises from the arch distal and posterior to the left subclavian artery and runs retroesophageal to supply the right upper extremity (0.5%, termed *aberrant right subclavian artery*).

While the brachiocephalic system possesses a unique origin, its pathophysiology is governed by the same set of universal principles applying to the arterial system as a whole. Thus, the potential pathologies affecting the brachiocephalic vessels can largely be categorized into two main groups: occlusive disease and aneurysmal disease. The location of these vessels, as well as their intimate relationship to central neurologic and upper extremity function, result in unique manifestations of arteriopathy in this region; it is these symptoms that drive the decision to intervene.

Historically, reconstruction of brachiocephalic pathologies has required open surgery. However, the nature of these vessels as tributaries of the aortic arch makes such open procedures challenging and maximally invasive. For this reason, endovascular therapy for lesions within the brachiocephalic system has recently expanded as an adjunct or replacement for many open surgical procedures in this region. Additionally, a growing indication for brachiocephalic reconstruction includes debranching procedures to facilitate endovascular repair of thoracic aortic aneurysms and dissections by increasing the proximal landing zone for stent graft placement.

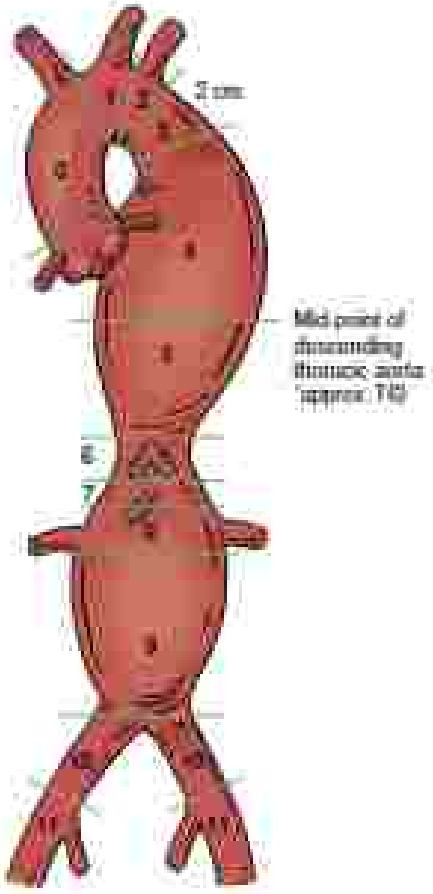

FIG. 1 Zones of the thoracic and abdominal aorta. [Modified from Singh M, Mukherjee MS. Hybrid thoracic surgery and endovascular therapy. Perioperative Medicine. 2019;8:1000. 1074.]

BRACHIOCEPHALIC PATHOLOGIES

The vast majority of lesions affecting the brachiocephalic vessels are occlusive or stenotic in nature (Figs. 3 and 4). Most frequently these are related to atherosclerotic disease, although large vessel vasculitis such as Takayasu's arteritis or complications of prior radiation to the head, neck, and mediastinum can also play a role. The progressive narrowing of vessels supplying the upper extremity and/or intracranial circulation may result in a number of distinct symptoms. Upper extremity ischemia may manifest as fatigue with routine activity and a changed or asymmetric pulse exam with exercise. However, limb ischemia symptoms related to proximal brachiocephalic lesions are relatively uncommon. This is due largely to the extensive collateral network that supplies the upper extremities.

Vertebrobasilar insufficiency results from a reduction of blood flow to the vertebral arteries, creating relative ischemia of the posterior circulation and resulting in vertigo, ataxia, visual symptoms and syncope. A subset of vertebrobasilar insufficiency is subclavian steal syndrome, which occurs when a high-grade stenosis or occlusion of the proximal subclavian artery causes reversal of flow in the ipsilateral vertebral artery. Classically, subclavian steal syndrome is exacerbated with exercise of the ipsilateral upper extremity. Likewise, some patients with proximal subclavian lesions and an ipsilateral internal mammary artery bypass graft may experience significant angina with upper extremity exertion (termed *coronary steal*).

Because the vast majority of occlusive disease in the brachiocephalic vessels is secondary to atherosclerosis, atheroembolic events of the supraaortic circulation can occur. Atheroembolism to the upper extremity circulation may manifest as discoloration or, in extreme and chronic cases, autoamputation of the digits. Atheroembolism to the intracranial circulation may manifest as a transient ischemic attack (TIA) or stroke symptoms. It is important to note that while cerebrovascular embolic phenomena frequently implicate carotid artery stenosis occurring at the carotid bifurcation, disease affecting

the ostia of the innominate or left common carotid arteries can result in hemispheric symptoms.

Aneurysms of the brachiocephalic vessels can also occur, most frequently affecting the left subclavian artery (Fig. 5). These are generally degenerative or traumatic in nature but can also be associated with connective tissue disorders (e.g., Marfan's syndrome, Ehlers-Danlos syndrome, Loeys-Dietz syndrome). When symptoms arise, these lesions are often identified incidentally on imaging studies performed for unrelated reasons. These patients frequently have concomitant carotid or additional peripheral aneurysms and should be evaluated for additional aneurysms when a brachiocephalic aneurysm is identified. When symptomatic, often the manifestation is one of a pulsatile mass or compression of surrounding structures. Particularly fusiform aneurysms can develop associated thrombus and may present due to subsequent thromboembolic sequelae.

DIAGNOSTIC EVALUATION

Evaluation of suspected brachiocephalic pathology is founded on a comprehensive history and physical exam with keen focus on the neurologic and vascular systems. History taking should include symptoms of vertebrobasilar insufficiency or steal phenomena, as well as prior TIA symptoms. The neurologic exam should focus on evaluation for deficits from prior stroke, and the upper extremities should be evaluated for asymmetry in strength and pulses. Brachial artery blood pressures should be taken bilaterally, with a difference of more than 15 mm Hg between extremities considered significant. All patients should be asked about standard atherosclerotic risk factors, including smoking history, diabetes, and radiation history. In the setting of patients suspected to have a connective tissue disorder or vasculitis, serologic testing including erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) labs and collection of a detailed family history may also be useful.

Duplex ultrasonography is generally the first line of imaging employed in the setting of brachiocephalic disease, as it is noninvasive, low risk, and provides dynamic flow information. Low flow velocities within the common carotid arteries with a dampened waveform are indicative of distal lesions or proximal stenosis. In the setting of high-grade subclavian or innominate disease, reversal of flow may be noted within the vertebral arteries. Classically, ipsilateral reversal of vertebral flow is noted in the context of subclavian steal syndrome; however, this finding is not uncommon in brachiocephalic disease and is often not associated with symptoms on history or physical exam. Transcranial Doppler ultrasound can provide additional data on intracranial flow patterns to help determine whether flow abnormalities are physiologically significant. In addition, axial imaging in the form of computed tomography angiography and magnetic resonance arteriography can provide high-quality images of the arterial anatomy that will aid in both the diagnosis and treatment planning for affected patients (Fig. 6). These imaging studies have largely replaced conventional catheter-based arteriography in most cases.

INDICATIONS FOR INTERVENTION

The decision to intervene on common carotid or subclavian artery disease is largely driven by cerebrovascular or upper extremity symptoms localizing to a specific lesion. As a general rule, asymptomatic subclavian artery stenoses do not need intervention, whereas aneurysmal pathology may require repair even in asymptomatic cases due to risk of progression and rupture. Lesions arising from an inflammatory process such as Takayasu arteritis should only be considered for intervention once the acute inflammatory phase has passed. This is usually monitored based on ESR and CRP levels, and in some instances positron emission tomography–computed tomography can be helpful to rule out the presence of active vasculitis.

For patients with asymptomatic common carotid artery lesions, it is generally accepted that stenosis of more than 75% is considered to be an indication for intervention even in the absence of attributable symptoms. If common carotid and bifurcation disease of more than 75% luminal stenosis are present concomitantly, common carotid repair via an endovascular or open approach may be considered at the time of carotid endarterectomy, although the data supporting this practice is controversial. In the setting of ipsilateralizing cerebrovascular symptoms or global cerebral hypoperfusion, any brachiocephalic lesions of more than 75% luminal stenosis can be considered for repair.

Subclavian artery stenosis or occlusion should not be intervened upon without clinically evident subclavian steal symptoms, reversal of vertebral flow on duplex alone is not criteria for intervention. Asymptomatic high-grade stenosis or occlusion of the subclavian arteries may require intervention in the setting of coronary revascularization with an internal mammary artery conduit. In order to maximize perfusion to the proximal coronary graft and to maintain accurate intraoperative continuous invasive blood pressure monitoring, a carotid-subclavian artery bypass or a subclavian-carotid artery transposition procedure may be considered.

The preferred threshold for brachiocephalic artery aneurysm repair is somewhat controversial. The rationale for intervention is to prevent aneurysm growth, which can lead to dissection, compression of nearby structures, or rupture. Rawanduzi et al. recently examined 147 brachiocephalic aneurysms and observed an average growth rate of 0.06 cm/y, with 19% demonstrating no growth over 4 years of follow-up. There were no instances of aneurysm rupture during the follow-up period. Based on these data, the authors recommended a repair threshold of 3.0 cm for asymptomatic brachiocephalic aneurysms. It should be noted that brachiocephalic aneurysms associated with dissection have been associated with faster rates of growth and may warrant repair at a lower size threshold.

OPEN SURGICAL APPROACHES

Open surgical revascularization of the brachiocephalic vessels may be accomplished via direct or extraanatomic means. Direct revascularization is usually performed in a transthoracic fashion, requiring a median sternotomy for lesions of the innominate and left common carotid arteries and a left posterolateral thoracotomy for left subclavian lesions. The transthoracic approach is associated with significant surgical insult and tends to be reserved for young, robust patients who are able to tolerate aortic cross-clamping. Most commonly, this approach is applied in patients with complex aneurysmal pathology, traumatic transection of the brachiocephalic vessels, or when brachiocephalic reconstruction is combined with coronary revascularization.

The open surgery alternative to a transthoracic approach for brachiocephalic reconstruction is an extraanatomic revascularization. This is usually performed via transverse supraclavicular and/or cervical incisions and is a viable approach for the majority of isolated

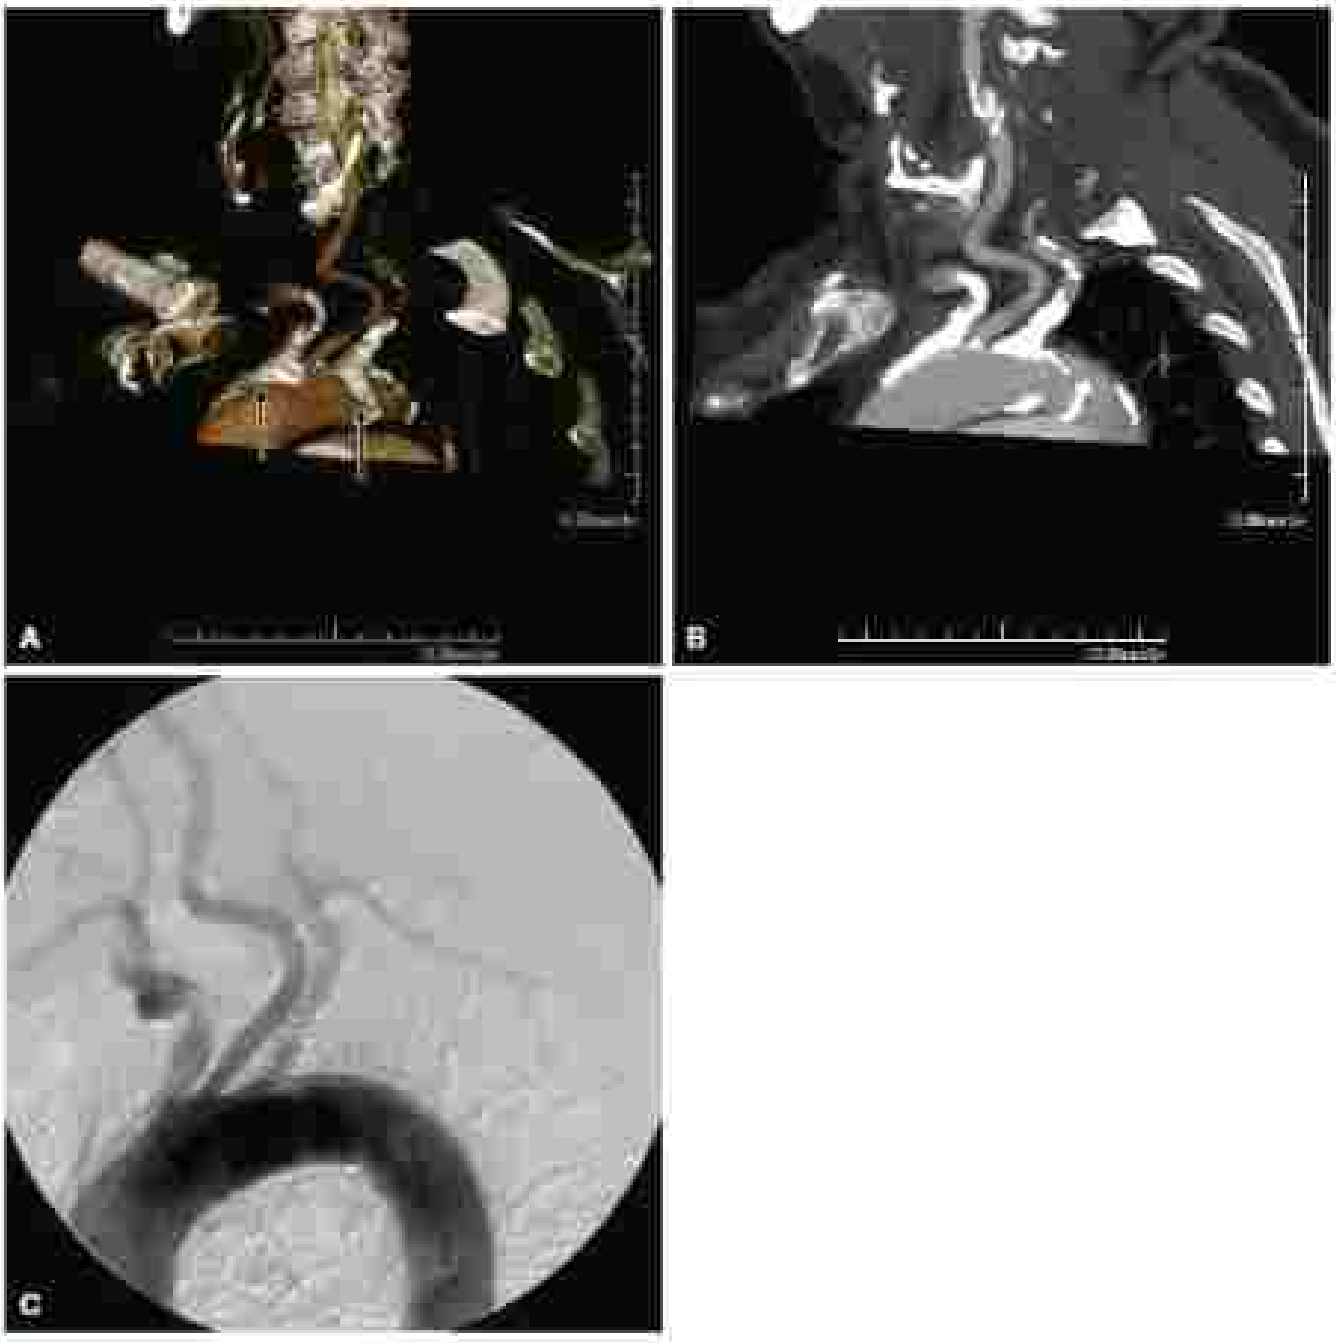

FIG 4 (A) Computed tomographic (CT) three-dimensional surface rendering of the aortic arch showing severe calcific disease of the origins of the innominate and left subclavian arteries (arrow). brachiocephalic lesions, with the exception of those affecting the innominate artery. Extraanatomic revascularization is the preferred approach for older patients unable to tolerate thoracotomy, those with prior sternotomy, minimal radiation, or severe calcific disease of the ascending aorta. This indirect approach is generally well tolerated and has low morbidity and mortality rates.

Innominate Artery Revascularization

Lesions of the innominate artery are uncommon, even among lesions of the brachiocephalic vessels. The optimal open surgical approach to lesions of the innominate artery is generally via a median sternotomy, although a mini-sternotomy that divides only the upper sternum from the sternal notch to a T incision at the third intercostal space can also be employed to expose the vessels (Fig. 5). For focal atherosclerotic disease of the mid-innominate artery, endarterectomy with patch angioplasty may be carefully considered. However, for more proximal lesions involving the innominate ostium with extension into the aortic arch, an attempt at endarterectomy is likely to be incomplete, resulting in potential atherothrombosis or aortic dissection.

More frequently, bypass grafting of the innominate is performed, from the lateral ascending aorta to one or more distal targets (Fig. 6). This approach utilizes a 10- to 12-mm Dacron tube graft anastomosed in an end-to-side fashion to the lateral ascending aorta, then

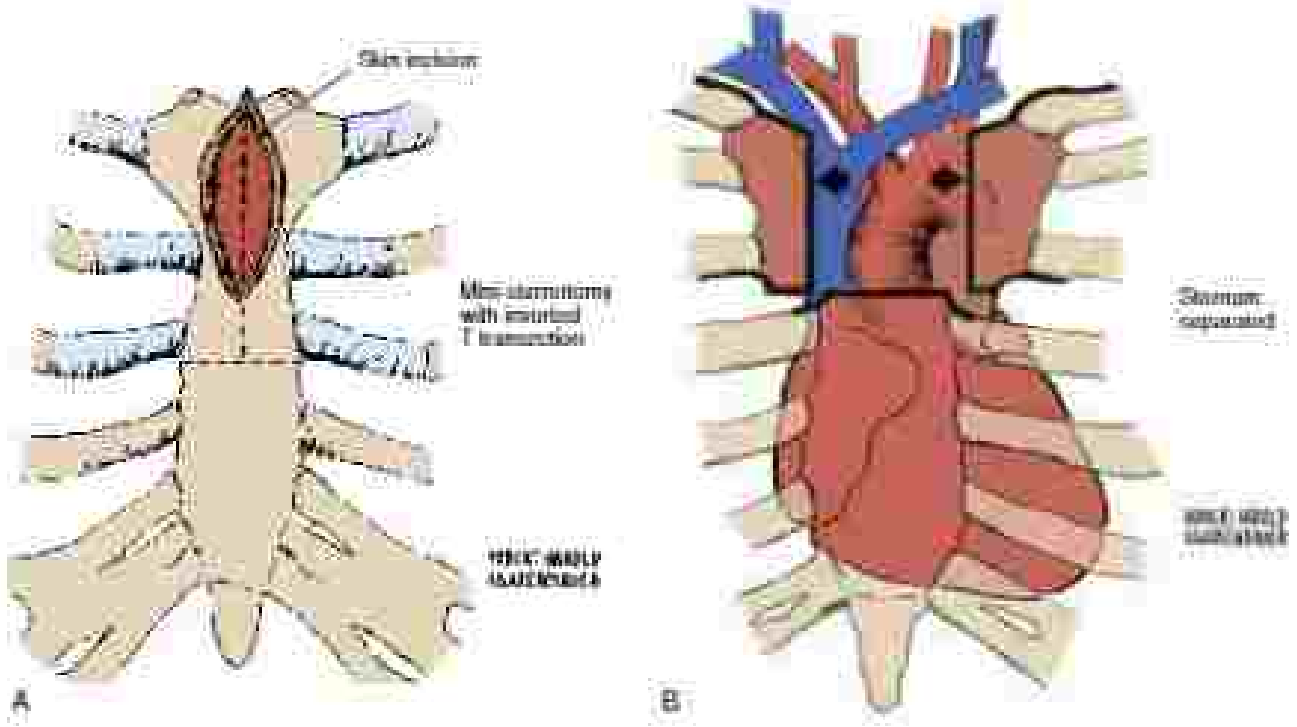

FIG. 7 (A) Skin incision and mini-sternotomy sternal division. (B) The upper sternum is divided and separated (arrows), exposing the ascending aorta and arch vessels. ramified posterior to the innominate vein to avoid compression in the retrosternal space. The distal anastomoses are performed in an end to end fashion; if more than one distal revascularization target is required, an 8 mm Dacron tube graft is anastomosed end to side to the larger tube graft proximally, and then end to end to the second distal target (generally the common carotid or subclavian artery). This configuration prevents redundancy and kinking of the grafts in the retrosternal space once the sternum is closed.

Shunting during open repair is not routinely required but should be considered in patients with a contralateral carotid stenosis and those who are otherwise at risk for cerebral malperfusion. When repairing the innominate artery via an open surgical approach, consideration must also be given to those patients with bovine arch anatomy, as clamping of the innominate artery in such a setting will result in complete cerebral ischemia.

Common Carotid Artery Revascularization

Stenosis of the left common carotid artery is the second most common brachiocephalic lesion after stenosis of the left subclavian artery.

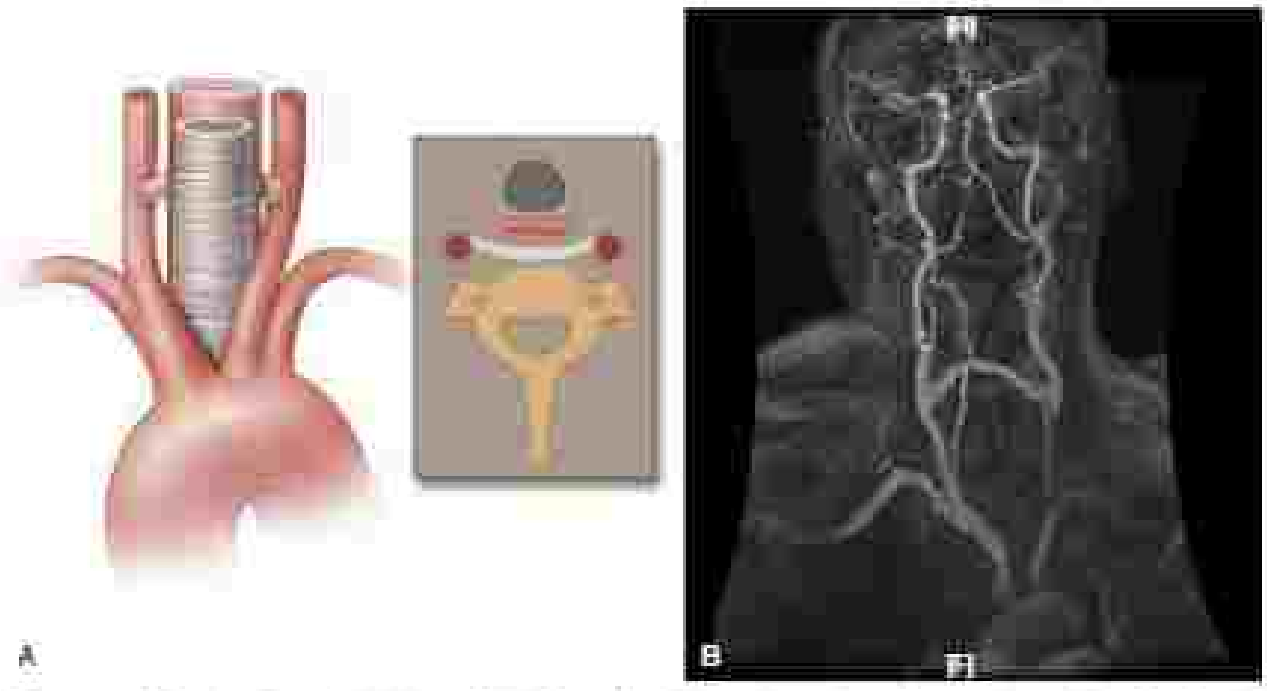

FIG. 9 Carotid-carotid bypass. (A) Illustration depicting a right-to-left carotid-carotid artery bypass using an 8-mm ringed prosthetic graft configured with end-to-side anastomoses at both common carotid arteries. (B) Completion angiogram after carotid-carotid bypass. (Modified from Chaikof, Lee KH, Hill AB, Veith FJ, Hallett Jr JW, Gloviczki P, Rutherford's Vascular Surgery and Endovascular Therapy, Philadelphia, [date]; 2019. p. 1[illegible].)

Due to the potential risk for cerebral atheroembolic events, left carotid artery lesions are the most common lesions to be repaired in asymptomatic patients. While a median sternotomy gives excellent access to the proximal left common carotid artery, the majority of common carotid lesions can be addressed via a cervical approach utilizing a carotid subclavian or carotid-carotid artery revascularization. Unique to carotid revascularization is the carotid-carotid artery bypass (Fig. 9). This procedure is performed by exposing the common carotid arteries bilaterally via anterior vertical neck incisions and tunneling an 8-mm prosthetic bypass graft via a direct path in the retropharyngeal space by passing a finger medial to the carotid artery and behind the esophagus. The graft can alternatively be passed anteriorly, but this tends to erode tissues with contents due to the superficial nature of the graft and presents an issue in the event that the patient needs a tracheostomy or intubation in the future.

Left Subclavian Artery Revascularization

Left subclavian artery stenosis is the most common brachiocephalic lesion requiring intervention. Carotid subclavian revascularization can be performed either as a bypass or as a transposition procedure, and both approaches can be utilized as a means to address pathology to either the subclavian or the common carotid artery. It is worth noting that in patients with subclavian disease, ligation of the diseased vessel proximal to the bypass must be performed in order to prevent continued subclavian steal following revascularization.

A carotid subclavian artery bypass (Fig. 10) is performed via a transverse supraclavicular incision lateral to the clavicular head of the sternocleidomastoid. The skin, subcutaneous fat, and platysma are divided, and the sternal head is retracted medially to expose the common carotid artery. Care must be taken to identify the phrenic nerve prior to division of the anterior scalene muscle, and to retract the vagus nerve and internal jugular vein laterally. During exposure of the subclavian artery on the left, attention must be also be given to the thoracic duct, which enters the posterior confluence of the internal jugular and subclavian veins. If the thoracic duct can be identified, it should be ligated to prevent a postoperative chyle leak. Once the

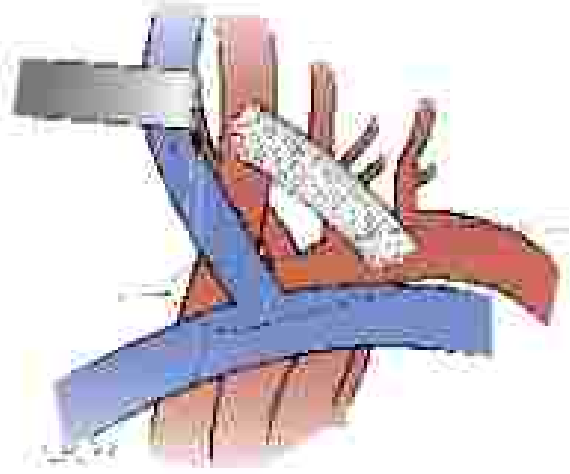

FIG. 10 Left carotid subclavian bypass using an 8-mm ringed prosthetic graft configured with end-to-side anastomoses to both targets.

common carotid and subclavian arteries are exposed and mobilized, a prosthetic graft is sutured to the common carotid artery proximally in an end-to-side fashion. It is then tunneled behind the internal jugular vein and sutured to the subclavian artery in an end-to-side or end-to-end fashion depending on the pathology being treated. Prosthetic grafts have been shown to have significantly better 5-year patency than autogenous veins in this setting (74% vs 54%, respectively); this difference is thought to be due to a lower rate of kinking and compression with prosthetic materials compared to vein.

An alternative to the carotid subclavian artery bypass is a subclavian-carotid artery transposition procedure (Fig. 11), which allows revascularization of the subclavian or carotid arteries without implantation of prosthetic material. To accomplish this procedure, a more extensive dissection of the subclavian artery must be performed to allow a tension free anastomosis with the common carotid. The

extent of the dissection and the mobility required of the subclavian artery to facilitate transposition precludes subclavian-carotid artery transposition in those patients with an existing or future need for an internal mammary graft to a coronary artery.

To perform a subclavian-carotid artery transposition, a transverse supraclavicular incision is made from the medial aspect of the sternal notch extending laterally. Dissection is performed between the heads of the sternocleidomastoid muscle, the omohyoid is divided, and the internal jugular vein is retracted laterally to expose the carotid artery. The thoracic duct should be identified and ligated at this point for all left-sided procedures. The vertebral vein is also identified and ligated,

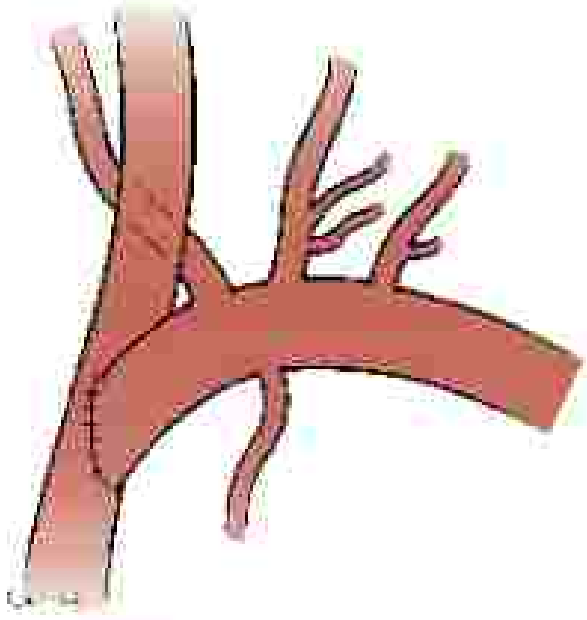

FIG. 11 Left subclavian-carotid transposition.

and the subclavian artery is dissected free proximal to the takeoff of the vertebral and internal mammary arteries. Once the carotid and subclavian arteries are exposed, the proximal subclavian artery is clamped, divided and suture ligated at least 1 to 2 cm proximal to the vertebral artery. It is critical that suture ligation of the proximal subclavian stump is performed immediately, as the artery is generally under tension to facilitate exposure and has the tendency to retract back into the thoracic cavity once divided. The distal end of the divided subclavian artery is then anastomosed to the carotid artery in an end-to-side fashion, with special attention paid to the orientation of the vertebral artery to prevent kinking.

Alternatives to carotid-subclavian revascularization include axillofemoral and subclavian-subclavian bypass procedures. These techniques are rarely utilized but can be used to address left subclavian or innominate disease that is not amenable to more standard open reconstruction approaches. Subclavian grafts are tunneled posterior to the sternocleidomastoid muscles, while axillary grafts run posterior to the pectoralis major muscles in the prosternal space. These grafts are relatively long and tunneled low in the prosternal space, making them at higher risk for compromised patency; however, they remain acceptable choices for revascularization in high-risk patients without other feasible options.

Right Subclavian Artery Revascularization

Right subclavian artery lesions are largely managed in the same manner as left subclavian artery lesions, but the pathologies tend to be slightly different. Although atherosclerotic disease can affect any of the brachiocephalic arteries and require subsequent revascularization, variant anatomy in the form of an aberrant right subclavian artery is much more common than an aberrant left subclavian artery. The aberrant right subclavian artery usually presents in patients aged 40 to 50 years of age as difficulty swallowing (i.e., dysphagia lusoria). In these cases, the right subclavian artery arises from the proximal descending thoracic aorta and courses dorsally between the esophagus and the spine to supply the right arm (Fig. 12). While this anatomy may be asymptomatic in some patients, the aberrant

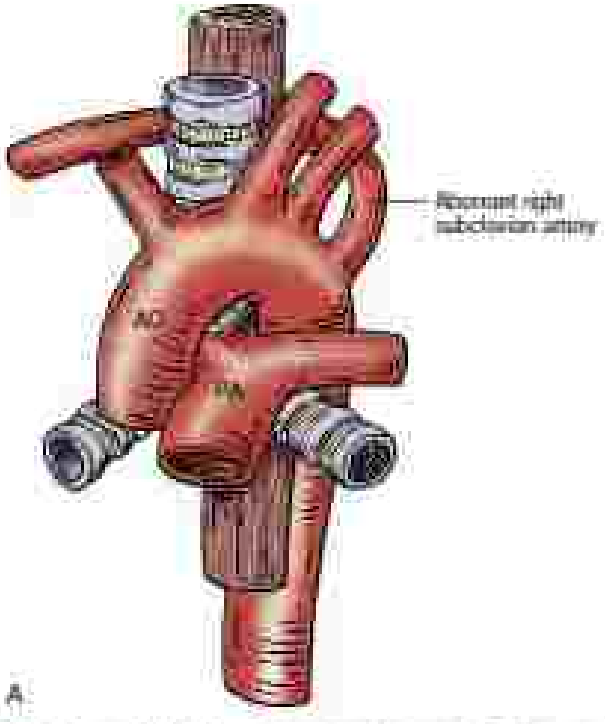

FIG. 12 Schematic (A) and digital subtraction angiogram (B) demonstrating the anatomic configuration of an aberrant right subclavian artery (arrow). Ao, Aorta; PA, pulmonary artery.

subclavian artery can compress the esophagus to the point that patients experience dysphagia. Patients presenting with this complaint should be fully worked up for gastrointestinal sources of their dysphagia via upper endoscopy, esophageal pH monitoring, and esophageal manometry prior to considering brachiocephalic reconstruction. Once other diagnoses have been exhausted, they can be considered for subclavian artery reconstruction. We prefer a carotid-subclavian artery bypass or subclavian artery transposition with proximal ligation of the subclavian artery via a supraclavicular incision. In most cases this procedure alone results in symptomatic relief. In patients with persistent symptoms after subclavian artery ligation and reconstruction, the subclavian artery stump can be completely resected via a left lateral thoracotomy or decompressed via a thoracic aorta stent graft placement (thoracic endovascular aortic repair [TEVAR]).

Brachiocephalic Artery Debranching

Even in the setting of normal brachiocephalic vessels, aneurysmal degradation or dissection of the adjacent descending thoracic aorta may require intervention on the brachiocephalic arteries. In the setting of aneurysm, dissection, or traumatic transection of the thoracic aorta, TEVAR is now employed as the treatment modality of choice. As the stent graft utilized in TEVAR requires a proximal landing zone of at least 2 cm, obtaining adequate exclusion or coverage of the aortic pathology in question would otherwise lead to coverage of one or more of the brachiocephalic vessels. Hybrid procedures, which combine open debranching of the brachiocephalic vessels with endovascular aortic stenting, increase the availability of complex thoracic aortic repair to patients who would otherwise be deemed nonoperative candidates due to their inability to tolerate open surgery.

The most common debranching procedure performed in anticipation of TEVAR is for planned left subclavian artery coverage. Historically, the left subclavian was not routinely revascularized prior to TEVAR; only patients with symptoms of arm claudication or ischemia postoperatively were offered revascularization. However, it is now appreciated that coverage of the left subclavian artery can iatrogenically result in vertebrobasilar and spinal cord ischemia as well. Controlla et al. examined outcomes of left subclavian coverage versus revascularization in the setting of TEVAR, and demonstrated 11% versus 3% stroke rates, respectively ($p = .0003$). Currently, it is recommended that left subclavian artery revascularization be performed preoperatively for all elective TEVAR procedures, usually in the form of a carotid-subclavian artery bypass or subclavian-carotid artery transposition. For emergent or urgent TEVAR requiring left subclavian artery coverage, revascularization can be considered on a case by case basis and may be performed postoperatively in asymptomatic patients. Importantly, left subclavian artery revascularization is considered mandatory in all patients with a left internal mammary coronary bypass graft, and strongly recommended in those patients with a left radial artery/venous fistula or antibrachial bypass.

Stent graft placement into the aortic arch with planned coverage of the left common carotid and/or innominate arteries requires a more complex revascularization approach. Given the role that these vessels play in cerebrovascular circulation, preoperative revascularization is not optional. In the setting of left common carotid coverage, a right-to-left crossover bypass in the form of a carotid-carotid, subclavian-subclavian or axillo-axillary bypass can be performed in conjunction with a left carotid-subclavian bypass or transposition to provide the necessary perfusion to the cerebrovascular bed. More proximal stent graft placement involving coverage of the innominate artery requires a total arch debranching procedure as described above (see Fig. 5). Extra-thoracic bypasses are uncommon in this setting, as the cerebrovascular perfusion would be entirely dependent on an antibrachial bypass graft or similar extra-anatomic configurations with concerning durability long term.

OUTCOMES OF OPEN SURGICAL REVASCULARIZATION

Overall, the results for open brachiocephalic revascularization procedures are satisfactory with an acceptable risk profile. It is generally accepted that cervical revascularization is better tolerated than transthoracic repair, with average perioperative mortality and stroke rates of 1.0% and 1.2% versus 6.6% and 5.6%, respectively. However, the long term patency of transthoracic reconstructions may be superior. Takach et al. reported results of their experience with transthoracic reconstruction versus cervical revascularization procedures in 457 consecutive patients and demonstrated no significant differences in perioperative mortality (2.7% vs 2.3%) and stroke (2.7% vs 0.8%) for both approaches, but a significantly improved freedom from graft failure 10 years after surgery in the transthoracic group (94% vs 60%, $P = .002$). This was not a randomized controlled trial and thus the equivalent morbidity and mortality between the operative approaches should be interpreted accordingly. The improved graft patency and repair durability noted among transthoracic reconstruction patients is likely secondary to the preservation of direct aortic inflow to the brachiocephalic vessels and, as such, most experts agree that this approach is the optimal approach for younger patients able to tolerate sternotomy.

For those patients unable to tolerate direct reconstruction of the brachiocephalic vessels, cervical revascularization remains well tolerated with acceptable patency. The reported patency rate for carotid-subclavian bypass procedures is estimated to be 94% to 96% and 89% at 5 and 10 years, respectively, and the 5 year patency rate for subclavian-carotid artery transposition procedures is approximately 90%. The favorable patency associated with prosthetic grafts in this setting, as well as the limited dissection associated with carotid-subclavian bypass over both preserves the internal mammary artery and provides a durable repair for young patients in need of subclavian revascularization.

Debranching of the brachiocephalic vessels for planned stent graft placement has excellent results in the current literature, equivalent or better than those found in the setting of revascularization for occlusive disease. Scali et al. compared the outcomes of left subclavian artery revascularization for occlusive disease versus TEVAR debranching and found 3 year patency rates of 73% and 93%, respectively. The estimated 1 year graft patency for debranching procedures incorporating the innominate, left common carotid, and left subclavian arteries is reported to be between 89% and 96%.

ENDOVASCULAR INTERVENTIONS

While the outcomes of open surgical brachiocephalic revascularization are excellent from a durability standpoint, the rapid progression of endovascular technology has led to a growing interest in less invasive revascularization techniques. In particular, the challenging exposure that is inherent to most open brachiocephalic revascularization procedures has made angioplasty and stenting an increasingly popular approach in this region. However, surgeons must be careful not to remove options for future open surgical repair should endovascular options fail. Optimal lesions to be addressed with catheter based interventions are those that involved isolated, short segment stenoses in the mid vessel. For those lesions that are occlusive, heavily calcified, aberrant, involving the aorta or a major branching vessel, surgical revascularization is preferred.

When cannulating the brachiocephalic vessels, careful thought must be paid to the risk of emboli to the cerebral circulation. Frequently, antegrade access to these vessels is obtained via a transfemoral approach; however, at times the angulation of the vessels with respect to the aortic arch makes antegrade selective cannulation challenging and increases risk of emboli with repeated attempts. This is particularly true in patients with heavily calcified aortic arches (i.e., eggshell aorta). In these cases, retrograde access via the ipsilateral brachial artery may be helpful, particularly for innominate artery lesions. Likewise, when concomitant endarterectomy of the carotid

bifurcation is performed, retrograde access via the ipsilateral common carotid artery is also an option. Embolic protection of the vertebral artery is not routinely employed during left subclavian artery interventions due to the low risk (<1%) of emboli to the vertebrobasilar system. The risk of emboli when cannulating the innominate or common carotid arteries is higher, but remains rare (3%). There are no good data to support routine use of cerebral protection in brachiocephalic angioplasty and stenting procedures, although use of an embolic protection device is now considered standard of care for carotid interventions, and, along with placement of a buddy wire in the external carotid artery, can serve as a stabilizing anchor for more proximal common carotid lesions (Fig. 13).

When treating proximal brachiocephalic lesions close to or involving the vessel ostium, an attempt should be made to extend the stent 1 to 2 mm into the aortic lumen. The effect of angioplasty and stenting on the neighboring vessels must be considered closely before deciding to intervene because the brachiocephalic vessels lie in close proximity to one another; treatment of one lesion can sometimes cause plaque shifts to adjacent vessels (Fig. 14). Similarly, treatment of subclavian or innominate artery lesions adjacent to the takeoff of a branching vessel can result in unintended "pulling" of that vessel. For innominate lesions, this may require use of a kissing stent technique in which the right subclavian and common carotid are stented simultaneously to preserve the origin of both branching vessels (Fig. 15). For protection of the vertebral artery, this may require passage of a single balloon expandable stent over two double wires, one extending into the axillary artery and one into the vertebral artery in order to protect the vertebral artery origin as the stent is expanded.

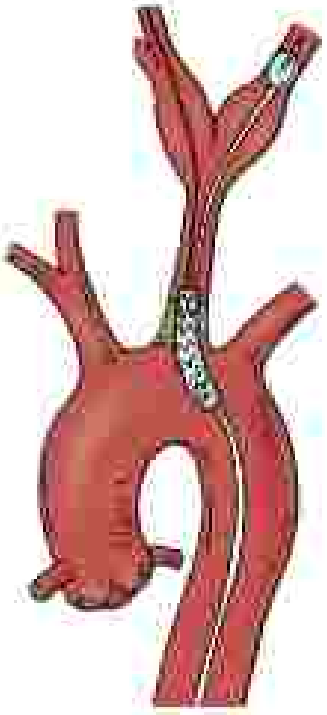

FIG. 13 Use of a balloon anchor in the internal carotid artery and a buddy wire into the external carotid artery to stabilize the plate at the origin of the carotid artery.

OUTCOMES OF ENDOVASCULAR INTERVENTIONS

Initial attempts at endovascular revascularization procedures in the brachiocephalic vasculature were limited to angioplasty and had limited durability. However, with improvements in endovascular technology, the durability of these interventions has become acceptable. Paukovits et al. described 7 year primary and secondary patency rates following percutaneous transluminal angioplasty and/or stenting of proximal innominate carotid artery lesions of 74% and 89%%, respectively. Suga et al. reported outcomes of endovascular interventions for subclavian artery stenosis and found primary and secondary patency rates of 80% and 88%, respectively at 5 years. Factors associated with reduced patency included long segment stenoses, smoking, and clinically evident subclavian steals at the time of intervention, including cerebrovascular disease and hand ischemia.

Perhaps the most important question to be answered is how the durability and safety of endovascular interventions for brachiocephalic lesions compares to that of open surgical reconstruction. Takach et al. examined 391 consecutive patients with aortic arch brachiocephalic arterial disease undergoing either operative bypass or percutaneous transluminal angioplasty and stenting. They reported that, although technical success, perioperative stroke and perioperative mortality rates

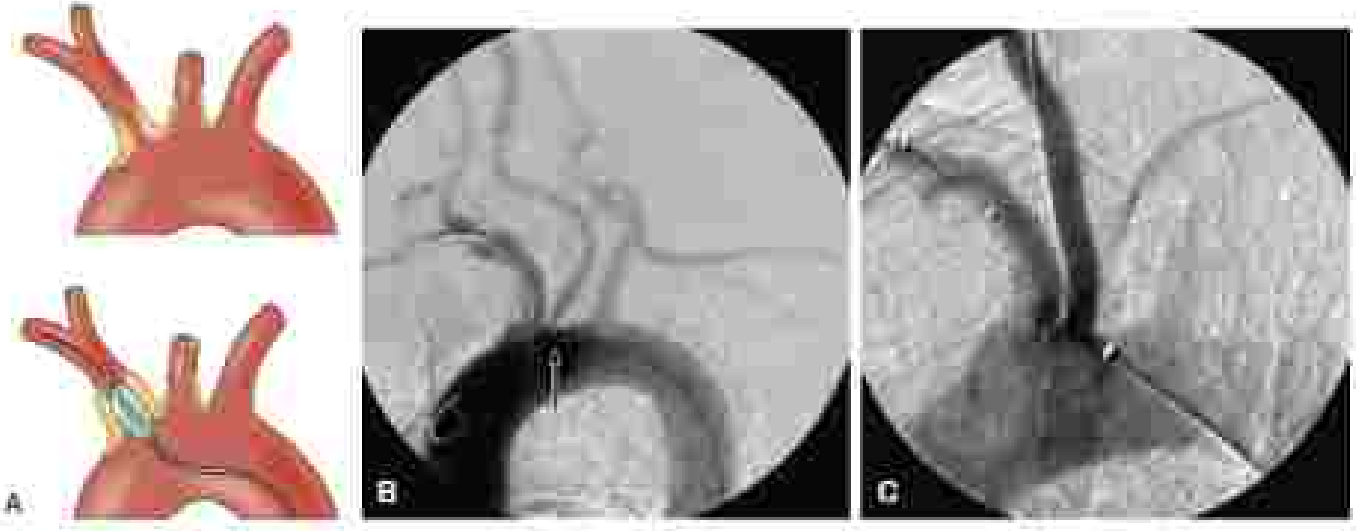

FIG. 14 (A) Treatment of a neighboring arch vessel can force treatment of an adjacent arch branch. After treatment of the innominate artery, the left common carotid can be impinged on by a shift of aortic plaque. (B) Angioplasty and stenting of the innominate artery has shifted aortic plaque, which resulted in narrowing at the origin of the left common carotid artery (arrow). (C) Treatment of the common carotid origin and simultaneous protection of the innominate artery's ostium origin.

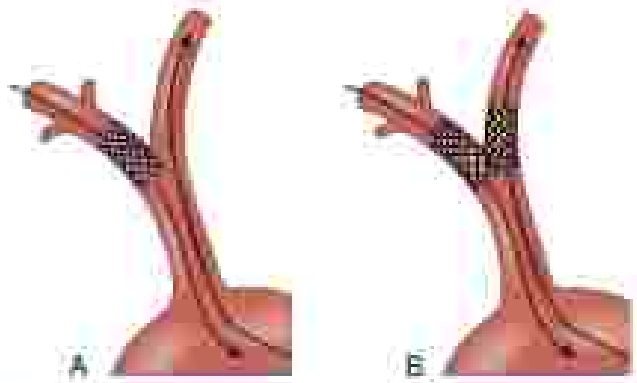

FIG. 13 (A) Treatment of the right subclavian artery origin can result in "piling" the origin of the right common carotid artery by the proximal end of the stent projecting into the common carotid lumen, as shown. (B) Treatment of the innominate artery branch origin with a kissing balloon stent technique to preserve both origins.

were equivalent between the two groups, the operative group had significantly better freedom from intervention failure at 5 years postoperatively even after risk adjustment (93% vs 84%, $P = .03$). Similarly, Abdulhannan et al. compared percutaneous transluminal angioplasty/stenting versus carotid subclavian bypass for isolated subclavian artery disease and reported 5-year primary patency rates of 70% versus 96%, respectively ($P < .0001$). Based on these data, most experts agree that open surgical reconstruction of brachiocephalic disease is associated with improved overall graft patency and fewer additional secondary procedures. However, endovascular interventions have been shown to be associated with potential short-term cost savings, eliminate the need for general anesthesia, and is likely better tolerated than more invasive open approaches, especially in patients with multiple other comorbidities. As a result, endovascular interventions should be considered as an adjunct in the armamentarium against brachiocephalic disease in selected patients.

Upper Extremity Arterial Occlusive Disease

Satinderjit S. Lachar, MBBS, MRCP(UK), RAD, and Mahmood K. Malas, MD, MHS, FACS

Symptomatic arterial occlusive disease of the upper extremity (UE) is seen by the vascular surgeon significantly less frequently than its lower extremity counterpart. Extensive collateral networks around the shoulder, elbow, and wrist, along with the lack of heavy load repetitive use activities of the UE compared with the lower extremity, allow many patients to remain asymptomatic despite significant occlusive lesions. However, when ischemic symptoms of the hands and digits do manifest, the loss of function can lead to significant disability and limitation. Although atherosclerosis is the most common cause of clinically significant arterial ischemia of the UE, many cases of UE ischemia are caused by nonatherosclerotic disease states. These factors make the diagnosis and treatment of UE ischemia more complex than the management of lower extremity ischemia.

Etiology

A wide variety of disease states may lead to UE ischemia. Box 1 offers a broad, conceptual categorization that is far from exhaustive. The most common cause of symptomatic UE ischemia is vasospasm involving the digital vessels, but this is rarely severe and is almost always managed medically (see chapter on Raynaud's phenomenon). Large artery vasospasm is rare but can be caused by ergot poisoning, most often from migraine medications containing ergotamine (Fig. 1).

Intrinsic Arterial Disease

Atherosclerosis of the UE vasculature is usually limited to the more proximal aortic arch vessels. The origin of the left subclavian artery is the most frequently involved segment. Atherosclerosis involving the distal extremity vasculature is seen most often in patients with end-stage renal disease with steal from hemodialysis access, especially with concomitant diabetes, leading to critical limb ischemia and is associated with a poorer prognosis.

A number of inflammatory diseases also can affect the UE arteries. Takayasu's disease and giant cell arteritis (GCA) are large vessel vasculitis. These diseases are associated with an initial inflammatory phase—which may have symptoms of fever, arthritis, and myalgias, along with laboratory findings of elevated erythrocyte sedimentation rate—before ischemic symptoms and signs such as effort fatigue and

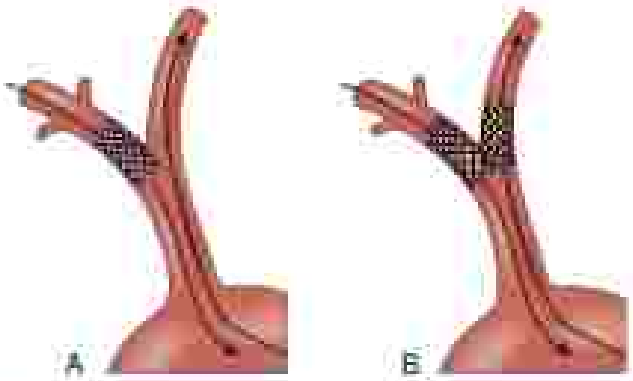

FIG. 13 (A) Treatment of the right subclavian artery origin can result in "piling" the origin of the right common carotid artery by the proximal end of the stent projecting into the common carotid lumen, as shown. Upper Extremity Arterial Occlusive Disease

Satinderjit S. Latcham, MBBSc, MRCS(Ed), BAO, and Mahmood B. Malas, MD, MHS, FACS

Symptomatic arterial occlusive disease of the upper extremity (UE) is seen by the vascular surgeon significantly less frequently than its lower extremity counterpart. Extensive collateral networks around the shoulder, elbow, and wrist, along with the lack of heavy load repetitive use activities of the UE compared with the lower extremity, allow many patients to remain asymptomatic despite significant occlusive lesions. However, when ischemic symptoms of the hands and digits do manifest, the loss of function can lead to significant disability and limitation. Although atherosclerosis is the most common cause of clinically significant arterial ischemia of the UE, many cases of UE ischemia are caused by nonatherosclerotic disease states. These factors make the diagnosis and treatment of UE ischemia more complex than the management of lower extremity ischemia.

Etiology

A wide variety of disease states may lead to UE ischemia. Box 1 offers a broad, conceptual categorization that is far from exhaustive. The most common cause of symptomatic UE ischemia is vasospasm involving the digital vessels, but this is rarely severe and is almost always managed medically (see chapter on Raynaud's phenomenon). Large artery vasospasm is rare but can be caused by ergot poisoning, most often from migraine medications containing ergotamine (Fig. 1).

Intrinsic Arterial Disease

Atherosclerosis of the UE vasculature is usually limited to the more proximal aortic arch vessels. The origin of the left subclavian artery is the most frequently involved segment. Atherosclerosis involving the distal extremity vasculature is seen most often in patients with end-stage renal disease with steal from hemodialysis access, especially with concomitant diabetes, leading to critical limb ischemia and is associated with a poorer prognosis.

These diseases are associated with an initial inflammatory phase—which may have symptoms of fever, arthritis, and myalgias, along with laboratory findings of elevated erythrocyte sedimentation rate—before ischemic symptoms and signs such as effort fatigue and

BOX 1 Causes of Upper Extremity Ischemia

Vasospasm

Raynaud phenomenon (palmar digital)
Drug induced: ergotamine, β-blockers, vasopressors

Intrinsic Arterial Disease

Atherosclerosis (uncommon: subclavian)
Radiation arteritis (uncommon: axillobrachial)
Anatomic: arteriopathy (radial/ulnar, palmar digital)

Inflammatory Diseases

Connective tissue disorders (palmar digital)
Hypersensitivity angiitis (palmar digital)
Thromboangiitis obliterans (Buerger's disease: radial/ulnar, palmar digital)
Takayasu's arteritis (uncommon: subclavian)
Temporal arteritis (axillobrachial)

Medical Diseases

Immunoglobulin states (palmar and digital arteries)
Myeloproliferative disorders (palmar and digital arteries)
Hepatitis associated vasculitis (palmar and digital arteries)
Cryoglobulinemia (palmar and digital arteries)

Environmental

Cold injury
Vinyl chloride exposure

Embolism

Cardiac (brachial)
Arterial source
- Arterial thoracic outlet syndrome (subclavian artery source)
- Peripheral aneurysm
- Atherothrombosis

Trauma

Blunt or penetrating trauma
Iatrogenic
- Angiography (brachial, radial)

Hypothenar hammer syndrome (ulnar)
Vibration (palmar, digital)
Sports or athletic injury (axillosubclavian)

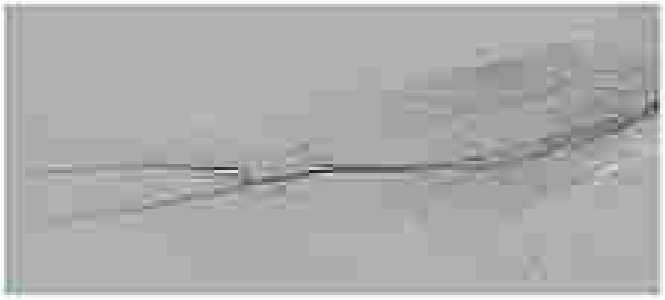

FIG. 1 Right upper extremity angiogram demonstrating severe brachial artery occlusion in a 45-year-old woman taking an ergotamine-containing medication for treatment of migraine headaches.

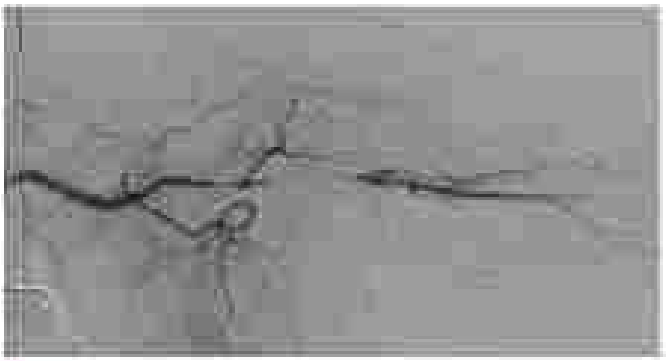

FIG. 2 Left upper extremity angiogram demonstrating an area of smooth tapering stenosis and adjacent occlusion in the brachial artery of a 52-year-old woman with gait and arm/leg claudication who experienced ulcer fatigue of the hand and forearm.

asymmetric brachial blood pressure measurements develop. In the case of GCA, patients can lose their vision if diagnosis is not confirmed and appropriate treatment with steroid not initiated early. Angiographic findings typically reveal a smooth tapering stenosis resulting from inflammation involving all three layers of the vessel wall. Takayasu's disease typically involves the carotid and subclavian arteries in women age 20 to 40 years. GCA usually affects older women (>50 years), most commonly involving the extracranial carotid artery. When GCA involves the UE it affects the distal subclavian artery, axillary artery, and brachial artery (Fig. 2). Thromboangiitis obliterans, or Buerger's disease, is a segmental, inflammatory, obliterative disease of the medium and small arteries of the extremities seen in heavy smokers (see chapter on Buerger's disease). It frequently affects the forearm and palmar digital arteries, sparing the more proximal arteries.

A number of connective tissue disorders can cause small vessel disease affecting the palmar digital vessels. These include scleroderma, CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome, lupus, and rheumatoid arthritis. A similar small vessel disease pattern can be seen with a variety of relatively rare medical disorders (e.g., cryoglobulinemia or hepatitis associated vasculitis), which should be looked for only after connective tissue disease have been excluded. In the absence of an identifiable cause, which occurs in approximately one third of cases, such small artery occlusive disease is termed hypothenar hammer syndrome.

Embolism

Most emboli to the UE are of cardiac origin and are macroemboli that typically lodge in the brachial artery just proximal to the take-off of the deep brachial artery or at its bifurcation into the ulnar and radial arteries. These emboli usually result in acute episodes of forearm or hand ischemia in patients with an underlying cardiac condition but may be seen more chronically in older or debilitated patients who do not use their UE enough to induce symptoms. However, up to 30% of UE emboli have an arterial site of origin and tend to be microemboli that lodge in more distal arterial segments (palmar digital). The most common culprit is an aneurysm or ulcerative lesion within the distal subclavian artery associated with thoracic outlet syndrome (see chapter on thoracic outlet syndrome). In this situation, repetitive compression of the subclavian artery by anomalous myofascial bands attached to a cervical rib (or other osseous anomaly) leads to a focal stenosis. Poststenotic dilatation (aneurysm) or intimal ulceration results in mural thrombus formation. Subsequent embolization of luminal debris can produce both large and small artery occlusions distally. Unilateral Raynaud's phenomenon is a common presentation. Degenerative aneurysms of the subclavian artery or posttraumatic aneurysms of other UE arteries (e.g., crutch induced axillary artery aneurysms) are other rare causes of ischemia and produce symptoms either through distal emboli or, less commonly, by in situ thrombosis. Ulcerative atherosclerotic plaques within the aorta or proximal brachiocephalic arteries also can lead, rarely, to emboli.

Trauma

Undiagnosed or neglected arterial injuries are a well recognized cause of UE occlusive disease. Although bleeding and significant ischemia are obvious manifestations of arterial injury requiring treatment in the acute setting, intimal injuries from both penetrating and blunt trauma may lead to delayed arterial thrombosis with less dramatic symptomatology. Iatrogenic injuries are particularly common. Brachial artery injuries are a well recognized complication of cardiac catheterization procedures performed via this approach. Such occlusions may go undetected in the acute setting because of the abundant collaterals around the elbow. The only manifestation may be the development of effort fatigue in the forearm on resumption of normal activities. Cumulative occupational trauma also can lead to significant vascular injury. Hypothenar hammer syndrome results from repetitive blunt trauma to the proximal portion of the ulnar artery in Guyon canal (formed by the pisiform, the hook of the hamate, and the transverse carpal ligament in the proximal palm). This injury is caused by repetitively striking objects with the base of the palm. Segmental occlusion or aneurysm formation of the ulnar artery, with or without distal digital artery embolism, can result (Fig. 1). Vibration-induced injury to the digital arteries occurs after prolonged exposure of the hands to vibratory tools or machinery. The tools most commonly implicated are pneumatic tools and chainsaws. Patients initially report neurologic complaints (i.e., numbness or paresthesia) in the affected hand and digits. As the syndrome progresses, Raynaud's phenomenon develops. Tissue loss is rare. Sports-related trauma is a rare cause of ischemia, but can occur in individuals who use a hand, repetitive UE motion in competitive athletic endeavors. Axillary and subclavian artery injuries in baseball pitchers are the most frequently encountered.

EVALUATION

Performing a thorough history and physical examination is the first step in narrowing down the multiple causes of UE arterial occlusive disease to come to the appropriate diagnosis, and thus be able to formulate a comprehensive treatment plan. Symptoms can range from the incidental finding of a blood pressure differential in the UE by a patient's primary care physician on physical examination, to color changes, coolness, numbness, weakness, effort-induced fatigue, and ischemic rest pain, and all the way to tissue loss. Raynaud's phenomenon, which may result from pure vasospasm, is also a frequent manifestation of distal occlusive lesions. Most patients will note only one or two of the classic vascular digital changes, pallor (white) to cyanosis (blue) to hyperemic rubor (red). Exercise-induced fatigue in the musculature is brought on by repetitive use and, like its lower extremity counterpart claudication, is relieved quickly by a short period of rest. This phenomenon usually results from large vessel occlusive disease. Symptoms manifested in the hand or digits may result from large vessel disease, small vessel disease, or multifocal disease. Digital tissue loss is nearly always associated with small artery occlusive disease, with or without more proximal involvement.

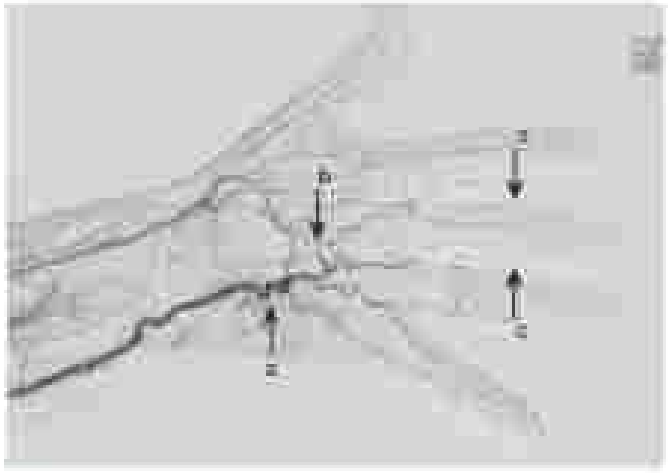

FIG. 1. Angiogram of the left hand of a patient with hypothenar hammer syndrome seen with color changes and pain in the fingers, specifically the middle finger. Note the irregularity of the distal ulnar artery (arrow a), embolic filling defect in the superficial palmar arch (arrow b), and occlusion of digital arteries of the middle finger (arrow c).

Laterality of symptoms should be assessed. Bilateral UE symptoms suggest the presence of a systemic cause, such as a connective tissue or inflammatory disease. Patients also should be questioned about possible underlying connective tissue disorders or associated symptoms—tight skin or dysphagia in scleroderma, facial rash in lupus, or joint complaints in rheumatoid arthritis. The patient also should be interrogated for other systemic symptoms such as weight loss and myalgias. Unilateral complaints suggest localized arterial pathology such as arterial thoracic outlet syndrome, arterial aneurysm, or hypothenar hammer syndrome.

Because atherosclerotic disease is the most common cause of UE arterial occlusive disease, pathology should be evaluated thoroughly in all cases and associated risk factors identified (i.e., tobacco use, dyslipidemia, hypertension, diabetes mellitus, renal insufficiency, and family history). Symptoms or history of arterial occlusive disease in other vascular beds, including the coronary arteries, lower extremities (claudication), and cerebrovascular circulation, should be sought. Specifically, if concomitant posterior cerebral circulation symptoms such as dizziness, ataxia, or diplopia are identified, possible involvement of the subclavian or proximate arteries proximal to the takeoff of the vertebral artery should be investigated.

In the medical history, one should inquire about hypercoagulable states, renal insufficiency, cardiac arrhythmias and disorders, medication and supplement use, and drug abuse. A history of prior trauma to the neck or UE should be sought. The history also should include any catheter-based procedures in the UE as well as catheters placed for invasive hemodynamic monitoring. Patients with renal failure should be evaluated for prior vascular access procedures. Social history includes occupational or environmental exposures, athletic activities, and hobbies that may be important. The family history should focus on connective tissue disorders, hypercoagulable states, and premature atherosclerotic disease.

The physical examination includes measurement of blood pressure in both UEs. A complete pulse examination of the neck, UEs, and lower extremities is essential and remains the primary modality for diagnosing UE occlusive disease. A decreased or absent pulse indicates a proximal high-grade stenosis or occlusion; however, the presence of a pulse does not completely exclude proximal disease, particularly in the setting of a chronic occlusion, given the rich collateral pathways present in the UE. An irregular pulse should prompt a more detailed cardiac examination to identify atrial fibrillation or other arrhythmias that may predispose to cardioembolism. Auscultation for bruits over all major arteries should be performed. The skin envelope of the digits is examined for signs of color or temperature differences, tissue loss, or trophic changes. In patients with unilateral complaints, the symptomatic extremity should be examined carefully for occult disease. Allen's test can be used to assess patency of the palmar arch. In this test the patient's radial and ulnar arteries are occluded with digital pressure while the patient opens and closes the hand. Once the hand is pale, the ulnar artery is released and reperfusion of the hand is assessed; then the maneuver is repeated, except the radial artery is released first.

Noninvasive Vascular Laboratory Assessment

All patients with ischemic symptoms should undergo bilateral UE arterial segmental pressure testing. This testing provides objective and reproducible data that may identify focal obstructions as well as indicate vasospasm and also quantify the degree of arterial

insufficiency. Serial examinations allow for objective assessment of disease status and evaluation of the effectiveness of therapeutic interventions. Bilateral brachial, upper forearm, and wrist systolic pressures are obtained along with associated Doppler waveforms. The normal pressure differential between arms should not exceed 15 mm Hg, and a pressure drop of 20 mm Hg or more between levels indicates an interceding hemodynamically significant lesion. Reduced brachial pressure bilaterally, particularly when associated with bruits or monophasic Doppler waveforms, should prompt high thigh pressure measurements to exclude the possibility of bilateral proximal UE arterial disease. Although digital pressures and waveforms are notoriously temperature dependent, they can be extremely helpful in documenting the presence of small artery occlusive disease or vasospasm. An absolute digital pressure less than 70 mm Hg, a wrist/digital gradient greater than 30 mm Hg, and an interdigital gradient greater than 15 mm Hg are all considered abnormal. The finding of normal or near normal digital pressures with vasospastic waveforms is helpful in establishing a diagnosis of Raynaud's phenomenon. Arterial duplex scanning may provide even more information than segmental pressures but has limited utility proximally because of the bony structures of the thoracic outlet. We have found it most useful when dealing with suspected lesions in the axillary, brachial, and forearm arteries.

Imaging

Advanced imaging usually is reserved for patients with critical limb ischemia or debilitating symptoms with evidence of proximal disease amenable to intervention. Significant improvements in imaging equipment and technique have increased the use of both computed tomographic angiography and magnetic resonance angiography in the evaluation of UE arterial disease. Both are valuable in evaluating the aorta arch and larger, more proximal vessels. The use of postprocessing techniques and three-dimensional reconstruction also is useful in planning invasive intervention. However, these modalities do have limits, specifically in providing adequate detailed imaging of the distal forearm, hand, and fingers. When such imaging is required, conventional catheter angiography remains the gold standard, using digital subtraction technology to minimize the radiocontrast load. Angiography also allows for concomitant administration of vasodilators, such as nitroglycerin or nitroglycerin, which are often necessary to adequately visualize the arteries of the hand and fingers. Selective studies of both UEs should be obtained because many disease processes affect both UEs. With the proliferation of endoluminal treatment modalities, catheter angiography also provides the opportunity for simultaneous therapeutic intervention.

Laboratory Testing

Specific laboratory studies are obtained based on the index of suspicion and are most useful when dealing with distal small artery occlusive disease. Routine chemistries, blood counts, and coagulation profiles should be drawn when the diagnosis is unclear. If a hypercoagulable state is considered, patients should be checked for factor V Leiden, antithrombin III deficiency, protein C and S deficiencies, antiphospholipid antibodies, the prothrombin gene mutation, and hyperhomocysteinemia. Testing for connective tissue disorders should include rheumatoid factor, antinuclear antibodies, complement levels, and a sedimentation rate. Additional tests looking for cryoglobulinemia, heparin, or myeloproliferative disorders may be helpful if the other, more common causes of small artery occlusive disease have been excluded. When a cardioembolic source is suspected, electrocardiography is obtained to evaluate for arrhythmia, and echocardiography may be obtained to evaluate for a cardiac structural abnormality or residual cardiac thrombus. Similarly, plain films of the neck looking for a cervical rib or other osseous abnormalities are useful to exclude most arterial thoracic outlet problems.

MANAGEMENT

Appropriate treatment of UE occlusive disease depends on both its etiology and its degree of symptomatology. Medical therapy is frequently the first-line treatment, as invasive intervention is neither indicated nor helpful for many of the causes of UE ischemia.

Patients with vasospasm are advised to abstain from tobacco and to avoid cold. Vasodilators, primarily calcium channel blockers, have been used with varying degrees of success to treat severely symptomatic Raynaud's phenomenon. Patients with atherosclerotic lesions should undergo aggressive risk factor modification implemented in the same way as occurs when atherosclerosis is identified in other vascular beds.
