Contributors

Maher A. Abbas, MD, FACS, FASCRS
Professor of Surgery
Director, Center for Colon and Rectal Disease
Duke University Medical Center
Durham, North Carolina

Mohamed Abdelsattar, MD, FACS
Assistant Professor
Division of Vascular and Endovascular Surgery
Department of Surgery
Mayo Clinic College of Medicine
Rochester, Minnesota

Adil F. Abdul-Aziz, MD
Professor of Surgery
Director, Vascular and Endovascular Surgery
Director, Center for Limb Preservation and Arterial Reconstruction
Department of Surgery
Robert C. Byrd Health Sciences Center
West Virginia University
Morgantown, West Virginia

Zachary S. Abuhamad, DO
Chief Anesthesiology Resident
Southern Arizona Medical Center
West Virginia Uniformed Services
Tucson, Arizona

Christopher A. Adams, Jr., MD
Chief, Division of Trauma, Surgical Critical Care
Department of Surgery
Randall L. Holcomb, Jr. Professor
Department of Surgery
Thomas Jefferson University School of Medicine
Philadelphia, Pennsylvania

David C. Adams, MD
Clinical Associate Professor, Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

Rajat S. Ada[illegible], MD
Chief, Department of Surgery
Richard A. Siemsen Professor of Surgery
University of Virginia
Charlottesville, Virginia

Olivia L. Adrales, MD, MPH, FACS
Chief, Division of Minimally Invasive Surgery
Director, Minimally Invasive Surgery
Trauma and Surgical Critical Care
Johns Hopkins University School of Medicine
Baltimore, Maryland

Sumit K. Agarwal, MD
Professor and Division Chief
Trauma, Acute & Critical Care Surgery
Department of Surgery
Duke University
Durham, North Carolina

Amir A. Agrawal, MD
Gastroenterology Fellow
Johns Hopkins University
Baltimore, Maryland

Sean A. Ahrendt, MD
Associate Professor
Department of Surgery
Division of Surgical Oncology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Zeina M. Akasha, MD
Fellow
Bariatric and Metabolic Institute
Cleveland Clinic Foundation
Cleveland, Ohio
Assistant Professor
Department of Surgery
College of Medicine and Health Sciences
United Arab Emirates University
Al Ain, Abu Dhabi, United Arab Emirates

Mohammad Al Efishat, MD
Chief Resident
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Asma Ali, MD
Resident
Department of General Surgery
Kaweah Delta Regional Medical Center
Visalia, California

John C. Alverdy, MD, FACS
Sara and Harold Lincoln Thompson
Professor of Surgery
Executive Vice Chair
Department of Surgery
University of Chicago
Chicago, Illinois

Robert Armajani, MD, FACS, FICS, FASCRS
Assistant Professor
Department of Surgery
University of Missouri-Kansas City School of Medicine
Kansas City, Missouri
MANAGEMENT OF LOWER EXTREMITY ISCHEMIA

Kumar S. Arumugam, MD, MRCS, FACS
Professor and Chief, Vascular and Endovascular Surgery
Department of Surgery
Division of Vascular Surgery
University of Connecticut, UCONN Health
Farmington, Connecticut
WINDOW TECHNIQUE AMPUTATION REVISION (MACNEIL AND HEALING)

Ali Armenian, MD
Associate Professor
Department of General Surgery
Cleveland Clinic
Cleveland, Ohio
CARDIOVASCULAR DISEASE RISK REDUCTION IN BARIATRIC SURGERY

Ciro Andolfi, MD
Fellow
Department of Surgery
Center for Medical and Surgical Simulation
Malcom Center for Clinical Medical Ethics
University of Chicago Medicine & Biological Sciences Division
Chicago, Illinois
VENOUS COMPUTER-BASED ONCOLOGIC OBSERVING

Gary Anthone, MD, FACS
Assistant Professor
Department of Surgery
Creighton University School of Medicine
Omaha, Nebraska
MANAGEMENT OF SPECIFIC COMPLICATIONS OF OBSERVATION TECHNIQUE

Maggie Arnold, MD, FACS
Assistant Professor of Vascular Surgery
Department of General Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
TREATMENT OF CLAUDICATION

Amanda L. Arrington, MD
Assistant Professor
Department of Surgery
University of Arizona
Tucson, Arizona
PROPHYLAXIS OF VENOTHROMBOEMBOLISM

Elliot A. Asare, MD, MS
Chief Resident, General Surgery
Department of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin
OBESITY AND MUSCULOSKELETAL DISEASES

Roland Assi, MD, MMS
Cardiothoracic Surgery Fellow
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania
MANAGEMENT OF TRACHEAL, TRACHEAL AND TRACHEOESOPHAGEAL FISTULAE

Hugh G. Auchincloss, MD, MPH
Assistant Professor of Surgery
Massachusetts General Hospital
Boston, Massachusetts
MYELOGENOUS ANOMALY

Dan E. Azagury, MD
Assistant Professor
Department of Surgery
Stanford University School of Medicine
Stanford, California
SURGICAL MANAGEMENT OF CARDIOVASCULAR HYPERLIPIDEMIA

Faris K. Azar, MD
Assistant Professor of Surgery
Florida Atlantic University
St. Mary's Medical Center
West Palm Beach, Florida
PANCREATIC AND DUODENAL INJURIES

Ali Azizzadeh, MD, FACS
Professor and Director, Division of Vascular Surgery
Vice Chair, Department of Surgery
Associate Director, Smidt Heart Institute
Cedars-Sinai Medical Center
Los Angeles, California
HEPATIC DISEASE (CHOLANGIOCARCINOMA)

Sudeep Banerjee, MD, MAS
Postdoctoral Fellow
Department of Surgery
University of California, San Diego
La Jolla, California;
General Surgery Resident
Department of Surgery
University of California, Los Angeles
Los Angeles, California
MANAGEMENT OF CYSTIC DISEASES OF THE BILE DUCTS

Philip S. Barie, MD, MBA, FIDSA, FACS, FCCM
Professor of Surgery
Division of Trauma, Burns, Critical and Acute Care
Professor of Public Health in Medicine
Division of Medical Ethics
Weill Cornell Medical College
New York, New York
MEDICAL MANAGEMENT OF THE BURN WOUND

Richard J. Barth Jr, MD
Professor of Surgery
Geisel School of Medicine at Dartmouth
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire
USE OF ORGETA IN ICE POSTOPERATIVE PAIN (ICED)

Richard J. Battafarano, MD, PhD
Associate Professor and Chief
Division of Thoracic Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
PERIOPERATIVE COMPLICATIONS

Joel M. Baumgartner, MD, MAS
Associate Professor
Department of Surgery
University of California, San Diego
La Jolla, California
MANAGEMENT OF PERIOPERATIVE VENOUS THROMBOEMBOLISM

Robert A. Beaudoin, MD
Resident
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
MANAGEMENT OF ACUTE ISCHEMIC STROKE

MANAGEMENT OF THROMBOEMBOLIC RISK IN CANCER

Cigdem Benlice, MD
Resident
Department of General Surgery
University of Ankara
Ankara, Turkey
MANAGEMENT OF SOME METABOLISM

Mitchell A. Bernstein, MD, FACS, FASCRS
Director
Division of Colon & Rectal Surgery
NYU Langone Health
New York, New York
RECTOVAGINAL FISTULA

Charisse Barry, MD, FACS
Assistant Professor of Surgery
Associate Trauma Medical Director
NYU Health+ Hospitals/Bellevue
New York University School of Medicine
New York, New York
MANAGEMENT OF OPEN ABDOMINAL INJURIES

Sanari Bhattacharya, DO
Assistant Professor
Department of Medical Oncology
Sidney Kimmel Cancer Center
Thomas Jefferson University
Philadelphia, Pennsylvania
MANAGEMENT OF RECURRENT AND METASTATIC BREAST CANCER

James H. Black '91, MD, FACS
David Caldfarb MD Associate Professor of Surgery
Vascular Surgery and Endovascular Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
MANAGEMENT OF ACUTE ACUTE LIMB ISCHEMIA

Alec B. Blair, MD
Surgical Resident
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
UNRESECTABLE CANCER

Kirby I. Bland, MD, FACS
Professor and Chair Emeritus
Department of Surgery
University of Alabama at Birmingham
Birmingham, Alabama
MULTIDISCIPLINARY APPROACH TO BREAST CANCER

Joseph-Vincent V. Blas, MD
Associate Program Director
Vascular Surgery Fellowship
Division of Vascular Surgery
Prisma Health Upstate
Greenville, South Carolina
ACUTE ISCHEMIC STROKE DUE TO ATRIAL FIBRILLATION

James N. Bogert, MD, FACS
Assistant Professor
Department of Surgery
Creighton University School of Medicine
St. Joseph's Hospital and Medical Center
Phoenix, Arizona
USE OF RESPIRATORY ENDOVASCULAR FIBRILLATION OCCLUSION OF THE AORTA IN RESUSCITATION OF THE TRAUMA PATIENT

Judy C. Boughey, MD, FACS
Professor of Surgery
Department of Surgery
Mayo Clinic
Rochester, Minnesota
CONSERVATIVE TREATMENT OF EARLY BREAST CANCER

Kelly A. Boyle, MD
Resident
Department of General Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin
ANTIBIOTICS FOR ORDINARY BITE WOUNDS

Rachel F. Brem, MD, FACR, FSBI
Professor and Vice Chair
Director, Breast Imaging and Interventional Center
Department of Radiology
George Washington University
Program Leader, Breast Cancer
George Washington University Cancer Center
Washington, DC
A SURGEONS PERSPECTIVE TO BREAST IMAGING

Megan Brenner, MD, MS, FACS
Professor of Surgery
University of California Riverside School of Medicine
Director of Surgical Research
Comparative Effectiveness and Clinical Outcomes Research Center (CECORC)
Riverside University Health System
Moreno Valley, California
USE OF RESPIRATORY ENDOVASCULAR FIBRILLATION OCCLUSION OF THE AORTA IN RESUSCITATION OF THE TRAUMA PATIENT

J. Michael Brewer, DO, MS
Assistant Professor
Department of Medicine
University of Mississippi Medical Center
Jackson, Mississippi
CARDIOVASCULAR PHARMACOLOGY

Olga I. Brewer Gutierrez, MD
Department of Gastroenterology and Hepatology
Johns Hopkins Hospital
Baltimore, Maryland
OBTAINING JEJUNAL ENDOSCOPIC ULTRASOUND

Benjamin N. Breyer, MD, MAS
Associate Professor
Department of Urology
University of California, San Francisco
San Francisco, California
ADVERSE SEXUAL AND REPRODUCTIVE OUTCOMES

William M. Briscoe, MD
Resident
Department of Surgery
University of California, San Francisco/East Bay
Oakland, California
MANAGEMENT OF PERIPHERAL ISCHEMIA

L.D. Britt, MD, MPH, FACS
Henry Ford Professor and Edward E. Brickhouse Chairman
Department of Surgery
Eastern Virginia Medical School
Norfolk, Virginia
WOUND MANAGEMENT IN DIABETES

Malcolm V. Brock, MD, FACS
Professor of Surgery
Division of Thoracic Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
USE OF ESOPHAGEAL STENTS

MANAGEMENT OF PERIPHERAL VASCULAR DISEASE

Carlos "J.R." Brown, MD
Professor of Surgery
Chief, Division of Acute Care Surgery
Dell Medical School
University of Texas at Austin
Austin, Texas
MANAGEMENT OF PANCREATIC PSEUDOCYST

F. Charles Brunicardi, MD
Mous Foundation Professor and Vice Chairman
Department of Surgery
University of California, Los Angeles
Los Angeles, California
MANAGEMENT OF DUODENAL ULCER

Kooby L. Buesing, MD, FACS
Associate Professor
Department of General Surgery
University of Nebraska Medical Center
Omaha, Nebraska
ACUTE KIDNEY INJURY IN THE INJURED AND CRITICALLY ILL

Marko Bukur, MD, FACS
Associate Professor of Surgery
Trauma Medical Director
Division of Trauma, Emergency Surgery, and Surgical Critical Care
Bellevue Hospital Center
New York University School of Medicine
New York, New York

Robert Bulat, MSc, MD, PhD
Assistant Professor of Medicine
Division of Gastroenterology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Richard A. Burkhart, MD
Assistant Professor
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Ronald W. Busuttil, MD, PhD
Distinguished Professor and Executive Chair
Department of Surgery
David Geffen School of Medicine at the University of California, Los Angeles
Los Angeles, California

Christian Cain, MD
Assistant Professor
Department of Surgery
Division of Trauma, Critical Care, and Acute Care Surgery
R. Adams Cowley Shock Trauma Center
University of Maryland Medical Center
Baltimore, Maryland

Rachael A. Callcut, MD, MSPH, FACS
Associate Professor of Surgery
Department of Surgery
University of California, San Francisco
San Francisco, California

Nicholas A. Caletta, MD
Resident
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Richard P. Cambria, MD
Chief, Division of Vascular & Endovascular Surgery
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Andrew M. Cameron, MD, PhD
Professor of Surgery
Division Chief of Abdominal Transplantation
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Melissa S. Camp, MD, MPH
Assistant Professor
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Karol D. Capek, MD
Physician
Burns and Surgical Critical Care
Galveston, Texas

Jonathan A. Cardella, MSc, MD, FRCS
Assistant Professor and Program Director
Division of Vascular Surgery
Yale University
New Haven, Connecticut

Paul Cartwright, MD
Resident
Department of Surgery
Medical Center of Central Georgia
Macon, Georgia

Cassius Iyad Ochoa Chaar, MD, MS
Assistant Professor
Department of Surgery
Section of Vascular Surgery
Yale School of Medicine
New Haven, Connecticut

Elliot L. Chaikof, MD, PhD
Johnson and Johnson Professor of Surgery
Harvard Medical School
Chair
Roberta and Stephen R. Weiner Department of Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Akhil Chawla, MD
Complex Surgical Oncology Fellow
Department of Surgery
Massachusetts General Hospital
Brigham and Women's Hospital
Dana Farber Cancer Institute
Harvard Medical School
Boston, Massachusetts

Po-Hung Chen, MD
Assistant Professor of Medicine
Division of Gastroenterology and Hepatology
Johns Hopkins School of Medicine
Baltimore, Maryland

Jill R. Cherry-Bukowiec, MD, MS
Associate Professor of Surgery
Director, Trauma Burn ICU
Assistant Director, Scientific Track
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Rachel L. Chesnut, MD
Assistant Professor
Department of Surgery
Division of Acute Care Surgery
Robert Wood Johnson University Hospital
Rutgers Robert Wood Johnson Medical School
New Brunswick, New Jersey

Michael A. Choti, MD, MBA, FACS
Chief, Department of Surgery
Division of Surgical Oncology
Banner MD Anderson Medical Center
Phoenix, Arizona
MANAGEMENT OF HEPATIC CANCERS

Kathryn Ely Pierre Chuquin, MD
Resident
Department of Surgery
Mount Sinai Hospital
New York, New York
MANAGEMENT OF RECURRENT INGUINAL HERNIA

Jose R. Cintron, MD
Chairman, Division of Colon and Rectal Surgery
Department of Surgery
John H. Stroger Hospital of Cook County
Associate Professor
Department of Surgery
University of Illinois College of Medicine at Chicago
Chicago, Illinois
MANAGEMENT OF HEMORRHOIDS

William G. Cioffi, MD
J. Murray Beardsley Professor & Chairman
Department of Surgery
Alpert Medical School of Brown University;
Chief of Surgery
Rhode Island Hospital and The Miriam Hospital
Providence, Rhode Island
SEPTIC SHOCK: PATHOPHYSIOLOGY AND MANAGEMENT

Bryan Clary, MD, MBA
Professor and Chair of Surgery
Surgeon-in-Chief
University of California, San Diego
San Diego, California
MANAGEMENT OF CYSTIC DISORDERS OF THE BILE DUCTS

Jordan M. Cloyd, MD
Assistant Professor
Department of Surgery
The Ohio State University
Columbus, Ohio
MANAGEMENT OF AMPULLARY TUMORS

Kathryn E. Coan, MD
Assistant Professor
Department of General Surgery
Creighton Medical School
Phoenix, Arizona
PARAMEDIAN REPAIR OF INCISIONAL HERNIAS

Hiram S. Cody III, MD
Attending Surgeon
Breast Service, Department of Surgery
Memorial Sloan Kettering Cancer Center
Professor of Surgery
Weill-Cornell Medical College
New York, New York
ANATOMY: LYMPHATICS AND LYMPH NODES

Thomas H. Cogbill, MD, FACS
Attending Surgeon
Department of General and Vascular Surgery
Gundersen Health System
La Crosse, Wisconsin
MANAGEMENT OF PENETRATING AND BLUNT TRAUMA OF ABDOMEN

Andrew J. Cohen, MD
Assistant Professor of Urology
Director of Trauma and Reconstructive Urologic Surgery
Brady Urologic Institute at Johns Hopkins School of Medicine
Baltimore, Maryland
HIGH-RISK URINARY INJURIES: PENNY AND LIFE LOST

Raul Coimbra, MD, PhD, FACS
Surgeon-in-Chief, Riverside University Health System Medical Center
Director, Comparative Effectiveness and Clinical Outcomes Research Center (CERCORE)
Riverside University Health System
Moreno Valley, California
Professor of Surgery
Loma Linda University School of Medicine
Loma Linda, California
PELVIC FLOOR: MANAGEMENT OF THE URINARY INCONTINENT

Kyle G. Cologne, MD
Associate Professor
Department of Surgery
Division of Colorectal Surgery
University of Southern California Keck School of Medicine
Los Angeles, California
MANAGEMENT OF ANORECTAL ABSCESS AND FISTULA

Paul M. Colombani, MD, MBA, FACS, FAAP
Chief Emeritus, Department of Surgery
Johns Hopkins All Children's Hospital
St. Petersburg, Florida
Professor of Surgery, Pediatrics, and Oncology
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
HERNIAS IN PEDIATRIC SURGERY

Jonathan Cools-Lartigue, MD, PhD
Resident
Department of Surgery
McGill University
Montreal, Quebec, Canada
MULTIMODALITY THERAPY IN PANCREATIC CANCER

Robert N. Cooney, MD, FACS, FCCM
Professor and Chairman
Department of Surgery
SUNY Upstate Medical University
Syracuse, New York
MECHANICAL VENTILATION IN OBESE BARIATRIC SURGERY

Gregory A. Coté, MD, MS
Professor
Department of Medicine
Division of Gastroenterology and Hepatology
Medical University of South Carolina
Charleston, South Carolina
PANCREATIC DIVISUM AND OTHER VARIANTS OF PANCREATIC DUCT ANATOMY

Bryan A. Cotton, MD, MPH
Professor
Department of Surgery
University of Texas Health Science Center, Houston
Senior Researcher
Center for Translational Injury Research
Houston, Texas
CONTROVERSIES AND NEW INDICATIONS FOR DAMAGE CONTROL

Martin A. Croce, MD
Professor
Department of Surgery
University of Tennessee Health Science Center
Senior Vice President and CMO
Regional One Health
Memphis, Tennessee
TRAUMA SPLEEN

Alisa Cross, MD
Assistant Professor
Department of Surgery
University of Oklahoma
Oklahoma City, Oklahoma
SURGICAL USE OF ULTRASOUND IN THE NONCARDIAC CRITICAL CARE SETTING

Alfred Crotteau, MD
Acute Care Surgeon
Department of Surgery
Hartford Healthcare
Director, Surgical Simulation (MCS-ACE) Center for Education, Simulation, and Innovation
Hartford Hospital
Hartford, Connecticut
Assistant Professor
Department of Surgery
University of Connecticut
Farmington, Connecticut
CARE OF THE SURGICAL PATIENT IN THE NONTRAUMA CARE UNIT

Gabriel Crowl, MD
Resident
Division of Vascular Surgery and Endovascular Therapy
University Hospitals Cleveland Medical Center
Cleveland, Ohio
MANAGEMENT OF ANEURYSMS OF THE DESCENDING AORTA AND VISCERAL ARTERIES

Steven C. Cunningham, MD, FACS
Director of Pancreatic and Hepatobiliary Surgery
Director of Research
Department of Surgery
Saint Agnes Hospital and Cancer Institute
Baltimore, Maryland
MANAGEMENT OF BENIGN SOLID BODY DISEASES

Leigh Anne Dagoforde, MD, MPH
Assistant Surgeon
Department of Surgery
Division of Transplantation
Massachusetts General Hospital
Assistant Professor of Surgery
Harvard Medical School
Boston, Massachusetts
MANAGEMENT OF ACUTE CHOLANGITIS

Paul D. Damicelson, MD, FACS, FAAP
Chief, Division of Pediatric Surgery
Johns Hopkins All Children's Hospital
St. Petersburg, Florida
Associate Professor of Surgery
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
ILEOSTOMY CLOSURE

Alan Dardik, MD, PhD
Professor and Vice Chairman (Faculty Affairs)
Department of Surgery
Interim Division Chief
Division of Vascular Surgery
Yale University School of Medicine
New Haven, Connecticut
Attending Surgeon
Department of Vascular Surgery
VA Connecticut Healthcare System
West Haven, Connecticut
BYPASS TO THE POPLITEAL

R. Clement Darling III, MD
Professor
Department of Surgery
Albany Medical College
Chief, Division of Vascular Surgery
Albany Medical Center Hospital
Albany, New York
MANAGEMENT OF RUPTURED ABDOMINAL AORTIC ANEURYSM

Hailey Darrach, BS
Medical Student
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
OMENTAL FLAP

Daniel T. Dempsey, MD, MBA
Professor
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania
JEJUNOJEJUNOSTOMY

Paula Deroya, MD, FACS, FASCRS
Associate Professor of Surgery
Program Director, Colorectal Surgery Residency Program
Co-Director, Stony Brook Inflammatory Bowel Disease Center
Clinical Human Physician, Cancer Committee
Stony Brook Medicine
Stony Brook, New York
USE OF SUBCUTANEOUS TISSUE IN CHRONIC DISEASE

E. Gene Deems, MD
Associate Professor
Department of Orthopedic Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
SURGICAL INFECTIONS OF THE HAND

Manpreet K. Dhillon, MD
Resident Physician
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California
HEALTHCARE-ASSOCIATED PNEUMONIA

Sandra R. DiBrito, MD, PhD
Resident
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
MANAGEMENT OF SMALL BOWEL ILEMORRHOIDS
MANAGEMENT OF HEMORRHOIDAL DISEASE

Ellen DiBenedetto, MD, FACS
Associate Professor of Surgery
Department of Vascular Surgery
Duke University
Durham, North Carolina
TREATMENT OF VARICOSE VEINS

Mary E. Dilhoff, MD, MS, FACS
Associate Professor
Department of Surgery
The Ohio State University College of Medicine
Columbus, Ohio
MANAGEMENT OF PYODERMA GANGRENOSUM

Joseph DiNorcia, MD
Assistant Professor of Surgery
Department of Surgery
David Geffen School of Medicine at the University of California, Los Angeles
Los Angeles, California

ROLE OF LIVER TRANSPLANTATION IN BENIGN LIVER RESECTION

Gerard M. Doherty, MD
Moseley Professor and Chair of Surgery
Harvard Medical School
Surgeon-in-Chief and Crowley Family Chair
Brigham and Women's Hospital
Boston, Massachusetts

INCIDENTAL GALLBLADDER CANCER

Jay Doucet, MD, MSc, FACS, FRCRC
Professor and Chief
Division of Trauma, Surgical Critical Care, Burns, and Acute Care Surgery
Department of Surgery
University of California, San Diego
San Diego, California

THE EVOLVING MANAGEMENT OF ILIAC VENOUS INJURY

Joseph Dubose, MD, FACS
Professor of Surgery
University of Maryland Medical System
R. Adams Cowley Shock Trauma Center
Baltimore, Maryland

THE UNIVERSE AND UNIVERSALITY OF LAPAROSCOPIC LIVER RESECTION

Quan-Yang Duh, MD
Professor and Chief
Section of Endocrine Surgery
University of California, San Francisco
Attending Surgeon
VA Medical Center
San Francisco, California

ADRENAL INCIDENTALOMA

Mark D. Duncan, MD, FACS
Vice Chair, Associate Professor of Surgery and Oncology
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland

LAPAROSCOPIC GASTRIC CANCER

MANAGEMENT OF SMALL BOWEL FISTULAS

Geoffrey P. Dunn, MD, FACS
Department of Surgery, Emeritus
UPMC Hamot
Erie, Pennsylvania

SURGICAL DELIRIUM: CARE

Brett L. Ecker, MD
Assistant Instructor
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

NEOADJUVANT AND ADJUVANT THERAPY FOR PANCREATIC CANCER

David T. Efron, MD, FACS
Professor
Department of Surgery
Johns Hopkins School of Medicine;
Vice Chair, Acute Care Surgery and Clinical Care Integration
Chief, Division of Acute Care Surgery
Johns Hopkins Hospital
Baltimore, Maryland

PELVIC SURVIVAL PROCEDURES

LAPAROSCOPIC TREATMENT OF SUPERIOR LABRAL TEAR

Jonathan Efron, MD
Professor of Surgery and Urology
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland

INFANCY IN RECONSTRUCTIVE SURGERY

Anna P. Ehlers, MD, MPH
Senior Fellow
Department of Surgery
University of Washington
Seattle, Washington

ENDOSCOPIC TREATMENT OF BARIATRIC COMPLICATIONS

Adam Ejaz, MD, MPH
Assistant Professor
Department of Surgery
The Ohio State University Wexner Medical Center
Columbus, Ohio

MANAGEMENT OF GASTRIC NEUROENDOCRINE TUMORS

Alexandra W. Elias, MD
Department of General Surgery
Mayo Clinic
Jacksonville, Florida

NEOADJUVANT AND ADJUVANT THERAPY FOR COLON CANCER

Mustapha El Lakis, MD
Clinical Assistant Professor
Department of Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

MANAGEMENT OF HYPERCALCEMIA

E. Christopher Ellison, MD, FACS
Robert M. Zollinger Professor Emeritus
Department of Surgery
The Ohio State University
Columbus, Ohio

MANAGEMENT OF ACUTE DIVERTICULITIS

Adham Elmously, MD
Resident
Department of Surgery
New York Presbyterian Weill Cornell Medical Center
New York, New York

MANAGEMENT OF SMALL BOWEL OBSTRUCTION

Michael J. Englesbe, MD
Professor
Department of Surgery - Transplantation
University of Michigan
Ann Arbor, Michigan

PEDIATRIC LIVER TRANSPLANTATION

Derek J. Erstad, MD
Chief Resident in Surgery
Massachusetts General Hospital
Boston, Massachusetts

MANAGEMENT OF BENIGN LIVER TUMORS

Juan A. Espinosa, MD
Resident
Department of General Surgery
Western Michigan University Homer Stryker MD School of Medicine
Kalamazoo, Michigan

SURGICAL SITE INFECTIONS

Eric W. Etchill, MD, MPH
Resident
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland

ACUTE LIVER FAILURE

David Exner, MD
Professor
Department of Surgery
Johns Hopkins University
Baltimore, Maryland

TUMOR BIOLOGY AND SURGICAL TIMELINE IN COLON CANCER

Cory R. Evans, MD
Associate Professor
Department of General Surgery
University of Tennessee Health Science Center
Memphis, Tennessee

PANCREATIC NECROSECTOMY

Douglas B. Evans, MD
Professor and Chair
Department of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

UNRESECTABLE PANCREATIC TUMORS

Heather L. Evans, MD, MS
Professor and Vice Chair of Clinical Research and Applied Informatics
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

ANTIFUNGAL THERAPY IN THE SURGICAL PATIENT

Timothy C. Fabian, MD
Professor Emeritus
Department of Surgery
University of Tennessee Health Science Center
Memphis, Tennessee

TRAUMATIC NECROTIZING FASCIITIS

Nadiege T. Fackche, MD
Postdoctoral Research Fellow
General Surgery
Division of Surgical Oncology
Johns Hopkins University
Baltimore, Maryland

USE OF SURVEILLANCE SCANS

LOCALLY ADVANCED CHOLANGIOCARCINOMA: ASSESSMENT AND ACCESS

MANAGEMENT OF PRIMARY CYSTIC TUMORS

Peter J. Fagenholz, MD
Department of Surgery
Division of Trauma, Emergency Surgery, and Critical Care
Massachusetts General Hospital
Assistant Professor of Surgery
Harvard Medical School
Boston, Massachusetts

MANAGEMENT OF ACUTE LIVER FAILURE

MANAGEMENT OF ACUTE MESENTERIC ISCHEMIA

Martina Famularo, DO
Integrated Vascular Resident
Department of Vascular Surgery
Cooper University Hospital
Camden, New Jersey

ENDOVASCULAR MANAGEMENT OF VISCERAL INJURY

Sandy H. Fang, MD
Assistant Professor
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland

MANAGEMENT OF DUODENAL DIVERTICULOSIS OF THE COLON

Alik Farber, MD
Chief, Division of Vascular and Endovascular Surgery
Associate Chair for Clinical Operations
Department of Surgery
Boston Medical Center;
Professor of Surgery and Radiology
Boston University School of Medicine
Boston, Massachusetts

CHRONIC MESENTERIC ISCHEMIA

David V. Feliciano, MD
Clinical Professor
Department of Surgery
University of Maryland School of Medicine;
Attending Surgeon
Shock Trauma Center
University of Maryland Medical Center
Baltimore, Maryland

PENETRATING ABDOMINAL TRAUMA

Carlos Fernandez-del Castillo, MD
Professor
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

INTRODUCTION: PREVALENCE AND DIAGNOSIS OF THE PANCREAS

Paula Ferrada, MD, FACS
Professor
Department of Surgery
Virginia Commonwealth University
Richmond, Virginia

PNEUMATOSIS INTESTINALIS AND THE PERFORATED VISCUS

Marco Ferrara, MD
Assistant Professor
Department of Surgery
University of Central Florida College of Medicine;
Associate
Colon and Rectal Surgery
Colon and Rectal Clinic of Orlando
Orlando, Florida

CARCINOMA, METASTATIC: SURGICAL MANAGEMENT OF LESIONS IN LUNG

Cristina R. Ferrone, MD
Associate Professor of Surgery
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

MANAGEMENT OF CARCINOID TUMORS

Alessandro Fichera, MD, FACS, FASCRS
Professor and Division Chief, Gastrointestinal Surgery
Department of Surgery
University of North Carolina Medical Center
Chapel Hill, North Carolina

MANAGEMENT OF COLONIC GASTROINTESTINAL STROMAL TUMORS

ILEOCECAL AND COLORECTAL TUMORS

Filippo Filicori, MD
Attending Surgeon
Lenox Hill Hospital
Assistant Professor of Surgery
Zucker School of Medicine at Hofstra/Northwell
New York, New York

MANAGEMENT OF SURVIVORS AND FAMILY

John Filtes, MD
Resident
Department of Radiology
Division of Interventional Radiology
New York Presbyterian/Columbia University Irving Medical Center
New York, New York

IMAGE-GUIDED BIOPSY OF LESIONS OF THE ABDOMEN AND PELVIS

Celeste C. Finnerty, PhD
Professor
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

BURN WOUND MANAGEMENT

Josef E. Fischer, MD
William Y. McDermott Distinguished Professor of Surgery
Department of Surgery
Harvard Medical School
Boston, Massachusetts

MANAGEMENT OF FATIGUE-RELATED DISORDERS

Thomas M. Fishbein, MD
Professor of Surgery and Executive Director
MedStar Georgetown Transplant Institute
MedStar Georgetown University Hospital
Washington, DC

MANAGEMENT OF BILIARY TRACT DISEASE

Marco P. Finocchiaro, MD
Associate Professor of Surgery
Department of Surgery
Harvard Medical School
Associate Chief of Surgery
Department of Surgery
West Roxbury VA
Boston, Massachusetts

SPECIFIC COMPLICATIONS OF LAPAROSCOPIC DISSECTION

Michael Fitzgerald, MD
Surgical Critical Care Fellow
University of Tennessee Health Science Center
Memphis, Tennessee

U.S. INJURY EPIDEMIOLOGY

Robert J. Fitzgibbons Jr, MD, FACS
Harry E. Stuckenhoff Professor and Chairman
Department of Surgery
Creighton University School of Medicine
Omaha, Nebraska

MANAGEMENT OF SPIGELIAN, UMBILICAL, AND OTHER UNCOMMON HERNIAS

James Fleshman, MD
Chairman
Department of Surgery
Baylor University Medical Center
Dallas, Texas

MANAGEMENT OF BENIGN ANORECTAL DISEASES

Guillermo Foncerrada, MD, MMS
Research Scientist
Department of Surgery
Shriners Hospital for Children
University of Texas Medical Branch
Galveston, Texas

BURN WOUND MANAGEMENT

Yuman Fong, MD
Sanghavi-Jones Chair and Chairman
Department of Surgery
City of Hope Medical Center
Duarte, California

RESECTION OF COLORECTAL LIVER METASTASES

Zhi Yan Fong, MD, MPH
General Surgery Resident
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

MANAGEMENT OF ACUTE MECHANICAL OBSTRUCTION

Debika S. Foster, MD, MA
General Surgery Resident
Department of Surgery
Stanford University
Stanford, California

MANAGEMENT OF UNRUPTURED ABDOMINAL AORTIC ANEURYSMS

Spiros G. Frangos, MD, MPH, FACS
Professor of Surgery
Chief of Surgery, NYC Health+Hospitals/Bellevue
Chief of Trauma, Emergency Surgery, and Surgical Critical Care
New York University School of Medicine
New York, New York

MANAGEMENT OF GENITOURINARY INJURIES

Todd D. Francone, MD, FACS, FASCRS
Staff Surgeon
Colon and Rectal Surgery
Massachusetts General Hospital
Assistant Professor of Surgery
Tufts Medical School
Boston, Massachusetts
Director, Division of Colon and Rectal Surgery
Director, Robotic Surgery
Associate Chair, Department of Surgery
Newton-Wellesley Hospital
Newton, Massachusetts

MANAGEMENT OF PERIANAL CROHN DISEASE

Adam Franklin, MD
Fellow
Section of Plastic Surgery
Oklahoma University Health Science Center
Oklahoma City, Oklahoma

ABDOMINAL WALL RECONSTRUCTION

Ryan B. Fratoman, MSc, MD
Surgical Resident
Department of Surgery
Johns Hopkins University
Baltimore, Maryland

MANAGEMENT OF COMPLICATIONS OF ILEOANAL POUCH

EMERGENCY DEPARTMENT MANAGEMENT OF SURGICAL EMERGENCIES

Jonathan Friedstat, MD, MPH, FACS
Assistant Surgeon
Department of Surgery
Massachusetts General Hospital
Instructor of Surgery
Harvard Medical School
Shriners Hospitals for Children
Boston, Massachusetts

CLINICAL INJURY SEVERITY SCORING

Julie A. Freischlag, MD
Chief Executive Officer
Wake Forest Baptist Health
Wake Forest Baptist Medical Center
Dean
Wake Forest School of Medicine
Winston-Salem, North Carolina

ENDOVASCULAR THERAPY

Christopher Frost, MD
Resident
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

METAL INJURY AND ITS TREATMENT

John Futchko, MD
Resident
Department of Cardiothoracic and Vascular Surgery
Montefiore Medical Center
New York, New York

ARTERIAL ACCESS, ENDOVASCULAR DEVICE SELECTION, AND CLOSURE

Alcelia Galvez-Kirker, MD
Assistant Professor
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland

THE UNDERSERVED AND VULNERABLE POPULATIONS

Michelle A. Gadd, MD
Assistant Professor of Surgery
Department of Surgical Oncology
Massachusetts General Hospital
Boston, Massachusetts
CHOLANGIOCARCINOMA

Michaela M. Gago, MD
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
MANAGEMENT OF INTRAHEPATIC, HILAR, AND DISTAL CHOLANGIOCARCINOMA
MANAGEMENT OF CHANGOLIOMELANOMA

Susan Galandiuk, MD
Professor of Surgery
Program Director, Section of Colon & Rectal Surgery
Hiram C. Polk Jr. MD, Department of Surgery
University of Louisville School of Medicine
Louisville, Kentucky
MANAGEMENT OF ULCERATIVE COLITIS

Samuel M. Galvagno Jr. DO, PhD, FCCM
Professor
Associate Director, Maryland Critical Care Network
Interim Medical Director, Long Term Care (LTCMU) unit
Deputy Director, Shock Trauma Go-Team
Department of Anesthesiology
Program in Trauma
R. Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland
ABDOMINAL MANAGEMENT IN THE TRAUMA PATIENT

Matthew Garner, MD, MPH
Research Fellow
Surgical Oncology
Johns Hopkins Hospital
Baltimore, Maryland,
General Surgery Resident
Albany Medical Center
Albany, New York
USE OF ESOPHAGEAL STENTS
MANAGEMENT OF NONMELANOMA SKIN TUMORS

Daron E. Garrido, MD
Assistant Professor
Vascular and Endovascular Surgery
University of Mississippi Medical Center
Jackson, Mississippi
BALLOON ANGIOPLASTY AND STENTS IN CAROTID ARTERY DISEASE

Susan L. Gearhart, MD
Associate Professor of Colorectal Surgery
Director, Colorectal Surgery Fellowship Program
Johns Hopkins University School of Medicine
Baltimore, Maryland
MANAGEMENT OF LARGE BOWEL OBSTRUCTION

Thomas Genuit, MD, MBA, FACS, FCCM
Professor and Chair
Program Director, General Surgery
Department of Surgery
Florida Atlantic University Charles E. Schmidt College of Medicine
Boca Raton, Florida
INITIAL ASSESSMENT AND RESUSCITATION OF THE TRAUMA PATIENT

Christos Georgiades, MD, PhD
Professor
Department of Radiology & Radiological Sciences
Johns Hopkins University
Baltimore, Maryland
IMAGING IN THE MANAGEMENT OF HEPATIC METASTASES

Bruce L. Gewertz, MD, FACS
Chair and Vice President, International Services
Department of Surgery
Vice Dean, Academic Affairs
Cedars-Sinai Medical Center
Los Angeles, California
BLUNT ABDOMINAL TRAUMA

Joseph S. Giglia, MD
Associate Professor
Department of Surgery
University of Cincinnati College of Medicine
Cincinnati, Ohio
ACUTE MESENTERIC ISCHEMIA AND INTESTINAL

Richard C. Gilmore, MD
Resident
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
ACUTE ISCHEMIA
SCREENING FOR BREAST CANCER

Armando E. Giuliano, MD, FACS, FRCSEd
Executive Vice Chair, Surgery
Chief of Surgical Oncology
Clinical Professor of Surgery
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California
ADJUVANT THERAPY FOR BREAST CANCER
DUCTAL CARCINOMA IN SITU

Natalia Glubova, MD, PhD
Assistant Professor
Section of Vascular and Endovascular Surgery
University of Colorado
Denver, Colorado
ANEURYSMS AND UNRUPTURED ABDOMINAL AORTIC ANEURYSMS: PROTOCOLS

Jaime M. Gloviczki, MD
Resident
Department of General Surgery
Mayo Clinic
Rochester, Minnesota
THE PHYSICAL MANIFESTATIONS OF CHRONIC VENOUS INSUFFICIENCY

Nassim Gourgiotis, MD
Resident
Department of Surgery
Saint Agnes Hospital
Transplantation Fellow
Department of Surgery
University of Maryland
Baltimore, Maryland
MANAGEMENT OF PERIANAL SKIN DISEASE, CLOSURE

Jeremy Goverman, MD
Assistant Professor
Department of Surgery
Harvard Medical School
MGH Trauma Fellow in Burns
Division of Burns
Massachusetts General Hospital
Boston, Massachusetts
ELECTRICAL INJURY AND ELECTROMAGNETIC INJURY

Michael D. Grant, MD
Section Chief of Breast Surgery
Baylor University Medical Center
Dallas, Texas

ROLE OF NEOADJUVANT BREAST BIOPSY IN THE MANAGEMENT OF BREAST CANCER

Michael P. Grant, MD, PhD, FACS
Paul N. Manson Distinguished Service Professor
Chief, Plastic and Reconstructive Surgery
Director, Maxillofacial Trauma Service
R. Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland

NONMELANOMA SKIN CANCERS: EVALUATION AND MANAGEMENT OF LOCOREGIONAL DISEASE

Laura Grenley, MD, MBA
Resident
Department of Surgery
University of Tennessee Medical Center
Knoxville, Tennessee

ANATOMIC PERSPECTIVE: "SPACES OF HEAD AND NECK"

Alessandro Gronchi, MD
Chair, Sarcoma Service
Department of Surgery
Fondazione IRCCS Istituto Nazionale dei Tumori
Milan, Italy

MANAGEMENT OF SOFT TISSUE SARCOMA

José G. Guillem, MD, MPH
Attending Surgeon
Memorial Sloan-Kettering Cancer Center
Professor of Surgery
Cornell University Medical College
New York, New York

SURGICAL MANAGEMENT OF COLON CANCER

Aakanksha Gupta, MD
Trauma Research Fellow
Division of Trauma, Burns, Critical and Acute Care
Weill Cornell Medicine
New York, New York

ANTIDEATH MANAGEMENT OF THE BURN PATIENT

Navtah Gupta, MD, FACS
Associate Professor
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California

SOFT TISSUE DISEASE OF THE RETROPERITONEUM, OMENTUM

John W. Harmon, MD, FACS
Professor of Surgery
Department of General Surgery
Johns Hopkins University
Baltimore, Maryland

MANAGEMENT OF EMERGENCIES OF THE SMALL BOWEL

Mehran Habibi, MD, MBA
Assistant Professor of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

MANAGEMENT OF SMALL BREAST CANCER

David J. Hackam, MD, PhD
Chief, Pediatric Surgery
Department of Surgery
Johns Hopkins University
Pediatric Surgeon-in-Chief and Co-Director
Johns Hopkins Children's Center
Baltimore, Maryland

APPENDICITIS

Adil H. Haider, MD, MPH, FACS
Penn
Medical College
Aga Khan University
Karachi, Pakistan

MANAGEMENT OF INTRAMUSCULAR INJECTIONS

Krista L. Haines, DO, MA
Assistant Professor
Department of Surgery
Duke University School of Medicine
Durham, North Carolina

BRACHYCEPHALY

Wassim J. Halabi, MD
Assistant Professor
Department of Surgery
University of California, Davis
Sacramento, California

ENTERAL STENTING FOR MALIGNANT COLONIC OBSTRUCTION

Christopher L. Hallemeier, MD
Assistant Professor
Department of Radiation Oncology
Mayo Clinic
Rochester, Minnesota

MANAGEMENT OF INCIDENTALLY DISCOVERED GALLBLADDER AND SMALL BOWEL CANCER

John B. Hanks, MD
C. Bruce Morton Professor and Chief
Department of Surgery
Division of General Surgery
University of Virginia Health System
Charlottesville, Virginia

MANAGEMENT OF SOLITARY METASTASES

Andrew Harris, BS
Research Fellow
Department of Orthopaedic Spine Surgery
Johns Hopkins University
Baltimore, Maryland

SPINE AND SPINAL CORD INJURIES

Jennifer L. Hartwell, MD
Assistant Professor
Department of Surgery
Indiana University
Indianapolis, Indiana

ABDOMINAL COMPARTMENT SYNDROME AND MANAGEMENT OF THE OPEN ABDOMEN

Gabrielle E. Hatton, MD
Resident
Department of Surgery
McGovern Medical School
University of Texas Health Science Center at Houston
Houston, Texas

ENDOCRINE CHANGES IN CRITICAL ILLNESS

Elliott R. Haut, MD, PhD, FACS
Associate Professor of Surgery, Anesthesiology/Critical Care Medicine (ACCM) and Emergency Medicine
Department of Surgery
Division of Acute Care Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

MANAGEMENT OF TRAUMATIC CARDIAC ARREST

Jason S. Hawksworth, MD
Associate Professor of Surgery
Medstar Georgetown Transplant Institute
Medstar Georgetown University Hospital
Washington, DC

MANAGEMENT OF INFECTIOUS FAILURE

Jin He, MD, PhD, FACS
Assistant Professor
Departments of Surgery and Oncology
Johns Hopkins University School of Medicine
Baltimore, Maryland

MANAGEMENT OF PANCREATIC CANCER

Sharon Henry, MD, FACS
Professor of Trauma Surgery
University of Maryland School of Medicine
Director, Wound Healing and Metabolism
R. Adams Cowley Shock Trauma Center
University of Maryland Medical Center
Baltimore, Maryland
GASTRIC NEOPLASIA OF THE ESOPHAGUS

Joseph M. Herman, MD, MSc
Department of Radiation Oncology & Molecular Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland
PATIENT EDUCATION FOR PANCREATIC CANCER

David N. Herndon, MD
Retired
Galveston, Texas
BURN WOUND MANAGEMENT

Caitlin W. Hicks, MD, MS
Assistant Professor of Surgery
Division of Vascular Surgery and Endovascular Therapy
Johns Hopkins University School of Medicine
Baltimore, Maryland
HAND BOOK PANIC IN CONSULTATION

O. Joe Hines, MD
Professor and Chief
Department of Surgery
Division of General Surgery
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, California
PANCREATIC DISRUPTIONS IN ACUTE PANCREATITIS, PANCREATECTOMY, & OTHER PANCREATIC PERITONEAL DISEASES

Julie L. Holihan, MD, MS
Clinical Instructor
Department of Surgery
McGovern Medical School
Houston, Texas
INCISIONAL, EPIGASTRIC, AND UMBILICAL HERNIAS

Courtenay M. Holscher, MD
Fulbright General Surgery Resident
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
CANCER ENHANCEMENT OF LIGHT TREATMENT OF CELLULITIS
ACUTE MESENTERIC ISCHEMIA

Kelvin Hong, MD
Division Chief
Interventional Radiology
Johns Hopkins University
Baltimore, Maryland
ACUTE PORTAL AND MESENTERIC VENOUS THROMBOSIS
PORTAL VEIN EMBOLIZATION

Michael G. Hoos, MD, FACS
Associate Professor
Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana
MANAGEMENT OF CALLOSOMETABOLIC UROGENITAL TUMORS

Cary Hsu, MD, FACS
Assistant Professor of Surgery
Michael E. DeBakey Department of Surgery
Division of Surgical Oncology
Baylor College of Medicine
Houston, Texas
DUCTAL AND LOBULAR CARCINOMA IN SITU OF THE BREAST

Ramon Huang, MD
Assistant Professor
Department of Surgery
Montefiore Medical Center
New York, New York
MANAGEMENT OF COLORECTAL POLYPS

Kevin Hughes, MD
Co-Director, Avon Comprehensive Breast Evaluation Center
Division of Surgical Oncology
Massachusetts General Hospital
Associate Professor
Department of Surgery
Harvard Medical School
Boston, Massachusetts
Medical Director
Bermuda Cancer Genetics and Risk Assessment Clinic
Hamilton, Bermuda
CARE OF CLOSED INCISIONS

Travis Hull, MD, PhD
General Surgery Resident
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts
MANAGEMENT OF ACQUIRED COLORECTAL-GENITOURINARY FISTULA

Ashley L. Huppe, MD
Assistant Professor
Department of Radiology, Breast Imaging
University of Kansas Health System
Kansas City, Kansas
RESURGENCE PANCREATIC CYSTIC NEOPLASMS

David F. Hutcheon, MD
Assistant Professor of Medicine
Department of Medicine
Johns Hopkins Medical Institutions
Baltimore, Maryland
ACUTE COLONIC PSEUDO-OBSTRUCTION [OGILVIE'S SYNDROME]

Irada Ibrahim-zada, MD, PhD
Surgical Oncology Fellow
Roswell Park Cancer Institute
Buffalo, New York
MANAGEMENT OF LOCOREGIONAL CANCER RECURRENCE IN THE LIVER
MANAGEMENT OF BENIGN BREAST DISEASE

Kamal M.F. Itani, MD
Chief of Surgery
VA Boston Health Care System
Professor of Surgery
Boston University
Boston, Massachusetts
ABDOMINAL WOUND AND SURGICAL INFECTIONS

Tomoaki Ito, MD
Department of Surgery
Juntendo University Shizuoka Hospital
Shizuoka, Japan
CLINICAL MANAGEMENT

Anna Sophia Jackson, MD
Research Fellow
Division of Thoracic Surgery
Swedish Cancer Institute
Seattle, Washington
Surgical Resident
Department of General Surgery
Medstar Georgetown University Hospital
Washington, DC
MANAGEMENT OF BENIGN ESOPHAGEAL DISEASES

Brian Jacob, MD
Associate Professor of Surgery
Department of Surgery
Icahn School of Medicine at Mount Sinai
New York, New York
MANAGEMENT OF RECURRENT INGUINAL HERNIA

Lisa K. Jacobs, MD, MSPH
Associate Professor of Surgery
Associate Professor of Oncology
Department of Surgery
Johns Hopkins University
Baltimore, Maryland
SURGERY: HORMONAL CANCERS

Richard A. Jacobson, MD
Resident Physician
Department of Surgery
Rush University Medical Center
Chicago, Illinois
CARCINOMA OF UNKNOWN ORIGIN

Ammar A. Javed, MD
Lead Postdoctoral Research Fellow
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
MANAGEMENT OF THE HEPATOBILIARY MANIFESTATIONS OF NEUROENDOCRINE TUMORS; OPERATIVE MANAGEMENT OF BENIGN AND MALIGNANT DISEASES OF THE PANCREAS

Fabian Johnston, MD, MHS, FACS
Associate Professor of Surgery and Oncology
Chief, Section of Gastrointestinal Surgical Oncology
Director, Peritoneal Surface Malignancy Program
Program Director, Complex General Surgical Oncology Fellowship
Division of Surgical Oncology
Johns Hopkins University
Baltimore, Maryland
MANAGEMENT OF CANCER AND NEOPLASMS

Douglas W. Jones, MD
Division of Vascular and Endovascular Surgery
Tufts Medical Center;
Assistant Professor of Surgery
Boston University School of Medicine
Boston, Massachusetts
CHRONIC MESENTERIC ISCHEMIA

Ronald C. Jones, MD
Chief Emeritus
Department of Surgery
Baylor University Medical Center
Dallas, Texas
BIOPSY OF THE COLORECTAL WALL AND BIOPSY BY THE MANAGEMENT OF BENIGN DISEASE

Kimberly Joseph, MD
Voluntary Attending Surgeon
Department of Trauma and Burns
John H. Stroger Hospital of Cook County
Chicago, Illinois
NUTRITION THERAPY IN THE CRITICALLY ILL SURGICAL PATIENT

Anthony N. Kalloo, MD
Minos and Helen Coulias Professor of Gastroenterology
Director, Division of Gastroenterology & Hepatology
Johns Hopkins Hospital
Baltimore, Maryland
GASTROINTESTINAL ENDOSCOPIC ULTRASOUND

Andreas M. Kaiser, MD, FACS, FASCRS
Professor of Clinical Surgery
USC Division of Colorectal Surgery
Keck School of Medicine at USC
University of Southern California
Los Angeles, California
SURGICAL MANAGEMENT OF ULCERATIVE COLITIS

Prithvi Kandagatla, MD
Resident
Department of Surgery
Henry Ford Hospital
Wayne State University
Detroit, Michigan
INFLAMMATORY BOWEL DISEASE

Lillian S. Kao, MD, FACS
Professor
Department of Surgery
McGovern Medical School
University of Texas Health Science Center at Houston
Houston, Texas
PANCREATIC CYSTS; BILIARY ATRESIA

Mark Katlic, MD, FACS
Chair
Department of General Surgery
Sinai Hospital of Baltimore
Baltimore, Maryland
MANAGEMENT OF GERIATRICS; OBESITY AND LIFESTYLE MODIFICATION

Vikram S. Kashyap, MD
Chief, Division of Vascular Surgery and Endovascular Therapy
Department of Surgery
University Hospitals Cleveland Medical Center
Cleveland, Ohio
MANAGEMENT OF ANEURYSMS OF THE EXTRACRANIAL CAROTID AND VERTEBRAL ARTERIES

Khaled M. Kassab, MD, FRCS
Professor
Department of Orthopedic Surgery
Johns Hopkins University
Baltimore, Maryland
SPINE AND SPINAL CORD INJURIES

Electron Kebebew, MD
Professor of Surgery
Chief, Division of General Surgery
Harry A. Oberhelman Jr. and Mark L. Welton Professor
Department of Surgery
Stanford University
Stanford, California
MANAGEMENT OF THYROID

Matthew P. Kelley, MD
General Surgery Resident
Department of Surgery
Division of Colon and Rectal Surgery
Johns Hopkins Hospital
Baltimore, Maryland
MANAGEMENT OF LARGE BOWEL OBSTRUCTION

Scott R. Kelley, MD, FACS, FASCRS
Assistant Professor of Surgery
Colon and Rectal Surgery
Mayo Clinic
Rochester, Minnesota
MANAGEMENT OF RADIATION INJURY TO THE LARGE AND SMALL BOWEL

Kaitlyn J. Kelly, MD
Assistant Professor of Surgery
Division of Surgical Oncology
University of California, San Diego
San Diego, California
MANAGEMENT OF PERITONEAL SURFACE MALIGNANCIES

Kevin Kemp, MD
Assistant Professor
Department of Surgery, University of Nebraska Medical Center
Omaha, Nebraska
CARE IN A SURGICAL INTENSIVE CARE UNIT

Aadil A. Khan, MD, MPH, PhD
Microsurgery Fellow
Department of Plastic Surgery
Johns Hopkins Hospital
Baltimore, Maryland

BREAST RECONSTRUCTION FOLLOWING MASTECTOMY, BREAST CANCER, AND BENIGN DISEASE

Umar Khan, MBBS, MD
Associate Professor
Department of Surgery
West Virginia University
Morgantown, West Virginia

LIVER AND BILIARY TRACT

Hiroki Kiguchi, MD
Assistant Professor and Assistant Program Director
Department of Vascular Surgery
MedStar Georgetown University Hospital
Washington, DC

TREATMENT OF VENOUS DISEASE

Mahroon T. Kiwan, MD, MS
Instructor
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

MANAGEMENT OF INFRADIAPHRAGMATIC INJURIES

Andrew Klein, MD, MBA, FACS
Professor and Vice Chairman
Department of Surgery;
Director
Comprehensive Transplant Center
Cedars-Sinai Medical Center
Los Angeles, California

MANAGEMENT OF RENAL CELL CARCINOMA

George Kokosis, MD
Resident
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

FINGER TRAUMA

Spogmai Komak, MD
Assistant Professor
Department of Surgery
McGovern Medical School
University of Texas Health Science Center at Houston
Houston, Texas

ENDOCRINE CHANGES IN CRITICAL ILLNESS

Kambiz Kosari, MD
Hepatic Pancreatic Biliary and Transplant Surgeon
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California

MANAGEMENT OF HEPATORENAL SYNDROME

Mark L. Kovler, MD
Resident
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

APPENDICITIS

Ashley N. Kreplins, MD
General Surgery Resident
Department of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

PALLIATIVE THERAPY FOR PANCREATIC CANCER

Helen Krontiras, MD
Professor of Surgery
Department of Surgery
Division of Surgical Oncology
University of Alabama at Birmingham
Birmingham, Alabama

MOLECULAR MARGINS IN BREAST CANCER

Armando Kuposov, MD
Breast Oncology Fellow
Department of Surgery
Mayo Clinic
Rochester, Minnesota

CURATIVE THERAPY IN LOCALLY ADVANCED COLON CANCER

Kelly J. Lafaro, MD, MPH
Assistant Professor
Department of Surgery
Johns Hopkins University School of Medicine

ABLATION OF COLORECTAL LIVER METASTASES

Mitchell Ryan Ladd, MD, PhD
Resident
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland

MULTIVISCERAL RESECTION AND PANCREATOBILIARY

Eric Lambright, MD
Associate Professor
Thoracic Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

MANAGEMENT OF ESOPHAGEAL PERFORATION

Glenn M. LaMuraglia, MD
Visiting Surgeon
Division of Vascular and Endovascular Surgery
Massachusetts General Hospital
Professor of Surgery
Harvard Medical School
Boston, Massachusetts

CAROTID ENDARTERECTOMY/PATCH

Rachael B. Lancaster, MD
Assistant Professor of Surgery
Department of Surgery
Division of Surgical Oncology
University of Alabama at Birmingham
Birmingham, Alabama

MULTIDISCIPLINARY APPROACH TO BREAST CANCER

William P. Lancaster, MD
Assistant Professor
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

MANAGEMENT OF PANCREATIC NECROSIS
MANAGEMENT OF CHRONIC PANCREATITIS

Ron G. Landmann, MD
Chief, Colon and Rectal Surgery
Baptist MD Anderson Cancer Center
Jacksonville, Florida

NEOADJUVANT AND ADJUVANT THERAPY FOR COLORECTAL CANCER

Julie R. Lange, MD, SciM
Associate Professor
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

BENIGN BREAST DISEASE
MANAGEMENT OF COMMON SOFT TISSUE TUMORS

Sean J. Langenfeld, MD
Associate Professor
Department of Surgery
Chief, Colon and Rectal Surgery
University of Nebraska Medical Center
Omaha, Nebraska

MANAGEMENT OF ANORECTAL ABSCESS AND FISTULA

Melissa Lazar, MD
Assistant Professor of Surgery
Department of Surgery
Thomas Jefferson University
Sidney Kimmel Medical College
Philadelphia, Pennsylvania

MANAGEMENT OF BENIGN AND MALIGNANT BREAST CANCER

Anna M. Ledgerwood, MD
Professor
Michael and Marian Ilitch Department of Surgery
Wayne State University
Trauma Medical Director
Department of Trauma Services
Detroit Receiving Hospital
Detroit, Michigan

BLUNT CARDIAC INJURY

MANAGEMENT OF OBESITY AND OBESITY COMPLICATIONS

Caroline T. Lee, MD
Cardiothoracic Surgery Fellow
Department of Cardiovascular and Thoracic Surgery
Allegheny General Hospital
Pittsburgh, Pennsylvania

EXTRACORPOREAL MEMBRANE OXYGENATION FOR RESPIRATORY FAILURE IN ADULTS

Jong O. Lee, MD
Professor
Department of Surgery
University of Texas Medical Branch
Medical Director, Burn Intensive Care Unit
Shriners Hospital for Children
Galveston, Texas

BURN WOUND MANAGEMENT

Sang W. Lee, MD, FACS, FASCRS
Charles W. and Carolyn Costello Chair in Colorectal Diseases
Professor and Chief of Colon & Rectal Surgery
USC Keck School of Medicine
Los Angeles, California

SURGICAL MANAGEMENT OF ILEAL POUCH SYNDROMES

Yano-Lani Larry Lee, MD, MS
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland

SPLENIC SALVAGE PROCEDURES

Ira L. Leeds, MD, MBA, ScM
Chief Resident
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

MANAGEMENT OF SMALL BOWEL DISEASE OF THE COLON

Ji Lei, MD, MSc, MBA
Director, MGH Islet Transplantation GMP Laboratory
Assistant Professor of Surgery
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts

PANCREATIC ISLET ISOLATION FOR CLINICAL TRANSPLANTATION

Isabelle C. Le Lasseur, MD, MEng
Fellow, Colon and Rectal Surgery
University of Minnesota
Minneapolis, Minnesota

MANAGEMENT OF CROHN'S COLITIS

Rebecca Levine, MD, FACS
Assistant Professor
Department of Surgery
Montefiore Medical Center
Einstein College of Medicine
New York, New York

MANAGEMENT OF COLONIC VOLVULUS

Eric J. Lay, MD
Associate Professor
Department of Surgery
Cedars Sinai Medical Center
Los Angeles, California
AMERICAN ASSOCIATION OF PANCREATOLOGY

Mike K. Liang, MD
Associate Professor
Department of Surgery
McGovern Medical School
Houston, Texas

INCISIONAL HERNIAS AND ABDOMINAL WALL RECONSTRUCTION

Yu Liang, MD
Assistant Professor
General Surgery
University of Connecticut Health Center
Farmington, Connecticut

MANAGEMENT OF MALIGNANT BOWEL OBSTRUCTION

Robert P. Liddell, MD
Assistant Professor
Department of Radiology and Radiological Sciences
Johns Hopkins School of Medicine
Baltimore, Maryland

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

ACUTE PERIPHERAL VENOUS OCCLUSION AND THROMBOTIC DISEASE

Anne O. Lidor, MD, MPH
Professor
Department of Surgery
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

MANAGEMENT OF MORBID OBESITY

Keith D. Lillemoe, MD
Chief of Surgery
Department of Surgery
Massachusetts General Hospital
W. Gerald Austen Professor of Surgery
Harvard Medical School
Boston, Massachusetts

MANAGEMENT OF ACUTE CHOLANGITIS

John C. Lipham, MD
Chief, Division of Upper GI & General Surgery
Professor of Surgery
James S. Pamela Maxey Endowed Chair in Upper GI Cancer
President, American Hiatal Society
Department of Surgery
Keck Medical Center of USC
University of Southern California
Los Angeles, California

MANAGEMENT OF ESOPHAGEAL PERFORATION

Jeremy M. Lipman, MD, MHPE, FACS, FASCRS
Program Director
General Surgery Residency
Cleveland Clinic
Cleveland, Ohio

SURGICAL MANAGEMENT OF CONSTIPATION

Pamela A. Lipsett, MD, MHPE, MCCM
Warfield M. Firor Endowed Professorship
Department of Surgery
Assistant Dean of Assessment and Evaluation
Program Director, General Surgery and Surgical Critical Care
Co-Director, Surgical Intensive Care Units
Johns Hopkins University School of Medicine
Baltimore, Maryland

MANAGEMENT OF COLOSTOMY AND ILEOSTOMY CARE

Evan C. Lipsitz, MD, MBA, FACS
Chief, Division of Vascular and Endovascular Surgery
Department of Cardiothoracic and Vascular Surgery
Montefiore Medical Center
Albert Einstein College of Medicine
New York, New York

ANKLE BRACHIAL INDEX (ABI), ANKLE TWO-POINT CUTOFF

Anna Livern, MD
Clinical Instructor
Resident Physician
Department of Surgery
Montefiore Medical Center
Albert Einstein College of Medicine
New York, New York

MANAGEMENT OF CYSTIC FIBROSIS AND ASSESSING THE SPLEEN

Satinderjit S. Locham, MBBS, MRCP(UK), BAO
Resident
Department of Surgery
University of California, San Diego
La Jolla, California

LIVER RESUSCITATION AND NON-OCCLUSIVE MESENTERIC ISCHEMIA

Joseph V. Lombardi, MD
Professor and Chief
Department of Vascular Surgery
Cooper University Hospital
Camden, New Jersey

UNDERSTANDING MANAGEMENT OF VASCULAR INJURIES

Bonnie E. Lonze, MD, PhD
Assistant Professor
Department of Surgery
New York University Langone Transplant Institute
New York, New York

DESENSITIZED ACCESS SURGERY

Brian E. Louie, MD, MHA, MPH, FRCSC, FACS
Director, Thoracic Surgery Research and Education
Co-Director, Minimally Invasive Thoracic Surgery Program
Surgical Chair, Swedish Digestive Health Institute
Division of Thoracic Surgery
Swedish Medical Center and Cancer Institute
Seattle, Washington

MANAGEMENT OF ACUTE ESOPHAGEAL PERFORATION

Gregory K. Low, MD
Resident Physician
Department of Surgery
Keck School of Medicine of the University of Southern California
Los Angeles, California

SURGICAL MANAGEMENT OF ILEAL INCONTINENCE

Andrew M. Lowy, MD
Professor of Surgery
Chief, Division of Surgical Oncology
University of California, San Diego
La Jolla, California

MANAGEMENT OF PERITONEAL SURFACE MALIGNANCIES

Charles E. Lucas, MD
Professor
Michael and Marian Ilitch Department of Surgery
Wayne State University
Surgeon
Department of Surgery
Detroit Receiving Hospital
Detroit, Michigan

BLUNT CARDIAC INJURY

MANAGEMENT OF EXTREMITY COMPARTMENT SYNDROME

Ying Wei Lum, MD
Associate Professor
Division of Vascular Surgery & Endovascular Therapy
Johns Hopkins Hospital
Baltimore, Maryland

MANAGEMENT OF RECURRENT CAROTID STENOSIS

George J. Magovern Jr, MD
Section Chair
Department of Thoracic and Cardiovascular Surgery
Allegheny Health Network
Pittsburgh, Pennsylvania

CONGENITAL AORTIC ARCH ANOMALIES: ANOMALOUS LEFT SUBCLAVIAN ARTERY

Martin A. Makary, MD, MPH
Professor of Surgery and Health Policy Management
Chief, Johns Hopkins Islet Transplantation Center
Director, Minimally Invasive Pancreas Surgery
Johns Hopkins Hospital
Baltimore, Maryland

TOTAL PANCREATECTOMY WITH ISLET AUTOTRANSPLANTATION

Mahmoud B. Malas, MD, MHS, FACS
Professor in Residence
Chief of Vascular and Endovascular Surgery
Vice Chair of Surgery for Clinical Research
University of California, San Diego Health System
La Jolla, California

LIVER LOCOREGIONAL OCCLUSION TECHNIQUES

Paul N. Manson, MD
Distinguished Service Professor
Department of Plastic Surgery
Johns Hopkins University
Baltimore, Maryland

NORMAL ANATOMY OF THE CHEST WALL

EVALUATION AND MANAGEMENT OF CHEST WALL INJURIES

MANAGEMENT OF CHEST WALL, LYMPHOMA, AND GOLD INJURIES

Nathalie Marcello, MD
Colon & Rectal Surgeon
Department of Surgery
Division of Colon & Rectal Surgery

Chief
Division of Transplant Surgery
Claude E. Welch Professor of Surgery
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts
SELECT AUTOIMMUNE MANIFESTATIONS OF CHRONIC PANCREATITIS

Stephen F. Markowitz, MD, MPH
Clinical Instructor
Department of Surgery
University of Toledo College of Medicine
Toledo, Ohio
MANAGEMENT OF DUODENAL ULCERS

Allison N. Martin, MD, MPH
Resident
Department of Surgery
University of Virginia
Charlottesville, Virginia
MANAGEMENT OF SECONDARY MEDIASTINITIS

Daniel Martin, DO
Fellow
Colon and Rectal Surgery
Colon and Rectal Clinic of Orlando
Orlando, Florida
LAPAROSCOPIC HEPATIC AND SURGICAL MANAGEMENT OF HYDATID DISEASE

Matthew J. Martin, MD, FACS, FASMBS
Director of Trauma Research
Scripps Mercy Hospital
Professor of Surgery
Uniformed Services University of the Health Sciences
Bethesda, Maryland
MANAGEMENT OF PANCREATIC PSEUDOCYST

Michael Martyak, MD
Assistant Professor
Department of Surgery
Eastern Virginia Medical School
Norfolk, Virginia
ACUTE ABDOMINAL HERNIA

Roxanne L. Massoumi, MD
Resident Physician
Department of General Surgery
University of California, Los Angeles
Los Angeles, California
PANCREATIC DEVELOPMENTAL ANOMALIES
PANCREATIC TRAUMA AND ACUTE, OR PANCREATIC PSEUDOCYSTS

Douglas J. Mathison, MD
Thoracic Surgeon
Department of Surgery
Massachusetts General Hospital
MEDIASTINAL MASSES

J. Greg Maves, MD
Senior Resident
Department of Orthopaedic Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
LATE MANAGEMENT OF PEDIATRIC SPINAL DEFORMITY

Laura H. Mazur, MD, MS
Assistant Professor of Surgery
Division of Minimally Invasive Surgery
University of Michigan
Ann Arbor, Michigan
SURGICAL MANAGEMENT OF GASTROESOPHAGEAL REFLUX DISEASE

Mary McCarthy, MD, FACS
Professor
Department of Surgery
Wright State University School of Medicine
Dayton, Ohio
CHEST WALL, PULMONARY, AND ESOPHAGEAL EMERGENCIES

Michael McColl, BS
Johns Hopkins University School of Medicine
Baltimore, Maryland
MANAGEMENT OF SMALL BOWEL CANCER

David W. McFadden, MD
Murray Holly Chairman and Professor

Department of Surgery
Indiana University Health Methodist Hospital
Indianapolis, Indiana
ANESTHESIA FOR PATIENTS UNDERGOING SURGERY

Anya Mezina, MD, MSc
Resident
Department of Medicine
Johns Hopkins Hospital
Baltimore, Maryland
MANAGEMENT OF FEBRILE NEUTROPENIA

Fabrizio Michelassi, MD
Lewis Atterbury Stimson Professor and Chairman
Department of Surgery
Weill Cornell Medical College
Surgeon in Chief
New York Presbyterian Hospital at Weill Cornell Medical Center
New York, New York
MANAGEMENT OF CROHN'S DISEASE OF THE SMALL BOWEL

David J. Milia, MD
Associate Professor
Department of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin
ANTIBIOTICS FOR GENERALIZED PERITONITIS

Barbra S. Miller, MD
Associate Professor
Director, NW Hutchinson Endocrine Surgery Fellowship
Department of Surgery
Section of General Surgery
Division of Endocrine Surgery
University of Michigan
Ann Arbor, Michigan
MANAGEMENT OF ADRENAL CORTICAL TUMORS

Emily J. Miraflor, MD
Assistant Professor
Department of Surgery
University of California, San Francisco East Bay
Oakland, California
MANAGEMENT OF PERIPROSTHETIC FRACTURES

Erica L. Mitchell, MD, MEd
Medical Director
Vascular and Endovascular Surgery
Salem Health Medical Group
Salem Health Hospitals and Clinics
Salem, Oregon
PERIOPERATIVE MEDICATIONS AND HOME MEDICATIONS

Daniela Molena, MD
Surgical Director of Esophageal Cancer Surgery Program
Thoracic Surgery
Memorial Sloane Kettering Cancer Center
New York, New York

George Molina, MD, MPH
Fellow in Complex Surgical Oncology
Department of Surgery
Massachusetts General Hospital
Brigham and Women's Hospital
Dana Farber Cancer Institute
Boston, Massachusetts

JoAn R. T. Monson, MD, FRCS, FACS, FASCRS
Executive Director, Colorectal Surgery
Center for Colon and Rectal Surgery
AdventHealth
Orlando, Florida

John R. Montgomery, MD
Research Fellow
Department of General Surgery
University of Michigan
Ann Arbor, Michigan

Derek T. Moore, MD
Department of Surgery
University of Massachusetts Medical School/ Baystate
Baystate Medical Center
Springfield, Massachusetts

Robert J. Moraca, MD

Benjamin Moran, MD
Visiting Instructor
Department of Surgery
University of Maryland Medical School
Baltimore, Maryland

Christopher R. Morse, MD
Assistant Professor
Thoracic Surgery
Massachusetts General Hospital
Harvard University
Boston, Massachusetts

Peter Muscarella II, MD
Professor
Department of Surgery
Montefiore Medical Center
New York, New York

Amol Narang, MD
Assistant Professor
Department of Radiation Oncology and Molecular Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland

Rahul Narang, MD
Assistant Professor of Surgery
Department of Surgery
Montefiore Medical Center
New York, New York

Mayur Narayan, MD, MPH, MBA, MHPE, FACS, FCCM, FICS
Associate Professor
Department of Surgery
Division of Trauma, Burns, Critical and Acute Care
Weill Cornell Medicine
Associate Attending Surgeon
Associate Program Director
Surgical Critical Care Fellowship
New York Presbyterian Hospital/Weill Cornell Medical Center
New York, New York

Nicholas A. Nash, MD
Associate Professor
Department of Surgery
University of Louisville
Louisville, Kentucky

Katie S. Nason, MD, MPH
Vice Chair of Surgery for Research
Department of Surgery
University of Massachusetts
Baystate Health Center
Springfield, Massachusetts

Yuval Nassori, MD, FACS, FASCRS
Attending Colorectal Surgeon
Cedars-Sinai Medical Center
Surgery Group of Los Angeles
Los Angeles, California

Nasim Nasseri, MD
Associate Professor of Surgery (Vascular)
Department of Surgery
Yale University School of Medicine
New Haven, Connecticut
Chief, Vascular and Endovascular Surgery
VA Connecticut Healthcare System
West Haven, Connecticut

Victoria Needham, MD
Resident
Department of Surgery
Montefiore Medical Center
New York, New York

Matthew A. Nehs, MD
Assistant Professor
Department of Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Lisa A. Newman, MD, MPH
Director, Interdisciplinary Breast Program
Department of Surgery
Weill Cornell Medicine, New York Presbyterian Hospital Network
New York, New York

Quang Nguyen, MD
Interventional Radiologist
Department of Radiology
Medistar Good Samaritan Hospital
Baltimore, Maryland

Madhuri V. Nishtala, MD
General Surgery Resident
Department of Surgery
University of Wisconsin
Madison, Wisconsin
MANAGEMENT OF SEXUAL MALFUNCTION

Nicholas Nissen, MD
Director, Liver Transplant and Hepato-Pancreato-Biliary Surgery
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California
MANAGEMENT OF BUDD-CHIARI SYNDROME

Bolin Niu, MD
Fellow
Division of Gastroenterology and Hepatology
Department of Medicine
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania
MANAGEMENT OF RETROCHOROPATHY

Erik R. Norris, MD, MS
Resident
Department of Surgery
Keck School of Medicine
University of Southern California
Los Angeles, California
SURGICAL MANAGEMENT OF THE POLYPOSIS SYNDROMES

Jeffrey A. Norton, MD
Professor
Department of Surgery
Stanford University School of Medicine
Stanford, California
MANAGEMENT OF PANCREATIC ENDOCRINE TUMORS EXCLUDING GASTRINOMA

Mulanie Nukala, MD
Vascular Surgery Fellow
Department of Vascular Surgery
Saint Louis University
St. Louis, Missouri
MANAGEMENT OF INFECTED GRAFTS

Ifeoma Y. Nwaogu, MD
Clinical Fellow
Department of Surgery
University of California, San Francisco
San Francisco, California
ACHALASIA

Isi Obokhare, MD
Associate Professor
General Surgery, Colon and Rectal Surgery
Advanced Laparoscopic/Robotic Surgery
Department of Surgery
Texas Tech University Health Sciences Center
Amarillo, Texas
MANAGEMENT OF THE MOBILE COLON

Brant K. Oelschlager, MD
Professor & Chief
Byers Endowed Professor of Esophageal Research
Division of General Surgery
University of Washington Medical Center
Seattle, Washington
ENDOSCOPIC MANAGEMENT OF BARRETT'S ESOPHAGUS

Terrence O'Keeffe, MBChB, FACS, FCCH
Professor
Department of Surgery
Banner University Medical Center
Tucson, Arizona
CONGENITAL AND ACQUIRED DISEASES OF THE ANUS

Charles S. O'Hara, MD, MBA
Professor
Associate Vice Chancellor for Clinical Affairs
Department of Surgery
University of Mississippi Medical Center
Jackson, Mississippi
ANATOMY AND PHYSIOLOGY AND TESTS IN CARDIOPULMONARY DISEASE AND ASSESSMENT OF OPERATIVE RISK

Patrick B. O'Neal, MD
Staff Surgeon
Veterans Administration–Boston Healthcare System
Assistant Professor
Department of Surgery
Boston University
Boston, Massachusetts
NEUROGENIC SEXUAL AND SEXUAL DYSFUNCTIONS

Cecilia T. Ong, MD
Surgical Resident
Duke University
Durham, North Carolina
MANAGEMENT OF COMMON BILIARY TRACT STONES

Mark S. Orloff, MD
Professor
Department of Surgery
University of Rochester
Rochester, New York
PORTAL HYPERTENSION: MEDICAL OR SURGICAL PROCEDURES

Tawakalitu O. Osemi, MD
Instructor
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts
MANAGEMENT OF HER2-POSITIVE BREAST CANCER

Greg M. Osgood, MD
Assistant Professor of Orthopedic Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
FAST-TRACK MANAGEMENT OF PELVIC FRACTURES

Shane E. Ottmann, MD
Transplant Surgeon
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
PORTAL HYPERTENSION: MEDICAL OR SURGICAL PROCEDURES

Heidi N. Overton, MD
Resident
Department of General Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
THE ANDROGEN INSENSITIVITY SYNDROMES

Shakiraz Oyetunji, MD, MPH
Chief Resident
Department of Cardiothoracic Surgery
University of Washington
Seattle, Washington
MANAGEMENT OF TRAUMATIC STENOSIS

M. Leon Pachter, MD, FACS
George David Stewart Professor
Chairman, Department of Surgery
New York University School of Medicine
New York, New York
MANAGEMENT OF CONTINGENCY PLANS

Javier Salgado Pagacnik, MD
Assistant Professor of Surgery
University of Texas Southwestern Medical Center
Dallas, Texas
MANAGEMENT OF BULIMIA CANCER

Bernard J.A. Palmer, MD, Med
Associate Professor
Department of Surgery
University of California, San Francisco, East Bay
Oakland, California
MANAGEMENT OF THE OBSTRUCTED

Nikhil Panda, MD
General Surgery Resident
Department of Surgery
Massachusetts General Hospital
Clinical Fellow in Surgery
Harvard Medical School
Boston, Massachusetts
MANAGEMENT OF ACQUIRED ESOPHAGEAL RESPIRATORY DISEASE

Theodore N. Pappas, MD, FACS
Distinguished Professor of Surgical Innovation
Chief of Advanced Oncologic and Gastrointestinal Surgery
Duke University School of Medicine
Durham, North Carolina
MANAGEMENT OF UNRESECTABLE DISEASE

Lisa Park, MD
Resident Physician
Department of General Surgery
Cleveland Clinic
Cleveland, Ohio
SURGICAL MANAGEMENT OF CONGENITAL

Pankaj Jay Pasricha, MBBS, MD
Professor
Departments of Medicine and Neuroscience
Johns Hopkins University School of Medicine
Baltimore, Maryland
MANAGEMENT OF MOTILITY DISORDERS OF THE STOMACH AND SMALL BOWEL

Andrew B. Peitzman, MD
Mark M. Ravitch Professor of Surgery
Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania
CHRONIC MANAGEMENT OF BILIARY INJURY

Marco G. Patti, MD
Professor of Medicine and Surgery
Department of Medicine and Surgery
Center for Esophageal Diseases and Swallowing
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina
MANAGEMENT OF UNANTICIPATED URINARY TRACT

Timothy M. Pawlik, MD, MPH, PhD, FACS, FRACS(Hon)
Professor and Chair
Department of Surgery
The Ohio State University
Columbus, Ohio
MANAGEMENT OF MALIGNANT HEPATIC TUMORS

Bruce A. Perler, MD, MBA
Julius H. Jacobson II Professor
Vice Chair for Clinical Operations and Financial Affairs
Chief Emeritus, Division of Vascular Surgery & Endovascular Therapy
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
Vice President
American Board of Surgery
Philadelphia, Pennsylvania
OPEN REPAIR OF ABDOMINAL AORTIC ANEURYSM

Erica Petrike, MD
Resident
Department of Surgery
Mount Sinai West Hospital
New York, New York
MANAGEMENT OF CELIAC DISEASE

Henry A. Pitt, MD
Professor of Surgery
Lewis Katz School of Medicine at Temple University
Philadelphia, Pennsylvania
MANAGEMENT OF BENIGN CYSTS

Armani D. Politano, MD, MS
Assistant Professor
Department of Vascular Surgery
Oregon Health & Science University
Portland, Oregon
PULMONARY EMBOLISM AND ARTERIOVENOUS DISEASE

Jason D. Prescott, MD, PhD
Assistant Professor
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
SURGICAL MANAGEMENT OF TUMORS CANCER

Leigh Ann Price, MD
Director, National Burn Reconstruction Center
Department of Surgery
MedStar Good Samaritan Hospital
Assistant Professor
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
ELECTRICAL INJURY AND LIGHTNING INJURIES

Brandon W. Propper, MD, FACS, RPVI
Program Director, General Surgery
Department of Vascular Surgery
San Antonio Military Medical Center
San Antonio, Texas,
Associate Professor of Surgery
Department of Surgery
Uniformed Services University of the Health Sciences
Bethesda, Maryland
DIAGNOSIS

Scott G. Prusiik, MD
Vascular Surgeon
Division of Vascular and Endovascular Surgery
St. Elizabeths Medical Center
Brighton, Massachusetts
NONOPERATIVE MANAGEMENT OF ABDOMINAL AORTIC ANEURYSM

Thaddaus J. Pursio, MD
Trauma and Surgical Critical Care Fellow
University of Texas Health Science Center at Houston
Houston, Texas
HEMOPERITONEUM

T. Robert Qaqish, MD, MSc
Chief Resident
General Surgery
Sinai Hospital of Baltimore
Baltimore, Maryland
MANAGEMENT OF DISORDERS OF ESOPHAGEAL MOTILITY

Andre R. Ramdon, MD
Department of Surgery
Philadelphia VA Medical Center
Philadelphia, Pennsylvania

MANAGEMENT OF HOSPITALIZED ABDOMINAL WOUNDS AND ODEMA

Christine Ramirez, MD
Acute Care Surgeon
St. Luke's University Health Network
Bethlehem, Pennsylvania
Clinical Assistant Professor
Department of Surgery
Temple University
Philadelphia, Pennsylvania

MANAGEMENT OF TRAUMATIC BRAIN INJURY

Daniel E. Ramirez, MD
Assistant Professor
Department of Vascular Surgery
University of Mississippi
Jackson, Mississippi

ANATOMY, ANATOMIC VARIANTS AND VARIANTS IN CARDIOVASCULAR DISEASE

Bruce Ramshaw, MD, FACS
Professor and Chair
Department of Surgery
University of Tennessee Graduate School of Medicine;
Adjunct Professor
Graduate and Executive MBA Program
Haslam College of Business
University of Tennessee
Knoxville, Tennessee

MINIMALLY INVASIVE SURGERY

Chandrajit P. Raut, MD, MSc
Associate Surgeon
Department of Surgery
Brigham and Women's Hospital;
Surgery Director
Center for Sarcoma and Bone Oncology
Dana-Farber Cancer Institute;
Professor of Surgery
Harvard Medical School
Boston, Massachusetts

MANAGEMENT OF SOFT TISSUE SARCOMA

Bradley N. Reames, MD, MS
Assistant Professor
Department of Surgery
Section of Surgical Oncology
University of Nebraska Medical Center
Omaha, Nebraska

MANAGEMENT OF CARCINOID AND NEUROENDOCRINOMA

MANAGEMENT OF PERIAMPULLARY CANCER

Christopher R. Reed, MD
Resident
Department of Surgery
Duke University Medical Center
Durham, North Carolina

BIOLOGY OF SEPSIS

Thomas Reifsnyder, MD
Associate Professor
Department of Surgery
Johns Hopkins Bayview Medical Center
Baltimore, Maryland

MANAGEMENT OF URGENT RENAL AND ARTERIAL OCCLUSIVE DISEASE

ACUTE ARTERIOMESENTERIC ISCHEMIA

EVIDENCE-BASED ACCESS SURGERY

Taylor S. Riall, MD, PhD
Professor
Department of Surgery
University of Arizona
Tucson, Arizona

PROPHYLAXIS OF VENOUS THROMBOEMBOLISM

J. David Richardson, MD
Professor
Department of Surgery
University of Louisville School of Medicine
Louisville, Kentucky

TIMING OF DAMAGE CONTROL

Charles G. Rickert, MD, PhD
Surgical Resident
Department of General Surgery
Massachusetts General Hospital
Boston, Massachusetts

ELECTROMYOGRAPHY IN CLINICAL PRACTICE

Addi Z. Rizzi, MD
Vascular and Endovascular Surgeon
Providence Vascular Institute
Sacred Heart Medical Center
Spokane, Washington

PERCUTANEOUS ACCESS TECHNIQUES

Thomas N. Robinson, MD, MS, FACS
Chief of Surgery
Rocky Mountain VA Medical Center;
Professor of Surgery
University of Colorado
Aurora, Colorado

OPTIMIZING PERIOPERATIVE CARE OF THE OLDER PATIENT

Sean P. Roddy, MD
Professor
Department of Surgery
Albany Medical College
Albany, New York

MANAGEMENT OF HOSPITALIZED ABDOMINAL WOUNDS AND EDEMA

Andrew P. Rogers, MD
General Surgery Resident
Department of Surgery
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

MANAGEMENT OF MORBID OBESITY

Yesenia Rojas-Khalil, MD
Assistant Professor of Surgery
Section of Colorectal Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

MANAGEMENT OF CLINICAL UNSTABLE COLON

John R. Romanelli, MD, FACS
Professor of Surgery
University of Massachusetts Medical School-Baystate;
Minimally Invasive Surgery Fellowship Director
Medical Director, Metabolic and Bariatric Surgery
Medical Director, Baystate General Surgery Practice
Baystate Medical Center
Springfield, Massachusetts

MANAGEMENT OF OBESITY AND METABOLIC DISEASE

Ronnie A. Rosenthal, MD, FACS
Professor of Surgery
Yale University School of Medicine
New Haven, Connecticut;
Chief, Surgical Service
VA Connecticut Health Care System
West Haven, Connecticut

OPTIMIZING THE PERIOPERATIVE CARE OF THE OLDER PATIENT

Gedge D. Rosson, MD
Associate Professor
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

NERVE INJURY AND REPAIR

Grace S. Rozycki, MD, MBA, RDMS
Professor
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
SURGICAL USE OF ULTRASOUND IN THE HUMAN AND CADAVER CARE SETTINGS

Mario Russo, MD, FACCS
Medical Director, Trauma and Surgical Critical Care
Site Director, Surgery Residency
St. Mary's Medical Center;
Assistant Professor of Surgery
Florida Atlantic University Charles E. Schmidt College of Medicine
West Palm Beach, Florida
ANESTHESIA MANAGEMENT AND RESUSCITATION OF THE TRAUMA PATIENT

Jonathon O. Russell, MD
Assistant Professor
Director of Endoscopic and Robotic Thyroid and Parathyroid Surgery
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University
Baltimore, Maryland
MANAGEMENT OF THYROID NODULES

Colleen M. Ryan, MD
Professor
Department of Surgery
Massachusetts General Hospital
Harvard Medical School
Staff Surgeon, Shriners Hospitals for Children–Boston
Boston, Massachusetts
ELECTRICAL INJURY AND LIGHTNING INJURY

Bethany C. Sacks, MD, MEd
Assistant Professor
Clerkship and Curriculum Director
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
MANAGEMENT OF INCIDENTALOMAS

Justin M. Sacks, MD, MBA, FACS
Assistant Professor
Director, Oncological Reconstruction
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
UPPER EXTREMITY

Bashar Safar, MBBS
Assistant Professor of Surgery
Department of General Surgery
Johns Hopkins University
Baltimore, Maryland
PANCREATIC AND PERIAMPULLARY MANAGEMENT IN LOCOREGIONAL CANCER

Zeyait T. Sahli, MD
Resident
Department of General Surgery
University of Virginia
Charlottesville, Virginia
SURGICAL MANAGEMENT OF SQUAMOUS AND BASAL CELL CARCINOMA

Joseph V. Sakran, MD, MPH, MPA
Assistant Professor
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
PREHOSPITAL AND DISASTER MEDICINE

Cesar A. Santa-Maria, MD, MSCI
Assistant Professor
Department of Oncology
Johns Hopkins University
Baltimore, Maryland
ADVANCES IN NEOADJUVANT AND ADJUVANT THERAPY FOR BREAST CANCER

Samuel Sarmiento, MD, MPH, MBA
Postdoctoral Fellow
Department of Plastic and Reconstructive Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
MANAGEMENT OF MALE BREAST CANCER

Robert Sawyer, MD, FACS, FIDSA, FCCM
Professor and Chair of Surgery
Western Michigan University Homer Stryker MD School of Medicine
Adjunct Professor of Engineering and Applied Sciences
Western Michigan University
Kalamazoo, Michigan;
Adjunct Professor of Surgery
University of Virginia School of Medicine
Charlottesville, Virginia
SURGICAL SITE INFECTIONS

Joseph R. Scalea, MD
Assistant Professor of Surgery and Immunology
Director, Pancreas Transplantation
Department of Surgery
Division of Transplantation
University of Maryland
Baltimore, Maryland
PANCREAS TRANSPLANTATION

Thomas M. Scalea, MD, FACS, FCCM
Francis X. Kelly Professor of Trauma Surgery
Director, Program in Trauma
Physician in Chief
University of Maryland School of Medicine
R. Adams Cowley Shock Trauma Center
Baltimore, Maryland
ADVANCE DIRECTIVES IN THE CRITICALLY ILL PATIENT
CRITICAL CONDITIONS IN THE PSYCHIATRIC PATIENT

Philip R. Schauer, MD
Professor of Surgery
Bariatric and Metabolic Institute
Cleveland Clinic
Cleveland, Ohio
CARDIOVASCULAR DISEASE RISK REDUCTION IN THE BARIATRIC SURGICAL PATIENT

ESOPHAGEAL FUNCTION TESTS

Richard J. Barrafarano, MD, PhD

The swallowing mechanism is a dynamic process that involves the coordinated interplay between the central and peripheral nervous systems, the esophagus, and the esophageal sphincters. Esophageal motility disorders can be broadly classified as primary esophageal motility disorders, secondary esophageal motility disorders, and mechanical obstruction. Primary esophageal motility disorders are those in which the esophagus is the only organ involved in the pathologic process. Secondary esophageal motility disorders are those in which the esophagus is involved as part of a systemic disease process. Mechanical obstruction is a process that results in esophageal dysfunction because of an intraluminal, intramural, or extramural process that physically impairs the passage of food from the mouth to the stomach. Esophageal manometry and ambulatory pH monitoring are the most commonly performed tests in the evaluation of esophageal motility disorders. Esophageal manometry is the only test that can accurately measure the pressure and coordination of esophageal contractions. Ambulatory pH monitoring is the most sensitive test for detecting pathologic gastroesophageal reflux. Esophageal manometry and ambulatory pH monitoring are complementary tests that provide different but important information about esophageal function. Each of these tests possesses its own diagnostic and interpretive pitfalls that must be understood to avoid misdiagnosis and inappropriate therapy.

ESOPHAGEAL MANOMETRY

Esophageal manometry has been considered the gold standard for the diagnosis of esophageal motility disorders. Esophageal manometry is performed by placing a pressure catheter through the nose into the esophagus and measuring the pressure changes that occur during swallowing. Esophageal manometry is the only test that can accurately measure the pressure and coordination of esophageal contractions. Esophageal manometry is performed by placing a pressure catheter through the nose into the esophagus and measuring the pressure changes that occur during swallowing. Esophageal manometry is the only test that can accurately measure the pressure and coordination of esophageal contractions.

Technique

Access to the body is usually gained through the nose. Patients are usually sedated with a topical anesthetic and an intravenous sedative. Although many centers have used water-perfused catheters, most centers now use solid-state catheters. The catheter is passed through the nose into the esophagus and positioned so that the pressure sensors are in the body of the esophagus. The patient is then asked to swallow a series of 5-mL water swallows. The pressure changes that occur during swallowing are recorded and analyzed.

ESOPHAGOGASTRIC JUNCTION OUTFLOW OBSTRUCTION

EGJ outflow obstruction was formerly called hypertensive lower esophageal sphincter. Using a definition of EGJ outflow obstruction based solely on the IRP with the exclusion of achalasia allows this diagnosis to be combined with another diagnosis dependent on the esophageal body motility. EGJ outflow obstruction may be

BOX 1 Indications for Esophageal Manometry

Definite

- Evaluation of unexplained esophageal symptoms
- Accurate placement of pH, pH impedance probes
- Evaluation of peristaltic function before antireflux surgery or esophageal myotomy
- Evaluation of postoperative dysphagia
- Evaluation of transplantation with impedance
- Evaluation of scleroderma

Likely

- Evaluation of peristaltic function before bariatric surgery and lung transplantation
- Diagnosis of achalasia prior therapy

From Vaezi MF, Pandolfino JE, Vela MF. ACG clinical guideline: diagnosis and management of achalasia. Am J Gastroenterol 2013;108:1238–49; quiz 1250. http://doi.org/10.1038/ajg.2013.196.

FIG. 1 Classic barium esophagram appearance of achalasia on a lateral esophagram.

caused by an anatomic abnormality in the cardia (hiatal hernia, diseases of the esophageal wall, etc.) or be idiopathic with normal anatomy. In the setting of an anatomic abnormality, such as a paraesophageal hernia, surgical correction is associated with excellent durable results. In patients without an anatomic abnormality, the clinical significance of this diagnosis is still uncertain because some investigators believe that EGJ outflow obstruction may be an early or incomplete expression of a variant of achalasia. Because a significant number of patients with EGJ outflow obstruction report a spontaneous resolution of their symptoms over time without intervention, the recommendation for invasive interventions such as POEM or laparoscopic distal esophageal myotomy should be made only in those patients with persistent symptoms and associated weight loss.

DIFFUSE ESOPHAGEAL SPASM

Diffuse esophageal spasm (DES) is an uncommon condition that accounts for less than 10% of esophageal motility abnormalities. DES is characterized by uncoordinated contractions of the esophagus that typically result in symptoms of chest pain, dysphagia, or both. The esophagogram may be abnormal, but manometry is usually necessary for the diagnosis. As with achalasia, the introduction of high-resolution manometry changed the diagnostic criteria for DES. Initially, the Chicago Classification based both high-resolution manometry (HRM) and conventional manometry on the same criteria of rapid or simultaneous contractions but modified this to a parameter known as distal latency, or which is only apparent with HRM and is a more reliable indicator of DES. Distal latency is more likely associated with the onset of inhibitory peristaltic sensory activity after contractions and seems shorter in patients with DES. This results in an increased state of contractions in the distal esophagus. Current guidelines define DES by HRM as patients who have a normal integrated relaxation pressure at the LES but who have a distal latency less than 4.5 seconds in 20% of wet swallows. Medical treatment options include nitrates, sildenafil, and tricyclic antidepressants, which may help to alleviate the noncardiac chest pain. Diazepam and lorazepam have been used if nitrates, sildenafil, or tricyclic antidepressants have failed to control symptoms. Use of proton pump inhibitors (PPIs) for treatment of concomitant GERD also may be helpful. Surgical interventions such as laparoscopic or thoracoscopic extended myotomy can be effective in well-selected patients with refractory DES.

HYPERCONTRACTILE "NUTCRACKER" ESOPHAGUS

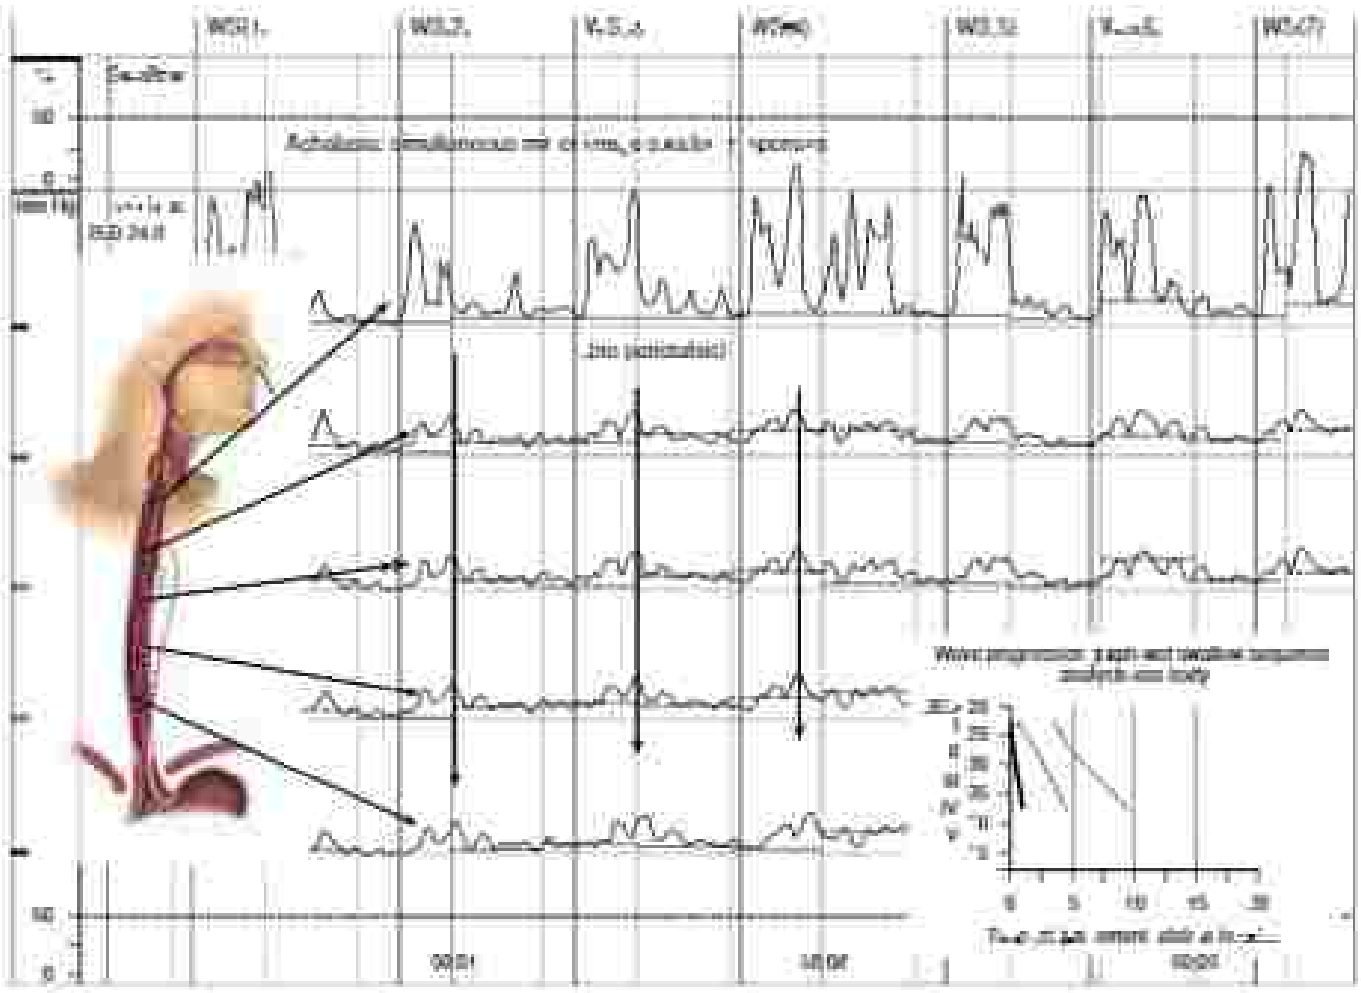
The definition of hypercontractile or "nutcracker" esophagus was updated in the latest version of the Chicago Classification to include [illegible] with a DCI greater than 8000 mm Hg cm in more than 20% of swallows, excluding patients with a single abnormal swallow (Figs. 5 and 6). In comparison to diffuse esophageal spasm, the peristaltic contractions propagate normally, and the LES relaxes appropriately. Diltiazem has been shown to lower distal peristaltic pressures and may reduce chest pain; however, these results are not reliably reproducible. As in DES, nitrates, sildenafil, and tricyclic antidepressants may be useful in the treatment of the noncardiac chest pain.

INEFFECTIVE ESOPHAGEAL MOTILITY

Ineffective esophageal motility is defined in the Chicago Classification system as a DCI of less than 450 mm Hg cm in 50% of the swallows. A variant of ineffective esophageal motility called fragmented peristalsis occurs when the patient's high-resolution manometry demonstrates normal DCI but greater than 5 cm breaks in more than 50% of the swallows. Finally, absent contractility is defined as a DCI less than 100 mm Hg cm in 100% of the swallows and is primarily observed in patients with connective tissue disorders such as scleroderma. Because there are no pharmacologic agents that restore or improve peristalsis in these patients, the patient's associated GERD is usually the focus of therapy.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is a common disorder that often brings patients to medical attention for acid suppression therapy. It is reported to affect approximately 9% of the US population and is associated with a significant cost to the US healthcare system. There is a degree of physiologic reflux that is considered normal and usually is limited and not substantial. The association of patient-reported symptoms and pathologic confirmed GERD is approximately 70% in many studies. Before recommending esophageal testing for diagnosis, most patients are empirically treated with a trial of PPI therapy. For those patients who



develop recurrent symptoms after a trial of PPI therapy, upper endoscopy with esophageal biopsy is the next step in the diagnostic algorithm. The identification of high-grade esophagitis (grades C or D), Barrett's metaplasia (Fig. 7), or a peptic stricture are considered confirmatory evidence for GERD. Grade B esophagitis provides adequate evidence for initiation of medical management of GERD. However, additional testing is warranted to confirm the diagnosis before committing a patient to long-term PPI therapy or antireflux surgery.

AMBULATORY ACID REFLUX MONITORING

Acid exposure in the esophagus is monitored with an intraluminal pH probe with one of two methods, either an intraluminal tube with a nasopharyngeal catheter or a wireless Bravo pH probe (Medtronic). Both methods provide the physician with similar data, particularly relating to the amount of time the esophagus is exposed to acid reflux. When the information is correlated with a symptom log, determination is possible of whether the patient's symptoms are related to acid exposure within the esophagus. This information is commonly expressed using the standard parameters (Box 2) to calculate a DeMeester score or a composite pH score. A score of less than 14.72 (fiftieth percentile of normal) is considered physiologic reflux, whereas a score greater than 14.72 is considered abnormal. Acid exposure in the esophagus is recorded according to the position of the patient (supine or upright) and the relation of acid exposure with meals. Accurate placement of either the indwelling esophageal catheter or the wireless probe is facilitated by placement during high-resolution esophageal manometry, and so these tests are often scheduled together.

ESOPHAGEAL IMPEDANCE

Impedance monitoring measures bolus transport by measuring the resistance to electrical conductivity of the esophagus and its contents. Impedance testing is an important adjunct to traditional pH testing because it can be useful for the evaluation of acid and bile (nonacid) reflux. Impedance measurement works by using low AC voltage to apply an electrical potential between two electrodes on a catheter separated by an isolator. Because air, liquid, and esophageal mucosa have unique impedance characteristics, identification of the material that is bridging the electrodes can be accurately assessed. Air is resistant to current flow and has a high impedance. Liquid has a low impedance value. Esophageal tissue has an indeterminate range and is used as a baseline during monitoring. With multiple electrodes along a catheter system, identification of changes in impedance makes possible determination of the direction of bolus transport within the esophagus and identification of reflux of a bolus that has cleared the esophagus but comes back up from the stomach (Fig. 8).

GERD Classification

The recently introduced classification of motor disorders in GERD characterizes morphologic and motor abnormalities in GERD, and this GERD classification is intended to be used in conjunction with the

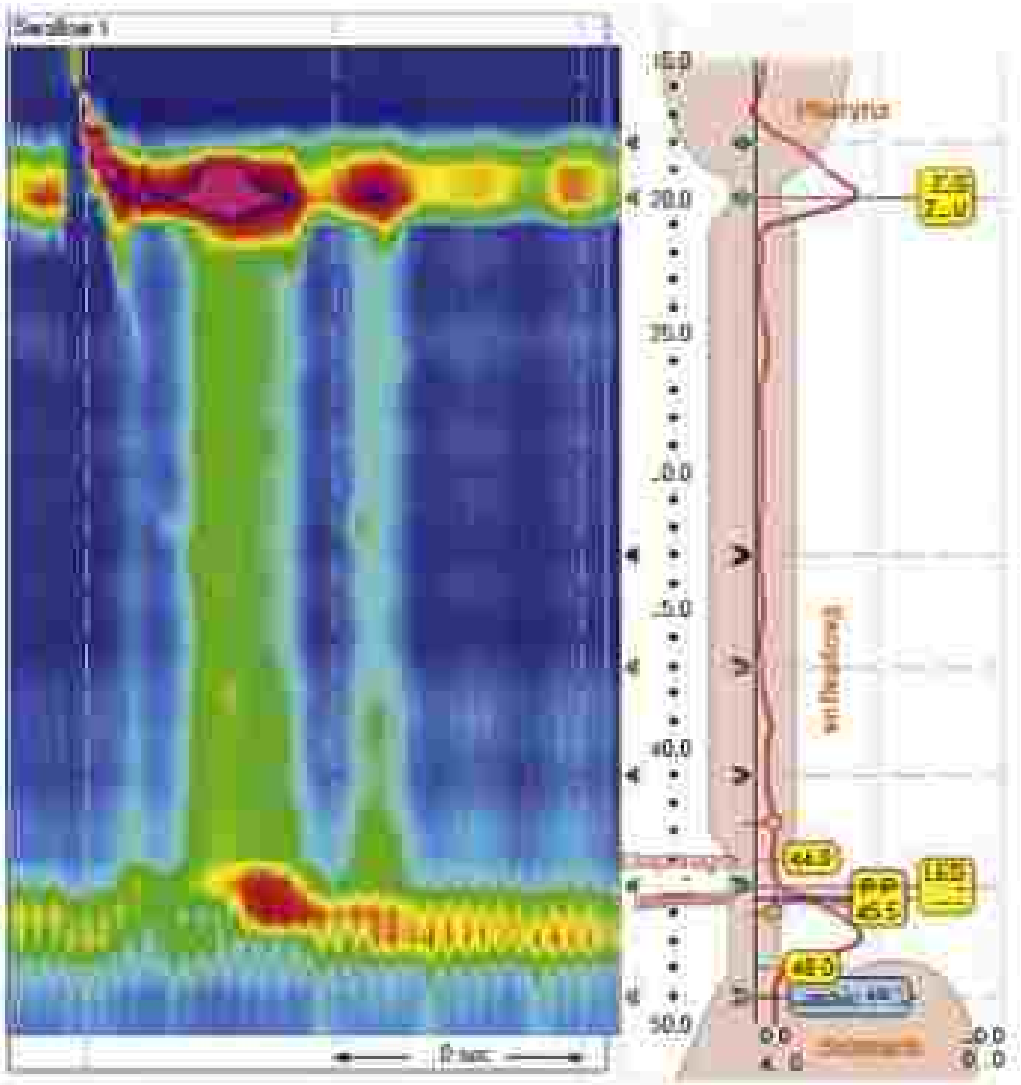


FIG. 3 High-resolution manometry in a patient with achalasia. Note the simultaneous contractions as a result of retrograde propagation. The lower esophageal sphincter is not hypertensive (i.e., no complete relaxation is not seen). LES, lower esophageal sphincter; P_{LES}, pressure in sphincter zone; —, upper esophageal sphincter.

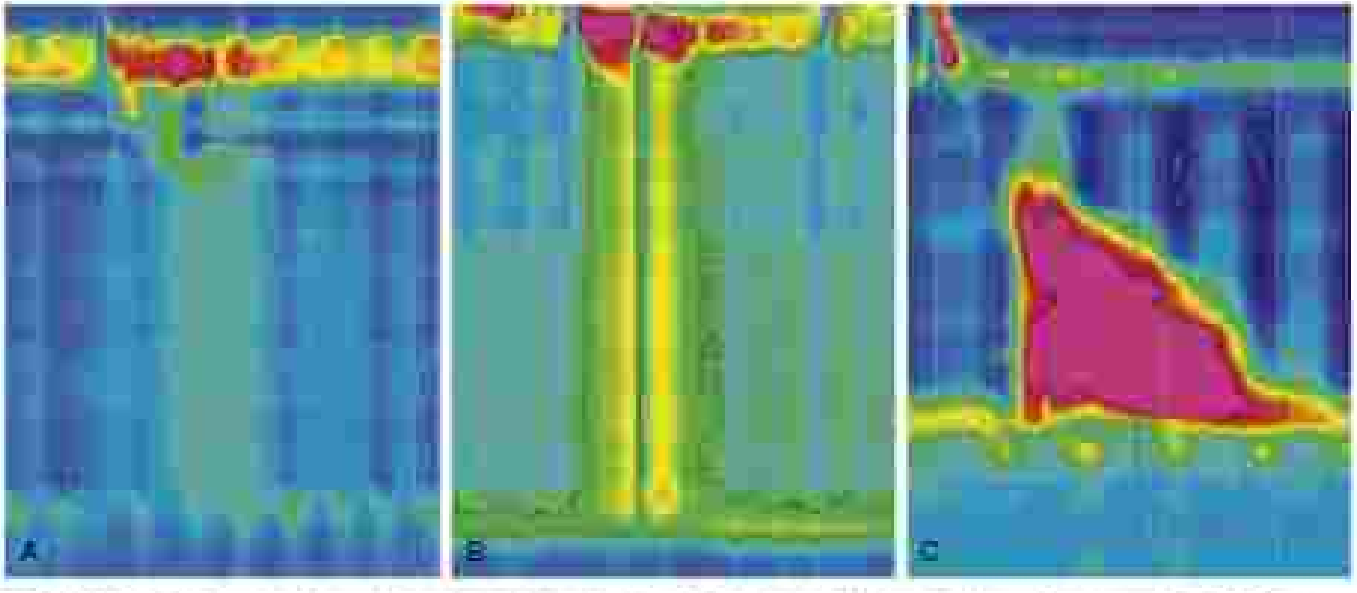

FIG. 4 High-resolution manometry demonstrating achalasia subtypes. (A) Type I is characterized by minimal esophageal pressurization. (B) Type II, with pan-esophageal pressurization was noted. (Bar denotes 20 mm Hg contour.) (C) Type III, with premature spastic contractions.

TABLE 1 Interpretation of High-Resolution Esophageal Manometry Chicago Classification V3.0

Subject	Metric	Motility disorder	Diagnostic criteria
EVALUATION OF ESOPHAGEAL FUNCTION			
Evaluation of EGJ function	Integrated relaxation pressure (IRP) abnormal if median value greater than upper limit of normal	Esophagogastric obstruction	EGJ obstruction present if IRP abnormal in ≥2 swallows Borderline EGJ obstruction present if IRP abnormal in 1 swallow
Evaluation for major motility disorders	Distal contractile integral (DCI): mean of distal contractile vigor (4–9 cm proximal to LES) in supine position Absent if DCI < 100 mm Hg·cm·s Weak if DCI 100–450 mm Hg·cm·s Normal if DCI > 450–8000 mm Hg·cm·s	Major motility disorder	Hypercontractile peristalsis: DCI > 8000 mm Hg·cm·s in ≥20% of wet swallows Distal esophageal spasm: DCI < 450 mm Hg·cm·s in ≥20% of wet swallows Absent contractility: DCI < 100 mm Hg·cm·s in ≥50% of wet swallows
Evaluation for minor motility disorder	Distal contractile integral (DCI): mean of distal contractile vigor (4–9 cm proximal to LES) in supine position Weak if DCI 100–450 mm Hg·cm·s Normal if DCI > 450–8000 mm Hg·cm·s	Minor motility disorder	Ineffective esophageal motility: DCI < 450 mm Hg·cm·s in ≥50% of wet swallows Distal esophageal spasm: DCI < 450 mm Hg·cm·s in ≥20% of wet swallows Fragmented peristalsis: ≥50% of wet swallows with DCI > 450 mm Hg·cm·s and a break ≥5 cm
CLASSIFICATION OF GERD			
Evaluation of EGJ			
Morphology	Separation between LES and CD	Hiatal hernia Hypotensive LES	Type I: superimposed LES and CD Type II: axially separated LES and CD pressure signals separated by <3 cm Type IIIa: >3 cm separation between the LES and CD pressure signatures with respiratory inversion point at the level of the CD Type IIIb: >3 cm separation between the LES and CD pressure signatures with respiratory inversion point at the level of the LES
Vigor	EGJ CI (mm Hg·cm)		DCI box set to encompass the LES and CD for a period of three complete respiratory cycles above a threshold pressure of the gastric baseline
Evaluation of Esophageal Motor Function			
	Distal contractile integral: DCI (mm Hg·cm·s) Defect (measure at 20 mm Hg isobaric contour)	Esophageal body motility	Intact: ≥50% of contractions with DCI >450 mm Hg·cm/s and no defect Fragmented: ≥50% of contractions with DCI >450 mm Hg·cm/s and defect >5 cm Ineffective esophageal motility: ≥50% of contractions with DCI <450 mm Hg·cm/s Absent peristalsis: 100% of contractions with DCI <100 mm Hg·cm/s
Provocative Tests			
MBS (five liquid swallows (2 mL each) taken 1 s apart)	Contractile response Failure of contractile response		Post-MBS DCI augmentation Absent post-MBS contraction
RRC (rapid water drinking of 200 mL of water within 30 s)	Retrograde premature LES relaxation Effective post-RRC contraction		

Abbreviations: DCI, distal esophageal contractile integral; EGJ, esophagogastric junction; LES, lower esophageal sphincter; MBS, multiple rapid swallows; RRC, rapid drink challenge.

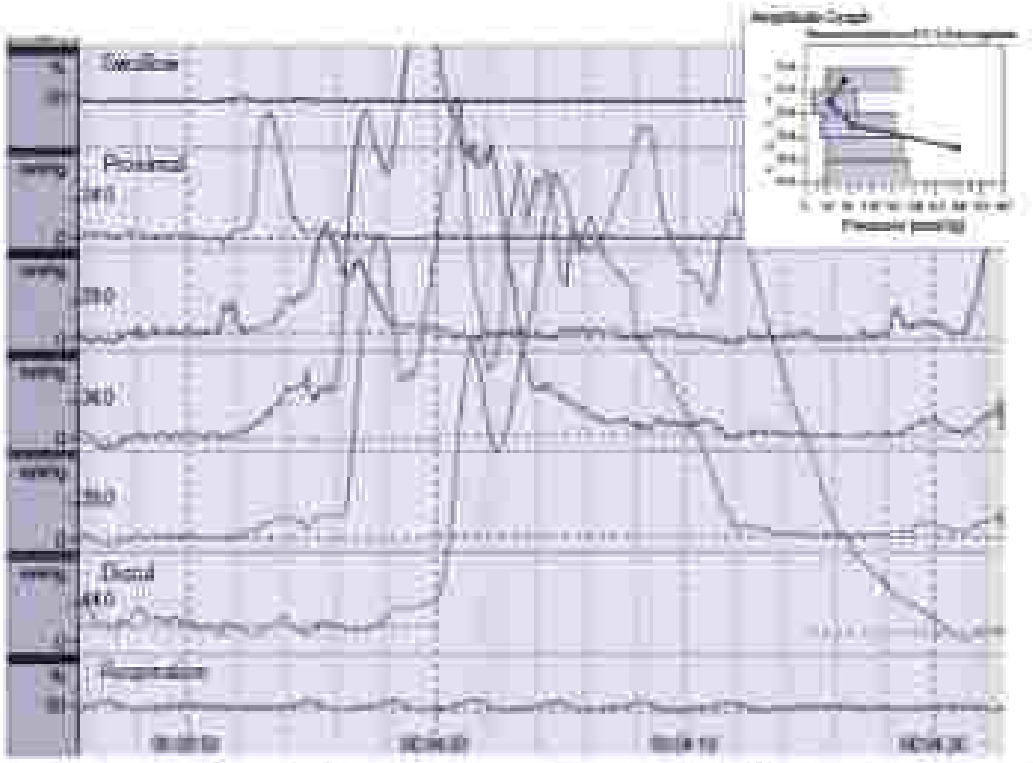

FIG. 5 Manometry showing hypercontractile esophageal body with pressure more than 180 mm Hg which is designated as a "nutcracker" esophagus.

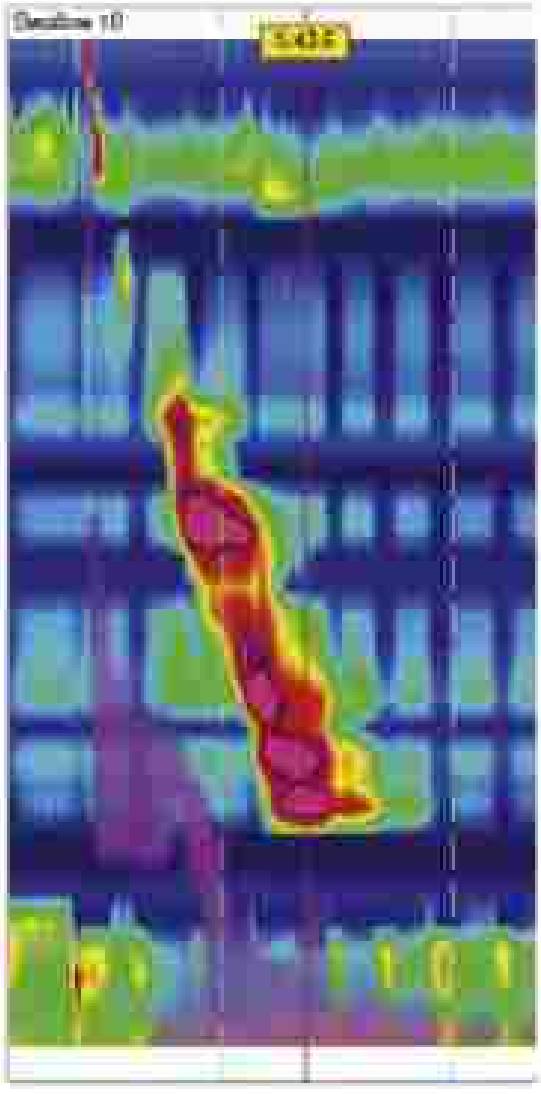

FIG. 6 High-resolution manometry showing "nutcracker" esophagus and relaxation after the swallow.

Chicago Classification. Two EGJ barrier characteristics are assessed: morphology and type. The intrinsic LES and the CD are normally superimposed to form an effective EGJ barrier against reflux of gastric contents into the esophagus (type 1 EGJ). A hiatus hernia exists when there is separation between the LES and CD. A type 2 EGJ is defined as being less than a 1 cm separation. A type 3 EGJ is defined as being greater than 3 cm. A mechanically dilated LES is diagnosed

FIG. 7 Saline-assisted maximal dilation seen in Barrett's esophagus.

BOX 2 Measured Parameters During 24-Hour Esophageal pH Monitoring

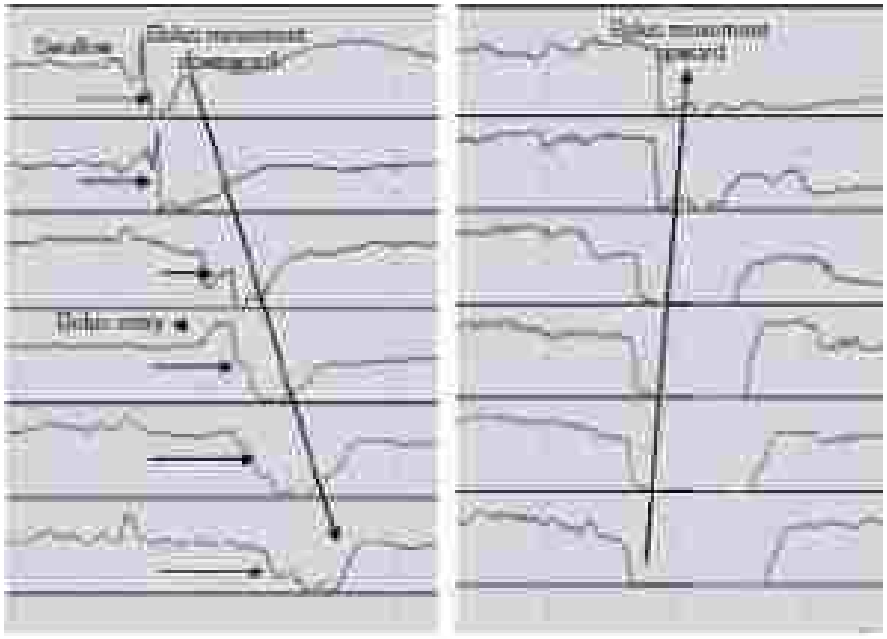
- Percent total time pH <4
- Percent upright time pH <
- Percent supine time pH <
- Number of reflux episodes
- Number of reflux episodes >5 minutes
- Duration of longest episode (in minutes)

when any one of three anatomic components is abnormal (pressure <6 mm Hg, total length <2 cm, abdominal length <1 cm). Invariably, the risk of GERD increases as the number of defective components rises and reaches more than 90% when all three LES components are abnormal.

The vigor of the EGJ barrier is assessed using a DCI like tool that measures length and pressure over three respiratory cycles (EGJ contractile integral). This metric is corrected for respiration by dividing the value with the duration of three respiratory cycles. Esophageal body motor function is characterized with Chicago Classification metrics into normal, fragmented peristalsis, ineffective, and absent contractility discussed above. Finally, the presence or absence of contraction reserve is assessed using the multiple rapid swallow (MRS) provocative test.

CLASSIFICATION OF MOTILITY FINDINGS IN GASTROESOPHAGEAL REFLUX DISEASE

The most common motility pattern in GERD is a normal study. However, either the EGJ or the esophageal body, or both can be abnormal. The EGJ can be hypotensive, with or without a hiatus hernia. Peristalsis can be fragmented, ineffective, or absent, with or without contraction reserve. The Lyon Consensus endorses the hierarchical classification of motility findings in GERD by first evaluating EGJ morphology and function with the LES and CD separation and the EGJ contractile integral (CI), which uses a nonwater test that encompasses length and vigor of the EGJ above the gastric baseline (Table 1). The measurement is made over three respiratory cycles during quiet rest, and corrected for duration of inspiration. The second level of evaluation is characterizing the integrity of peristalsis as normal, weak, fragmented, or absent. The third level, evaluating for contraction reserve. With MRS, five 2 mL swallows are taken less than 4 seconds apart, and with a rapid drink challenge 200 mL of water is swallowed within 30 seconds. The Lyon Consensus proposes that every HRM study should be accompanied by at least one of these provocative tests. Post-MRS contractions are an indication of contraction reserve in the esophagus, the phenomenon wherein the post-MRS contraction has greater DCI than the preceding test swallows. Recent data suggest three MRS sequences for reliable assessment of contraction reserve. The absence of contraction reserve in HRM is predictive



A B

FIG. Impedance study showing antegrade (A) and retrograde (B) movement of a swallowed bolus.

of the poor efficacy of proton pump drugs, higher acid exposure time in nonerosive reflux disease, and EGJ outlet obstruction. The absence of contraction reserve in IEM is also predictive of the subsequent benefit from dilation after antireflux surgery and the persistence or development of IEM after antireflux surgery. Absent contraction reserve is also the most common manometric finding in scleroderma. In contrast to the MRS provocative test, the most important clinical application of the rapid drinking challenge is in distinguishing EGJ obstruction from achalasia (by identifying LES relaxation in the former, and an exaggerated pressure gradient across a normalized EGJ in the latter). Therefore the rapid drinking challenge is most helpful in detecting paraesophageal herniation in achalasia, identifying increased resistance to EGJ outflow, and uncovering latent hypercontractility.

SUMMARY

The diagnosis of esophageal function disorders can be made from a careful history and the use of appropriate diagnostic testing. Several tests frequently are needed for the thorough evaluation of these disorders. Surgeons must understand the utility of these tests to evaluate whether a patient is a good surgical candidate for intervention and to determine the best treatment for a particular patient. A surgeon who is not familiar with these tests is not able to achieve optimal outcomes in the management of complex esophageal disorders. We also stress the importance of close collaboration between the radiologist, gastroenterologist, and surgeon in evaluating and treating this complicated group of patients.

SURGICAL MANAGEMENT OF GASTROESOPHAGEAL REFLUX DISEASE

[illegible] and [illegible]

Gastroesophageal reflux disease (GERD) is the most common gastrointestinal diagnosis in the Western world, impacting 10% to 20% of the population and resulting in approximately $11 billion annually in healthcare spending. GERD refers to the symptoms that result from reflux of stomach contents through the lower esophageal sphincter, primarily into the esophagus but also into the pharynx, larynx, and airway. This refluxed fluid results in inflammation and irritation, leading to the clinical manifestations of GERD. If untreated, the inflammation can progress to esophagitis, stricture, columnar metaplasia of the normal squamous epithelium (Barrett esophagus), and adenocarcinoma of the esophagus.

PRESENTATION OF GERD

The classic presentation of GERD is burning chest pain, often nocturnal, and often in a chronic and relapsing fashion. Patients will sometimes report sleeping upright to minimize the nocturnal symptoms. Risk factors include obesity, hiatal hernia, pregnancy, delayed gastric emptying, and connective tissue disorders. Although the symptoms alone are usually enough to diagnose GERD and begin medical therapy, it is necessary to consider and rule out more alarming conditions. These include acute coronary syndrome, achalasia, and esophageal cancer.

The symptoms of GERD can be divided into typical (esophageal) symptoms, atypical (extraesophageal) symptoms, and alarm symptoms that should warn of the development of complications. These are summarized in Table 1. Classic symptoms include burning "heartburn" chest pain (pyrosis), regurgitation of a sour fluid (water brash), a sensation of a lump or tightness in the throat (globus sensation), and pain on swallowing (odynophagia). Atypical symptoms, caused by reflux into the pharynx, larynx, or airway, can include cough, wheezing, hoarse voice, sore throat, postnasal drip, dental erosion, recurrent pneumonia, and ear pain. The presence of atypical symptoms in the absence of typical symptoms is "silent reflux."

Alarm symptoms include dysphagia, early satiety, hematemesis, melena, vomiting, and weight loss. The presence of alarm symptoms should raise concern for the development of complications of long-term reflux, including esophagitis, strictures, or esophageal cancer. These symptoms warrant immediate referral for upper endoscopy.

DIAGNOSIS AND PREOPERATIVE EVALUATION

The preoperative evaluation of patients referred for antireflux surgery (ARS) has three distinct goals: (1) confirm the diagnosis of GERD; (2) rule out other etiologies for the symptoms; and (3) define the anatomy. The standard preoperative tests are summarized in Table 2.

Confirm the Diagnosis

1. Ambulatory pH monitoring. This is the gold standard in diagnosing acid reflux. A pH sensor is connected either to a transnasally placed catheter or a wireless capsule that is attached to the distal esophagus with endoscopy. Patients eat a normal diet and record symptoms. A reflux episode is defined when the esophageal pH drops below 4. After 24 hours, the sensor is removed and the tracing is computer analyzed. The best predictor of endoscopic damage is the total amount of time with pH less than 4, although the computer program will also calculate the number of reflux episodes, the duration of episodes, and the relationship between pH and patient-reported symptoms. The result is a composite or DeMeester score. A DeMeester score greater than 14.7 is considered diagnostic of GERD.
2. Upper gastrointestinal endoscopy. Endoscopy can identify a hiatal hernia or short esophagus, diagnose an esophageal mass, and show complications of GERD, such as esophagitis, strictures, Barrett's esophagus, or cancer. Endoscopy can also classify the severity of esophagitis (see Table 3).

of the poor efficacy of proton pump drugs, higher acid exposure time in nonerosive reflux disease, and EGJ outlet obstruction. The absence of contraction reserve in IEM is also predictive of the subsequent benefit from dilation after antireflux surgery and the persistence or development of IEM after antireflux surgery. Absent contraction reserve is also the most common manometric finding in scleroderma. In contrast to the MRS provocative test, the most important clinical application of the rapid drinking challenge is in distinguishing EGJ obstruction from achalasia (by identifying LES relaxation in the former, and an exaggerated pressure gradient across a normalized EGJ in the latter). Therefore the rapid drinking challenge is most helpful in detecting paraesophageal herniation in achalasia, identifying increased resistance to EGJ outflow, and uncovering latent hypercontractility.

SUMMARY

The diagnosis of esophageal function disorders can be made from a careful history and the use of appropriate diagnostic testing. Several tests frequently are needed for the thorough evaluation of these disorders. Surgeons must understand the utility of these tests to evaluate whether a patient is a good surgical candidate for intervention and to determine the best treatment for a particular patient. A surgeon who is not familiar with these tests is not able to achieve optimal outcomes in the management of complex esophageal disorders. We also stress the importance of close collaboration between the radiologist, gastroenterologist, and surgeon in evaluating and treating this complicated group of patients.

Surgical Management of Gastroesophageal Reflux Disease

Laura M. Mazzei, MD, MS, and Dan E. Azagury, MD

Gastroesophageal reflux disease (GERD) is the most common gastrointestinal diagnosis in the Western world, impacting 10% to 20% of the population and resulting in approximately $11 billion annually in healthcare spending. GERD refers to the symptoms that result from reflux of stomach contents through the lower esophageal sphincter, primarily into the esophagus but also into the pharynx, larynx, and airway. This refluxed fluid results in inflammation and irritation, leading to the clinical manifestations of GERD. If untreated, the inflammation can progress to esophagitis, stricture, columnar metaplasia of the normal squamous epithelium (Barrett esophagus), and adenocarcinoma of the esophagus.

PRESENTATION OF GERD

The classic presentation of GERD is burning chest pain, often nocturnal, and often in a chronic and relapsing fashion. Patients will sometimes report sleeping upright to minimize the nocturnal symptoms. Risk factors include obesity, hiatal hernia, pregnancy, delayed gastric emptying, and connective tissue disorders. Although the symptoms alone are usually enough to diagnose GERD and begin medical therapy, it is necessary to consider and rule out more alarming conditions. These include acute coronary syndrome, achalasia, and esophageal cancer.

The symptoms of GERD can be divided into typical (esophageal) symptoms, atypical (extraesophageal) symptoms, and alarm symptoms that should warn of the development of complications. These are summarized in Table 1. Classic symptoms include burning "heartburn" chest pain (pyrosis), regurgitation of a sour fluid (water brash), a sensation of a lump or tightness in the throat (globus sensation), and pain on swallowing (odynophagia). Atypical symptoms, caused by reflux into the pharynx, larynx, or airway, can include cough, wheezing, hoarse voice, sore throat, postnasal drip, dental erosion, recurrent pneumonia, and ear pain. The presence of atypical symptoms in the absence of typical symptoms is "silent reflux."

Alarm symptoms include dysphagia, early satiety, hematemesis, melena, vomiting, and weight loss. The presence of alarm symptoms should raise concern for the development of complications of long-term reflux, including esophagitis, strictures, or esophageal cancer. These symptoms warrant immediate referral for upper endoscopy.

DIAGNOSIS AND PREOPERATIVE EVALUATION

The preoperative evaluation of patients referred for antireflux surgery (ARS) has three distinct goals: (1) confirm the diagnosis of GERD; (2) rule out other etiologies for the symptoms; and (3) define the anatomy. The standard preoperative tests are summarized in Table 2.

Confirm the Diagnosis

1. Ambulatory pH monitoring. This is the gold standard in diagnosing acid reflux. A pH sensor is connected either to a transnasally placed catheter or a wireless capsule that is attached to the distal esophagus with endoscopy. Patients eat a normal diet and record symptoms. A reflux episode is defined when the esophageal pH drops below 4. After 24 hours, the sensor is removed and the tracing is computer analyzed. The best predictor of endoscopic damage is the total amount of time with pH less than 4, although the computer program will also calculate the number of reflux episodes, the duration of episodes, and the relationship between pH and patient-reported symptoms. The result is a composite or DeMeester score. A DeMeester score greater than 14.7 is considered diagnostic of GERD.
2. Upper gastrointestinal endoscopy. Endoscopy can identify a hiatal hernia or short esophagus, diagnose an esophageal mass, and show complications of GERD, such as esophagitis, strictures, Barrett's esophagus, or cancer. Endoscopy can also classify the severity of esophagitis (Table 3).

TABLE 1 Presentation of Gastroesophageal Reflux Disease

Typical (Esophageal) Symptoms	Atypical (Extraesophageal) Symptoms	Alarm Symptoms
Pyrosis	Coughing	Dysphagia
Water brash	Wheezing	Bloody saliva
Globus sensation	Hoarse voice	Hematemesis
Odynophagia	Sore throat	Melena
	Postnasal drip	Vomiting
	Dental erosion	Weight loss

TABLE 2 Preoperative Evaluation

Study	Findings
CONFIRM THE DIAGNOSIS OF GERD	
Ambulatory pH monitoring	Gold standard: DeMeester score >14.7 (calculated as a composite based on duration of time pH <4, number and duration of reflux episodes)
Upper gastrointestinal endoscopy	Complications of GERD (esophagitis, strictures, Barrett's)
RULE OUT OTHER ETIOLOGIES OF SYMPTOMS	
Esophageal manometry	Rule out achalasia, evaluate esophageal motility
Gastric scintigraphy	Diagnose gastroparesis
DEFINE THE ANATOMY	
Upper gastrointestinal series	Presence/size of hiatal hernia, presence of short esophagus
Computed tomography scan	General anatomy

GERD, gastroesophageal reflux disease.

TABLE 3 Los Angeles Classification of Esophagitis

Grade A	One or more mucosal break >5 mm that does not extend between the tops of two mucosal folds
Grade B	One or more mucosal break >5 mm that does not extend between the tops of two mucosal folds
Grade C	One or more mucosal break that is continuous between the tops of two or more mucosal folds but <75% of the circumference
Grade D	One or more mucosal break which involves at least 75% of the esophageal circumference

Rule Out Other Etiologies: Achalasia, Delayed Gastric Emptying

1. Esophageal manometry: It is essential to rule out achalasia and evaluate esophageal motility prior to surgical treatment of GERD in patients with esophageal dysmotility who also have confirmed reflux, there is a higher risk of postoperative dysphagia. On the other hand, effective GERD control will improve esophageal motility for some patients. Some surgeons elect to perform a partial rather than total fundoplication in this population to minimize postoperative dysphagia; others will perform a Nissen fundoplication in the setting of dysmotility to maximize GERD relief.
2. Gastric scintigraphy: Delayed gastric emptying (gastroparesis) can cause or exacerbate symptoms of GERD, and it is hard to differentiate postoperatively an iatrogenic vagal nerve injury from preexisting gastroparesis. ...how diagnosed preoperatively, the fundoplication can be combined with a pyloroplasty to facilitate drainage. Gastric scintigraphy is not routinely performed before surgery, however, and should be reserved for patients with suspected gastroparesis. A thorough history and physical, including long standing diabetes or symptoms of delayed gastric emptying, can help identify patients who need this test.

Define the Anatomy

1. Upper gastrointestinal series (UGI): UGI is a double contrast barium esophagogastrogram followed by video fluoroscopy. This test can document the presence and size of a hiatal hernia, the presence of a short esophagus, and esophagogastric dysmotility. Although UGI can show reflux of contrast, this test cannot conclusively diagnose GERD and does not eliminate the need for pH monitoring.
2. Computed tomography scan: A computed tomography scan can help understand the anatomy, especially in cases of a very large hiatal hernia to assist with preoperative planning. CT is preferred in most instances for preoperative planning.

INDICATIONS FOR SURGICAL MANAGEMENT

There are three goals for treatment of GERD: (1) control of symptoms, (2) healing of reflux esophagitis, and (3) prevention of complications. Initial management is medical, and proton pump inhibitors (PPIs) have dramatically changed management of GERD. Most patients obtain significant symptom relief with a combination of lifestyle modification, including weight loss and abstaining from trigger foods, and once-daily PPI. When this treatment is not effective, it should prompt a diagnostic workup to rule out complications or other diagnoses including motility disorders. If the workup confirms a diagnosis of GERD, PPI dosage can be increased to twice daily or an H2 receptor blocker can be added. Most patients with GERD have excellent response to medical therapy. A poor response may indicate a misdiagnosis, development of a complication of GERD, or poor compliance. In the latter two situations, ARS should be considered. ARS can also be considered for patients who experience side effects from PPIs, most commonly headache, nausea and vomiting, or diarrhea. In general, studies have shown that ARS and PPIs are equally effective at symptom management, with both strategies showing 80% to 90% resolution of symptoms at 5 years. Neither strategy is without risk, including long-term PPI use, which carries an increased risk of osteoporosis and opportunistic infections. Patients with a good response to PPI may elect to proceed with surgery if they do not wish to continue on lifelong medical therapy. Specific indications for surgery are listed in Table 4.

Contraindications to ARS, in addition to patient inability to tolerate the operation, include esophageal cancer or high-grade dysplasia, which should be managed with appropriate resection rather than ARS. Additionally, morbid obesity is a relative contraindication, increasing the likelihood of recurrent symptoms after ARS. Patients should be referred for bariatric surgery evaluation, specifically Roux-en-Y gastric bypass, which should be the procedure of choice for patients with a body mass index of 35 kg/m^2 or greater and should be considered in patients with a body mass index greater than 30 kg/m^2.

TABLE 1 Indications and Contraindications for Surgical Treatment

Indications	Contraindications
Failed medical management	Inability to tolerate surgery
Patient preference	Esophageal cancer or high-grade dysplasia
Gastroesophageal reflux disease complications (stricture, esophagitis)	Morbid obesity (consider gastric bypass)
Contraindications to proton pump inhibitor	
Lung transplant patients	
Atypical symptoms with documented reflux	

SURGICAL TECHNIQUE

Type of Fundoplication

The relationship between hiatal hernia and GERD was not appreciated until the 1950s, when Allison and Barrett in London published what can be considered the first modern antireflux surgery. They described a transthoracic reduction of the herniated stomach with fixation to the diaphragm and reapproximation of the crura, but with a recurrence rate that approached 50%. In the following decade, identification of the lower esophageal sphincter and the first use of manometry provided the physiologic basis to advance ARS. In the late 1950s, Rudolf Nissen described wrapping the stomach around the esophagus, initially to prevent leakage after a repair of an esophageal perforation. He also first described repair of hiatal hernia through an abdominal incision. Dor later described an anterior fundoplication in 1963, and Toupet proposed a posterior fundoplication in 1963.[3] More recently, the procedures have transitioned to laparoscopic and robotic techniques, and endoscopic options are currently being explored.

The most common types of fundoplication are the total, 360 degree wrap (Nissen), the 180 to 270 degree posterior wrap (Toupet), and the 180 degree anterior wrap (Dor) (Fig. 1). Other, less common, options include the DOR procedure, which involves a posterior gastropexy, or the Belsey procedure, a transthoracic posterior plication. Several randomized clinical trials have compared the three most common methods of fundoplication and mostly show equivalent outcomes in terms of safety and symptom resolution. Overall, the Nissen fundoplication provides better GERD control with a slightly increased rate of dysphagia and gas bloat. In general, we favor the total fundoplication with an emphasis on performing a "floppy" Nissen. Some surgeons will perform a partial wrap in patients who have some degree of esophageal dysmotility.

Steps of the Procedure

The steps below describe the most common type of antireflux surgery, a laparoscopic 360 degree Nissen fundoplication. There are a few considerations that can alter this approach in specific patients specifically, the need for mesh placement or an esophageal lengthening procedure. We briefly mention these options, but our focus is on the standard laparoscopic Nissen fundoplication for a patient with a small- to moderate-sized hiatal hernia.

1. Setup and port placement
   a. The patient is placed supine in split-leg positioning. The surgeon usually stands between the patient's legs, with the assistant on the patient's left side. Laparoscopic towers, suction, and camera should be at the head (Fig. 2). The patient will be in a steep reverse Trendelenburg position during the procedure, so some combination of a beanbag "saddle," an axillary pad, foot boards, and/or leg and chest straps are necessary.
   b. Access to the abdomen can be gained either with a Veress needle at Palmer's point or an open Hasson cut down at the 10 mm supraumbilical camera port. The remaining ports are placed roughly in a straight line, with a 5 mm right lateral liver retractor, one 10 mm operating port, one 5 mm right working port, and a 5 mm left lateral assistant port (Fig. 3).
   c. A 10 mm 30 degree scope is typically used. A 0 degree scope can be very useful during the mediastinal dissection.
2. Dissection of the crura and reduction of hiatal hernia
   a. Divide the gastrohepatic (gastrohepatic ligament). There may be an accessory or replaced left hepatic artery here arising from the left gastric; this is preserved if possible and sacrificed if necessary. If the decision is made to take the replaced left hepatic, its actual diameter should be assessed. Some surgeons advocate for temporary reversible clamping if there is a doubt as to its level of contribution. The hepatic branch of the vagus nerve can typically be preserved (Fig. 4).
   b. Identify the right crus and open the pleuroesophageal ligament. Mobilize the right crus away from the esophagus, starting at the 12 o'clock position and working posteriorly to identify the left crus. The dissection is completed bluntly, with care to identify and preserve the anterior vagus nerve. The dissection plane should leave the peritoneal covering on the muscle of the crura. Stripping the peritoneum off the muscle will weaken the crural repair (Fig. 5).
3. Mobilize the esophagus
   a. When the crural dissection is complete, a ¼ inch Penrose drain is placed around the esophagus. It can be secured with large clips or a loop suture tie. This can then be used to provide safe but adequate traction on the esophagus.
   b. The dissection should be carried up into the chest circumferentially around the esophagus, taking care to avoid injuring the anterior and posterior vagus nerves. This dissection can usually be done bluntly, using a bipolar-type cautery device as necessary when small vascular structures are visualized (Fig. 6).
   c. Continue mobilizing cephalad until at least 3 cm and ideally 5 cm of esophagus comes into the abdomen without tension.
4. Ligate and divide the short gastrics
   a. The gastrosplenic ligament is identified and the lesser sac entered at around the level of the bottom of the spleen. Using an energy device, divide the short gastric vessels along the greater curve up to the angle of His, stay slightly away from the stomach to avoid causing thermal injury. Care must be taken to avoid tearing the capsule of the spleen superiorly (Fig. 7).
   b. Confirm that the stomach is mobile enough and that all posterior attachments are fully cleared before crural closure. We will typically place a marking stitch on the lateral edge of the stomach wall, approximately 5 cm distal to the gastroesophageal junction. Pass the fundus posterior to the gastroesophageal junction. The marking stitch should become visible as the fundus is passed from left to right. The fundus should remain in place to the right of the esophagus; if it retracts back after it is released, it is a sign there are more attachments to the spleen or diaphragm that need to be released. Perform a "shoeshine" maneuver by grasping both sides of the fundus and pulling back and forth around the esophagus to demonstrate that the stomach is adequately mobilized (Fig. 8).
5. Crural closure
   a. Release the stomach back to its anatomic position and begin crural closure. At this point, the right crus tends to run mostly straight up and down, whereas the left crus is at an angle. The crural stitches should be placed at a right angle to a line bisecting the triangle made by the two crura, meaning that the stitches will look like they slant downward to the patient's left. This prevents unnecessary tension on the left crus (Fig. 9A).
   b. The crura are reapproximated with three to four nonabsorbable 0 sutures. We prefer to use small polytetrafluoroethylene pledgets for these stitches, taking care to make sure they lie flush against the muscle (Fig. 9B).

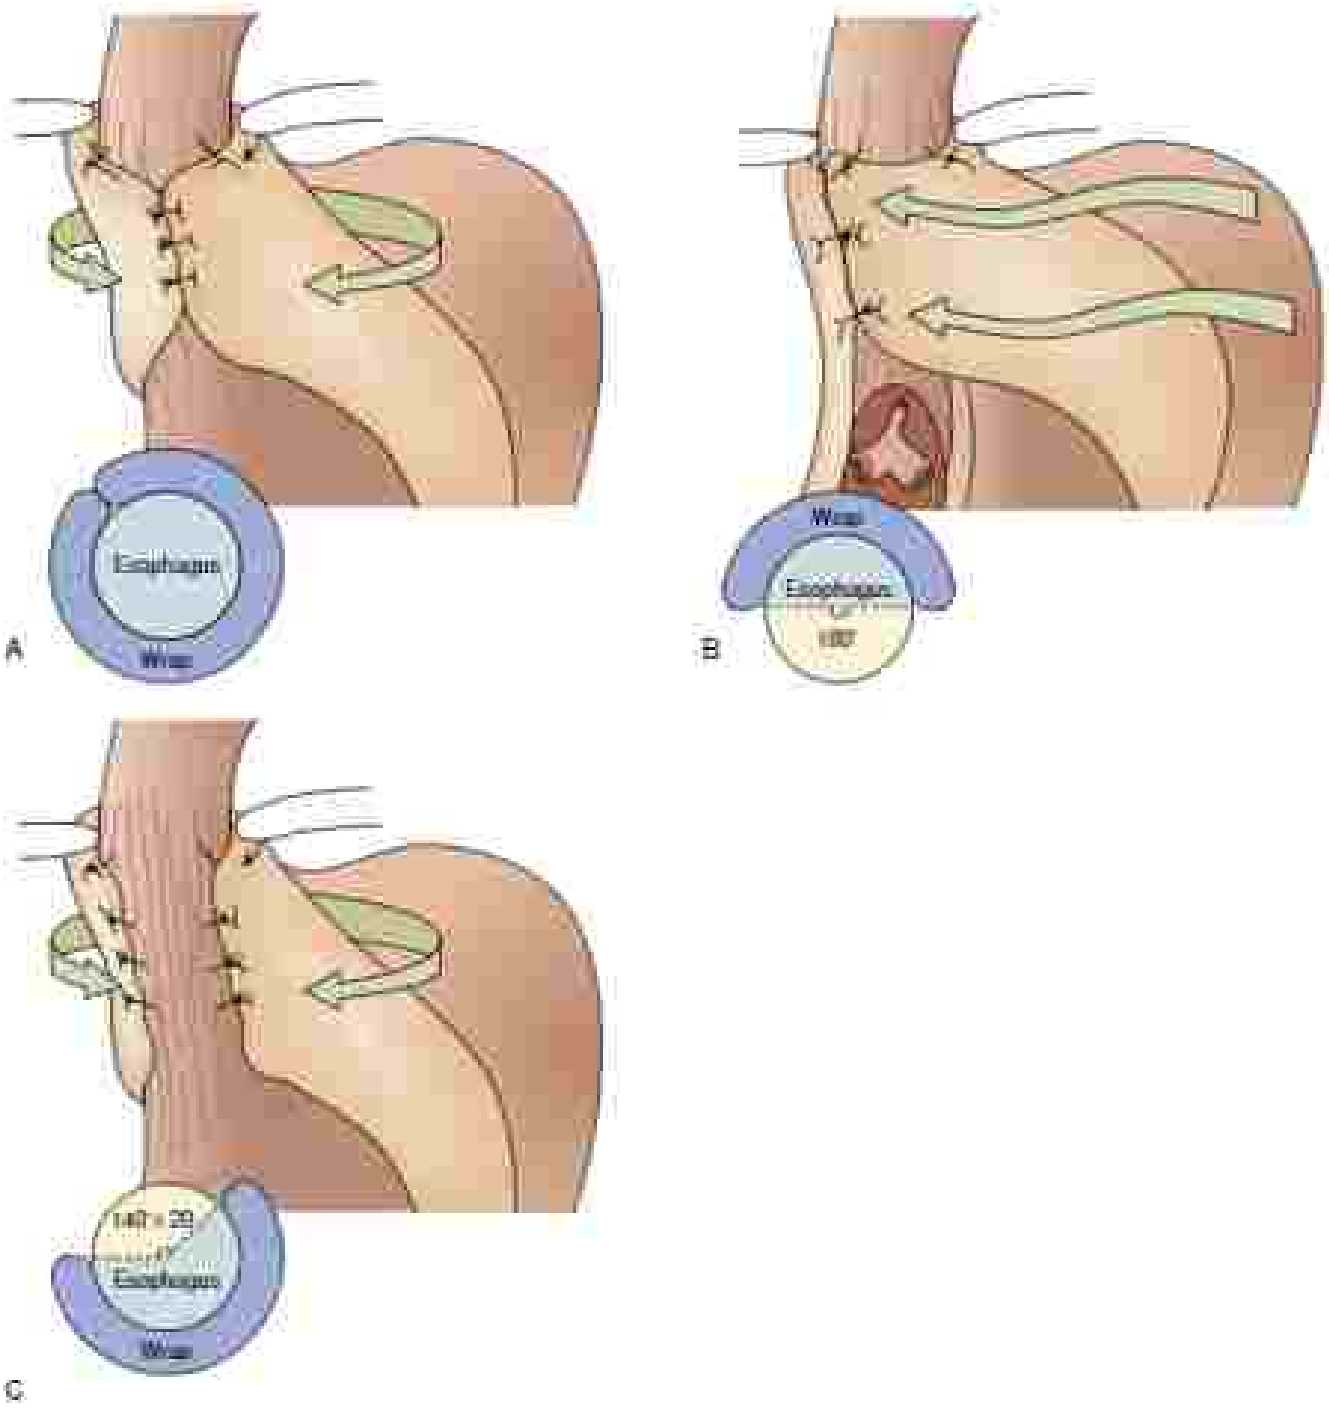

FIG. 1 Types of fundoplication. The most common types of fundoplication are pictured. (**A**) A 360-degree Nissen fundoplication. (**B**) A 180-degree anterior Toupet fundoplication. (**C**) A 300-degree posterior Thal fundoplication.

c. Fundoplication
   a. It is critical not to twist the stomach; the marking stitch helps confirm that the stomach has not twisted as it is passed behind the esophagus.
   b. It is easier to begin the fundoplication before placing a bougie down the esophagus because there will be more laxity. The first two stitches, starting at the marking stitch, should grab stomach on each side. We use nonabsorbable 2-0 braided sutures. The wrap needs to incorporate the fundus, not the body of the stomach.
   c. After the first two stitches are in place, a 52 bougie is placed down the esophagus. There should be no resistance.
   d. Before the third stitch is placed, the thickness of the wrap is verified by easily passing two instruments under the wrap and lifting it away from the esophagus. The third stitch is now placed, taking a small bite of esophageal musculature as well as stomach.
   e. The goal is to create a short, floppy wrap, no more than 3 cm in length (Fig. 1B).
   f. The Penrose is cut and pulled out of the abdomen.

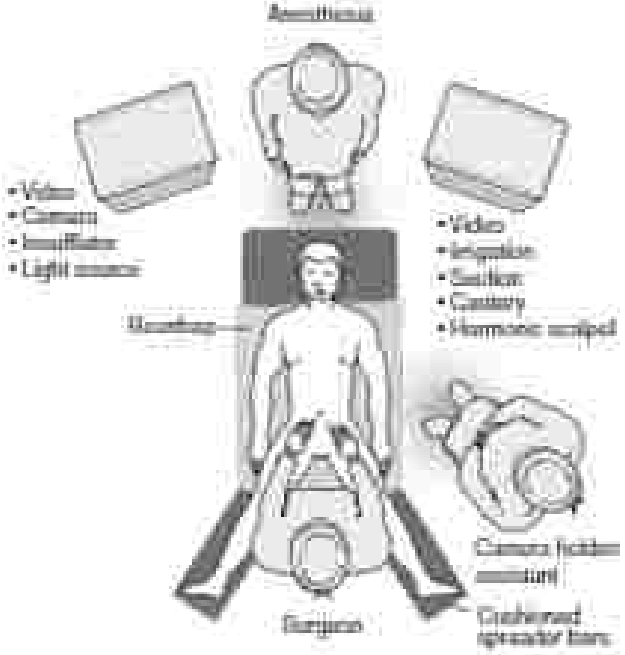

FIG. 2 Patient and room setup for laparoscopic hiatal hernia repair and fundoplication.

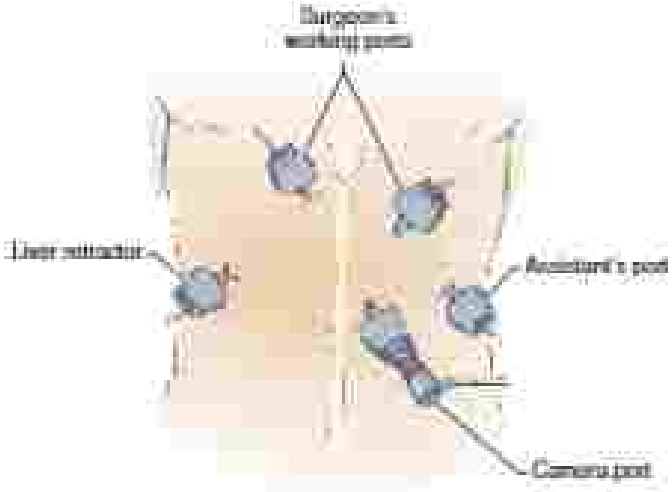

FIG. 3 Typical port positioning for laparoscopic fundoplication. (From Peterson CA, Pearson's Diseases and Disorders. Surgery, ed 2. Philadelphia: Churchill Livingstone; 2008.)

SPECIAL CONSIDERATIONS

When to Use Mesh

Use of prosthetic or biologic mesh has been proposed to further support the crural repair and prevent recurrences and recurrence. The risks of mesh include erosion or infection. Unfortunately, the indications for mesh use are not well defined, and most data come from single surgeon or single center case series. At this time, there are insufficient data to support routine mesh use. In selected patients with very attenuated diaphragm muscles, where crural stitches are very tenuous, surgeons may elect to use a mesh to reinforce the repair. We typically never use mesh in our practice.

When to Do a Lengthening Procedure

Rarely, it is impossible to get adequate intra-abdominal esophageal length because of a short esophagus. In this situation, a Collis

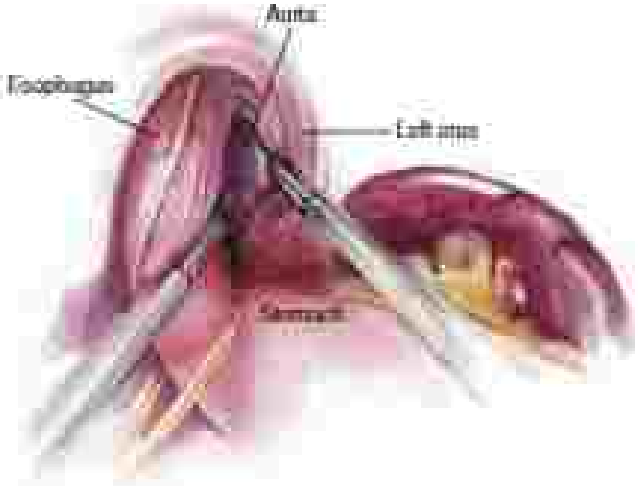

FIG. 6 Dissection around the esophagus. Using a Penrose (nondistensible) for retraction, dissection is completed mostly bluntly with an energy device to minimize axial flaws or muscle that may bleed. (Courtesy Connor Sanders. From Gamblin TC, Sanders C. Atlas of Gastrointestinal Surgery, ed 1. Philadelphia: Lippincott Williams & Wilkins; 2007.)

FIG. 7 Dividing the short gastrics. (From Taylor MJ, Swanstrom LL, Colavita PD, et al. Mastery of Endoscopic and Laparoscopic Surgery. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2005:139.)

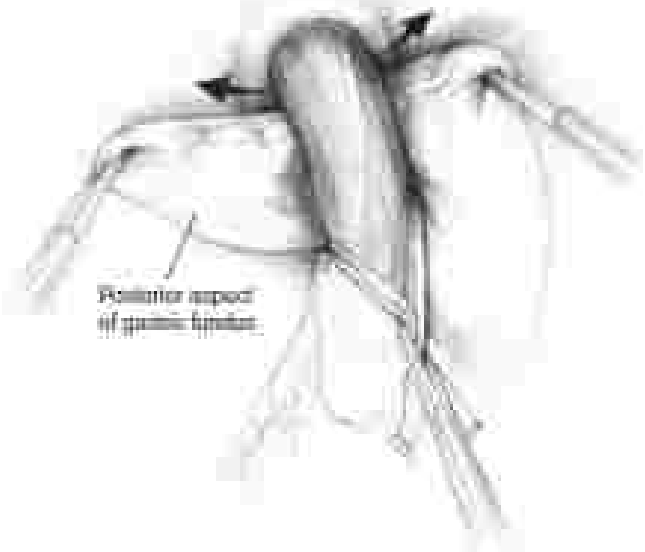

FIG. 8 Posterior mobilization. (From Atlas of Minimally Invasive Surgical Operations. New York: McGraw-Hill; 2000. Fig. 6.2 courtesy Caroline Sanders; copyright John Hopkins University.)

gastroplasty is necessary. A linear stapler is used to create a 4- to 5-cm tube of proximal stomach, using a bougie to prevent narrowing the neoesophagus. The gastric tube still contains acid-secreting mucosa, so ongoing acid reflux is more likely when a gastroplasty is performed. In our experience, in the absence of risk factors such as radiation or prior antireflux surgery, this procedure is rarely necessary if adequate time and care is taken for the esophageal dissection.

When to Consider an Open Approach

An open approach is usually needed only if the laparoscopic approach is not possible because of adhesions, technical difficulties, or uncontrolled bleeding. An upper midline laparotomy from the xiphoid process to the umbilicus is made. The left triangular ligament is divided to retract the left lobe of the liver laterally. From there, the steps of the operation are the same as described for the laparoscopic approach.

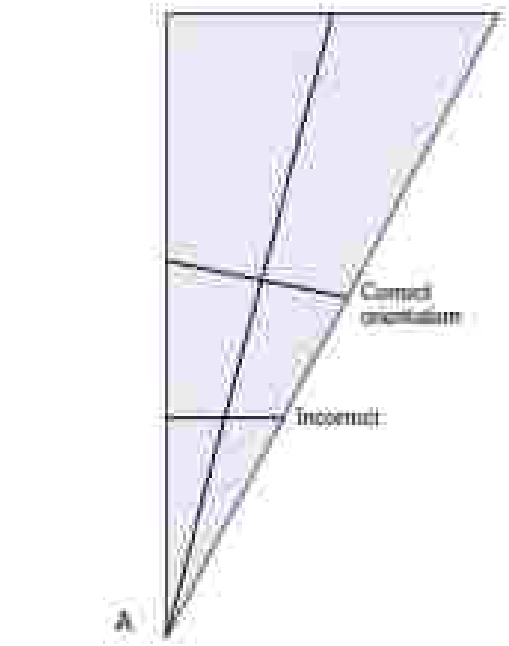

FIG. 9 Closure of the crura. (A) Anatomy of the crura; the right crus is oriented mostly vertical and the left crus is angled. Sutures should be placed at a right angle to a line bisecting the change, rather than at a right angle to the crus itself. (B) Three crural stitch.

When to Consider a Thoracic Approach

It is possible to perform a fundoplication through a thoracotomy. This approach can be helpful in the setting of a hostile abdomen, extremely large hiatal hernia, or short esophagus. The 270 degree Belsey Mark IV fundoplication is performed through a thoracic approach.

POSTOPERATIVE CARE

Patients are generally admitted overnight, with medications for pain and nausea. Many surgeons choose to obtain a barium esophagogram on the first postoperative day. After the swallow study, patients are started on a full liquid diet and discharged. They stay on a soft diet for 4 to 6 weeks. Acid reducing medications should be discontinued after 6 weeks at the latest, and all pills should be crushed

for the first 3 to 4 weeks. Although most patients will complain of dull upper abdominal and chest pain from the midsternal dissection, acute onset of severe chest pain or respiratory distress in the immediate postoperative period should trigger a UGIS to rule out acute wrap herniation.

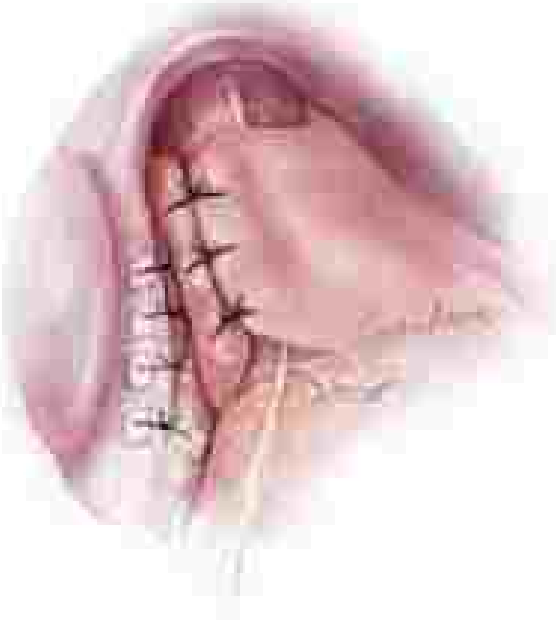

FIG. 10 Completed fundoplication. (Courtesy Cotton Sanders from Cameron JL, Sanders C. Atlas of Gastrointestinal Surgery, ed 1. Hamilton, Ontario: B.C. Decker's Medical Publishing; 2004.)

POSTOPERATIVE COMPLICATIONS AND REDO FUNDOPLICATION

1. Dysphagia. Mild dysphagia is extremely common and patients can usually be instructed to eat a soft diet until symptoms resolve. In less than 5% of patients, dysphagia persists beyond 6 weeks and requires further workup. Causes include a tight wrap, slippage, or herniation. For a tight wrap, endoscopic dilation is safe beginning at six weeks postoperatively.
2. Gas bloat syndrome. The wrap can prevent patients from belching, and the accumulation of gas in the stomach can present as epigastric pain, abdominal distention, and inability to belch or vomit, with increased flatus. Most patients will experience some level of gas bloating and should be appropriately counseled preoperatively. With adequate dietary and lifestyle modifications, symptom improvement or resolution usually occurs within 6 weeks, but if severe symptoms persist, an endoscopy for possible dilation might be useful.
3. Recurrent GERD. The majority of patients with recurrent symptoms do not actually have documented reflux on pH testing. This emphasizes the importance of pH testing preoperatively to have a comparison study. True recurrence of reflux can be treated with PPI or considered for revision of the fundoplication, especially if it is accompanied by an anatomic failure.
4. Esophageal or gastric dysmotility. Dysmotility that is present preoperatively can result in a failure of ARS postoperatively, and again highlights the importance of a preoperative workup. If the esophagus had normal motility preoperatively, postoperative dysmotility can result from an overtight wrap. If there was no gastroparesis preoperatively, symptoms of gastric dysmotility can be caused by an iatrogenic vagal injury. Treatment options include pyloric flutes, gastric pacing, or pyloromyotomy.
5. Anatomic failures (Fig. 11). Anatomic failure of the wrap can result in any of the symptoms mentioned. Most failures occur within 2 years of the primary operation. By far the most common

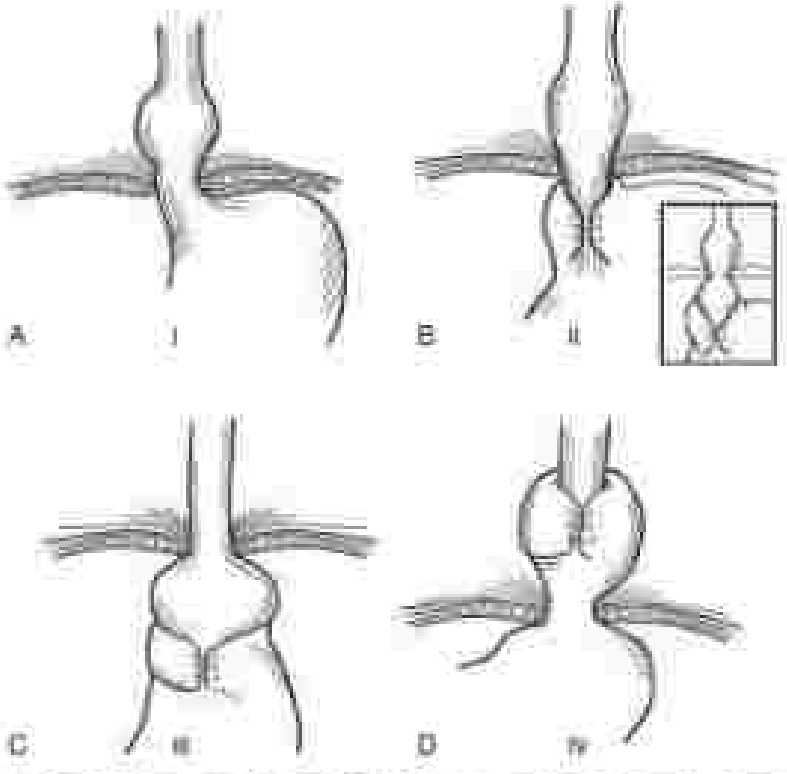

FIG. 11 Patterns of wrap failure. (A) Complete disruption. (B) "Upper" wrap. (C) Migrated wrap. (D) Paraesophageal herniation. (From Mellow MH, Carson esophageal reflux disease. In: Bell RJ, Gibbons RJ, Mulholland MW, eds. Digestive Tract Surgery. Scientific and Action Philadelphia: Lippincott-Raven; 1995:1.)

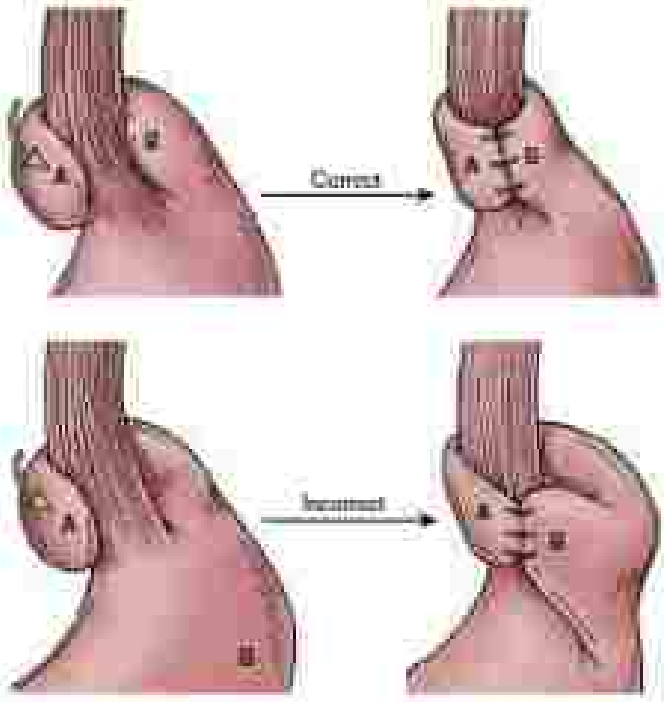

FIG. 12 Plain radiograph of misplaced wrap. The wrap is rotated with the gastric body instead of the fundus. (From Small CJ, McCluskey DA, Brand MA, Todorovic M, Hazey JL. Does fundoplication fail well? Ann Surg 2005;241[5]:861–869.)

reason for failure is herniation of the wrap into the chest (Fig. 11D). Other causes include wrap disruption (Fig. 11A), slipped wrap (Fig. 11B), or crural stenosis/tight wrap. Technical errors from the index operation can result in a need for reoperation, but in experienced hands this is rare. The most common technical failure is a misplaced fundoplication, using the gastric body instead of the fundus for the wrap (Fig. 12).

Magnetic Augmentation of the Lower Esophageal Sphincter

Andrew M. Bauer, MD, et al

HISTORY

Gastroesophageal reflux disease (GERD) is a condition of high prevalence and increasing incidence in the western world linked to the development of Barrett's metaplasia and its progression through dysplasia to esophageal cancer. The magnetic sphincter augmentation device (MSA) (LINX, Torax Medical) provides an equally efficacious alternative to circumferential gastric fundoplication of the esophagus to treat GERD. The MSA can be used regardless of the presence of a hiatal hernia or the surgical absence of the gastric fundus, with lower rates of a postoperative inability to belch or vomit than with traditional procedures. The MSA device is associated with early dysphagia and odynophagia, which improves over time and resolves completely in more than 95% patients.

MECHANICS AND PHYSIOLOGY

The MSA device is operatively placed proximally to the anatomic gastroesophageal junction (GEJ) at the high pressure efferent zone of the lower esophageal sphincter (LES). The device's function is optimized by alignment with the compressive force exerted by the diaphragmatic crura and, as such, requires the reduction of any hiatal hernia and the restoration of normal physiologic approximation of the crural rails at the time of implantation. (See sphincter legend text). In this position, the MSA dynamically augments the pathologically weak LES, restoring a competent physiologic acid barrier with minimal impact on normal peristaltic or regurgitative functions of the stomach and esophagus. The device is not compressive and does not squeeze the LES closed. The device rests loosely around the esophagus and prevents opening of the LES, thereby increasing the yield pressure. The MSA expands by bead separation to allow passage of a liquid or solid bolus propelled distally by peristalsis, or as a bolus or retrieval bolus moves proximally from the stomach into the esophagus. After bolus transit, the magnetic beads are reapproximated by the force of magnetic attraction (Fig. 1). Normal or near normal peristaltic force is required to reliably open the MSA device during swallowing and to avoid troublesome postoperative dysphagia and stasis.

INDICATIONS

The MSA device is indicated in the treatment of any patient with adequate esophageal motility and an appropriate work up confirming a diagnosis of GERD, with several exceptions. The MSA device cannot be implanted in the setting of intraabdominal infection, at the time of resection of an enteric lumen, in patients with a nickel or titanium allergy or in those who have a future need for magnetic resonance imaging greater than 1.5 Tesla. In addition to these contraindications, precautions currently listed by the Food and Drug Administration can be seen in Box 1. The MSA device is useful not only as an alternative to complete (Nissen) fundoplication, but also potentially in patients who have previously undergone sleeve gastrectomy—a population in whom fundoplication is generally not an option due to inadequate gastric fundus. Clinical trials on its efficacy in this population are currently ongoing. Like the Nissen fundoplication, the MSA

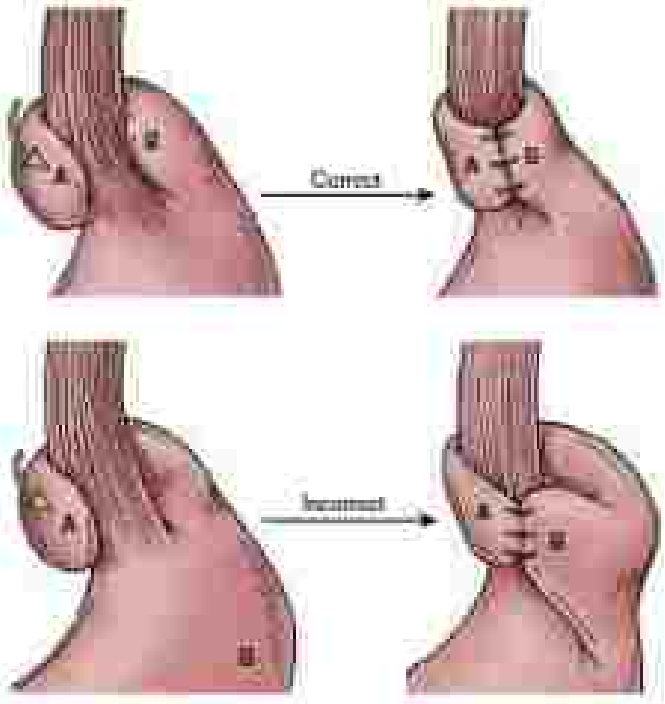

FIG. 12 Plain anterior view of implanted wrap. The wrap is secured with the gastric body instead of the fundus. (From Small CJ, McCarthy DA, Brand MA, Lederman AB, Hazey JC. When fundoplication fails redo? Ann Surg 2005;241[5]:861–869.)

reason for failure is herniation of the wrap into the chest (Fig. 11D). Other causes include wrap disruption (Fig. 11A), slipped wrap (Fig. 11B), or cranial stenosis/tight wrap. Technical errors from the index operation can result in a need for reoperation, but in experienced hands this is rare. The most common technical failure is a misplaced fundoplication, using the gastric body instead of the fundus for the wrap (Fig. 12).

Magnetic Augmentation of the Lower Esophageal Sphincter

James M. Tatum, MD, and John C. Lipham, MD

HISTORY

Gastroesophageal reflux disease (GERD) is a condition of high prevalence and increasing incidence in the western world linked to the development of Barrett's metaplasia and its progression through dysplasia to esophageal cancer. The magnetic sphincter augmentation device (MSA) (LINX, Torax Medical) provides an equally efficacious alternative to circumferential gastric fundoplication of the esophagus to treat GERD. The MSA can be used regardless of the presence of a hiatal hernia or the surgical absence of the gastric fundus, with lower rates of a postoperative inability to belch or vomit than with traditional procedures. The MSA device is associated with early dysphagia and odynophagia, which improves over time and resolves completely in more than 95% patients.

MECHANICS AND PHYSIOLOGY

The MSA device is operatively placed proximally to the anatomic gastroesophageal junction (GEJ) at the high pressure efferent zone of the lower esophageal sphincter (LES). The device's function is optimized by alignment with the compressive force exerted by the diaphragmatic crura and, as such, requires the reduction of any hiatal hernia and the restoration of normal physiologic approximation of the crural rails at the time of implantation. (See sphincter legend ends). In this position, the MSA dynamically augments the pathologically weak LES, restoring a competent physiologic acid barrier with minimal impact on normal peristaltic or regurgitative functions of the stomach and esophagus. The device is not compressive and does not squeeze the LES closed. The device rests loosely around the esophagus and prevents opening of the LES, thereby increasing the yield pressure. The MSA expands by bead separation to allow passage of a liquid or solid bolus propelled distally by peristalsis, or as a bolus or retrieval bolus moves proximally from the stomach into the esophagus. After bolus transit, the magnetic beads are reapproximated by the force of magnetic attraction (Fig. 1). Normal or near normal peristaltic force is required to reliably open the MSA device during swallowing and to avoid troublesome postoperative dysphagia and stasis.

INDICATIONS

The MSA device is indicated in the treatment of any patient with adequate esophageal motility and an appropriate work up confirming a diagnosis of GERD, with several exceptions. The MSA device cannot be implanted in the setting of intraabdominal infection, at the time of resection of an enteric lumen, in patients with a nickel or titanium allergy or in those who have a future need for magnetic resonance imaging greater than 1.5 Tesla. In addition to these contraindications, precautions currently listed by the Food and Drug Administration can be seen in Box 1. The MSA device is useful not only as an alternative to complete (Nissen) fundoplication, but also potentially in patients who have previously undergone sleeve gastrectomy – a population in whom fundoplication is generally not an option due to inadequate gastric fundus. Clinical trials on its efficacy in this population are currently ongoing. Like the Nissen fundoplication, the MSA

FIG. 1 Magnetic sphincter augmentation device (LINX). The MSA device consists of an expandable bracelet-like ring of magnetic beads as its placed around the distal esophagus. The beads are connected by interposed titanium wires, limiting meaningful separation and maintaining basal spacing. (A) At rest the magnetic forces keep the MSA device in the closed configuration without creating pressure on the wall of the esophagus, maintaining its configuration to human anti-design. (B) It passes. (Courtesy Torax Medical, Inc.)

BOX 1 Contraindication and Precautions to the Use of the MSA

Contraindications

- Known or suspected allergy to titanium, nickel, steel, or any implant metal

Precautions

- Scleroderma
- Suspected or confirmed esophageal or gastric cancer
- Prior esophageal or gastric surgery or endoscopic intervention
- Distal esophageal motility < 45 mm Hg peristaltic amplitude on wet swallows or <70% (productive) peristaltic sequences on high-resolution manometry equivalent, or known motility disorder
- Symptoms of dysphagia more than once wk within the last 3 months
- Esophageal or gastric varices
- Lactating, pregnant, or planning to become pregnant
- Age <21 yr
- Los Angeles Classification grade C or D esophagitis or known Barrett's metaplasia
- Patients with electrical implants such as pacemaker, defibrillator, or other metallic abdominal implants

Warning

- Conditional compatibility with MR imaging up to 0.7 0.7T MRI or 1.5 1.5T, depending on early or late generation MSA device

MRI, Magnetic resonance imaging; MSA, magnetic sphincter augmentation device.

device to be advised in patients with abnormal esophageal motility. These patients may be better served by partial fundoplication, bypass, or medical therapy alone.

The MSA device, although not initially indicated for use in patients at the time of the repair of a large hiatal hernia, has in preliminary studies been shown to be equally effective while also potentially preventing early recurrence of hiatal hernias. The low hiatal hernia recurrence rate is likely the result of the adhesive inflammatory response generated at the diaphragmatic hiatus after implantation, as well as the improved ability to vent the stomach when compared with a Nissen fundoplication, preventing early mechanical stress on the healing crural plication.

PATIENT EVALUATION, SELECTION, AND EXCLUSION

The evaluation of patients with suspected reflux is the same as it would be in preparation for a fundoplication procedure. Upper endoscopy must be performed to assess for hiatal hernia, esophagitis, metaplasia, dysplasia, or tumor. We routinely perform endoscopic biopsy of squamocolumnar junction, as well as any abnormal appearing tissue at the time of endoscopy and deploy an ambulatory pH probe. The diagnosis of GERD requires the objective documentation of pathologic levels of acid reflux into the esophagus, because such pH testing is performed in all patients. Adequate motility must be confirmed before offering any surgical procedure. All patients in our practice undergo diagnostic evaluation with a video swallow esophagram to assess for both hiatal hernia and adequacy of bolus transport. Any suggestion of motility disorder or pseudoesophagus is followed by formal high-resolution manometric (HRM) studies. Patients with evidence of inadequate peristalsis are not candidates for MSA. HRM demonstrating ineffective esophageal motility by the Chicago Classification Criteria (v3.0) (>50% ineffective swallows with a distal contractive index <450 mm Hg • s • cm) are offered at most partial fundoplication.

SURGICAL TECHNIQUE

Preparation and Positioning

The patient is placed in low lithotomy with arms tucked and legs secured to facilitate deep reverse Trendelenburg positioning. Legs are kept neutral at the hips and spread at an angle to accommodate the surgeon positioned between the patient's legs. This is the same patient positioning used when performing laparoscopic Nissen fundoplication.

An initial 5-mm optically guided trocar is placed without insufflation into the supra-abdomen, approximately 2 cm superior and 2 cm to the left of midline with a 0 degree scope. The abdomen is insufflated, and the 5-mm 0 degree laparoscope is switched to a 5-mm 30-degree laparoscope. An 8 mm trocar is introduced through the left upper quadrant to midclavicular line 2 cm caudal to the costal margin. This 8-mm trocar facilitates the later introduction of the MSA device, as well as suture to repair the hiatal hernia. A 5-mm trocar is then placed in the right upper quadrant at the mid-clavicular line 2 cm inferior to the costal margin. A Nathanson liver retractor is introduced through a trocar stab wound directly below the xiphoid along the midline. An additional 5-mm assistant's port is placed approximately 5 cm caudal and 5 cm lateral to the 8 mm port.

Dissection of the Crura and Hiatus

Complete dissection of the GEJ at the hiatus is standard in our practice, given the poor sensitivity and reliability of videoesophagography or endoscopy for the diagnosis of small hiatal hernia and the added benefit of a right hiatus in maintaining the competence of the physiologic acid barrier. The gore flaccida is opened toward the hiatus with the hepatic branch of the posterior vagus

nerve. Taken with impunity. If encountered, an accessory left hepatic artery can be compressed to occlusion with an atraumatic grasper while the left lobe of the liver is observed. A change in perfusion mandates preservation of the artery; otherwise when encountered is ligated and divided. Sharp then blunt dissection of peritoneum and phrenoesophageal membrane is carried out in a clockwise fashion around the crura. The stomach is then again retracted laterally toward the patient's left, and careful dissection inferior to the esophagus is completed with the creation of a retroesophageal window, through which a Penrose drain is passed and secured around the esophagus and grasped by the assistant. Retraction on the Penrose facilitates exposure and traction of the esophagus allowing completion of the hiatal dissection and reduction of hiatal hernia if present. At least 3 cm of esophagus should be easily reducible into the abdomen.

Crural Closure

The right and left crura are approximated with two to three figure-of-eight 0 braided absorbable sutures to create a snug hiatal opening. The esophageal hiatus should only allow the easy passage of a single 5 mm laparoscopic grasper (Fig. 2).

Identification and Dissection of the Posterior Vagus Nerve

After the hiatal portion of the procedure, the posterior vagus nerve must be identified. The nerve passes from the posterior to the right side of the intraabdominal esophagus. The nerve is taut and has a character reminiscent of the vas deferens. Once identified, a site approximately just proximal to the anatomic GEJ (located approximately where the phrenoesophageal ligament/hiatal hernia sac inserts on the esophageal wall) is identified, and the nerve is gently hooked and pulled away from the body of the esophagus with a Maryland grasper. A passage is dissected between the nerve and the esophageal body by gentle and precise dissection with the closed scissors and closed Maryland grasper. The passage between the vagus and esophageal body must only be large enough for the grasper to easily fit through. A grasper is then passed between the posterior vagus nerve and the esophagus from medial to lateral and through the retroesophageal window (Fig. 3). A Penrose drain is placed into the left-hand grasper with the surgeon's right hand and then retracted medially through the tunnel, anterior to the posterior vagus nerve and around the esophagus. The ends of the drain are dropped.

Device Sizing

Any temperature probe or gastric tubes placed by anesthesia are to be removed before sizing. Torax medical has a proprietary measurement that is necessary for device sizing. The instrument consists of a magnet tipped probe extendable from a hard plastic housing. The device is placed following the course of the previously placed Penrose drain, between the posterior vagus nerve and the esophageal wall. The magnet tipped probe is the extended and wrapped around the esophagus, loosely attaching by means of magnetism to a metal band on the rigid plastic housing and making a loop around the esophagus (Fig. 4). To obtain the appropriate measurement, we use two visual cues. A ratcheting device on the tool's handle is gently retracted, tightening the sizing loop as a lasso. The first visual cue is when the sizing loop rests comfortably around the esophagus, without compression of the tissue. The device should not compress the esophagus; instead, it should rest loosely around the esophagus. The second visual cue is obtained by continuing to ratchet down the sizing loop until the magnet separates and the sizing loop opens. There sizes above the loop separation measurement is the appropriate size and should correlate with the first visual cue—where the sizing loop rests comfortably around the esophagus without compression. The two sizing methods are then compared. If they do not correlate, the larger one is used for device selection. A window on the device's handle indicates the size of the esophagus throughout this process. The measuring procedure is repeated twice to ensure correct measurement.

FIG. 2 Closure of the esophageal crura (Illustrated by Tiki Ly, copyright UIC Department of Surgery).

FIG. 3 Dissection of the posterior vagus nerve from the esophageal wall. (Illustrated by Tiki Ly, copyright UIC Department of Surgery)

Device Placement

The sizing device is removed, and the Penrose drain is left in place. The MSA device is then brought into the abdomen through the 8 mm trocar. There is a looped suture at each end of the

FIG. 4 Insertion of ring dilator between the posterior vagus nerve and esophageal wall. (Illustrated by Yale Jay, copyright UNC Department of Surgery)

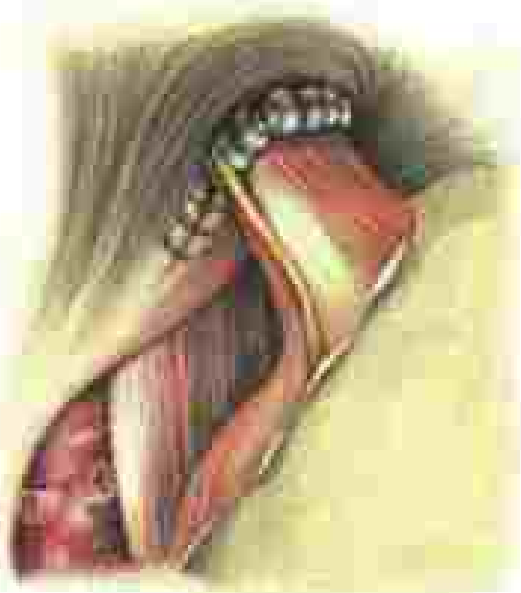

FIG. 5 MSA device placed with clasp secured in its final position, approximately 3 cm caudad to the insertion of the gastroesophageal ligament on the esophageal wall, in the plane and flush with the diaphragmatic crura. (Illustrated by Yale Jay, copyright UNC Department of Surgery)

device, allowing it to be grasped with the laparoscopic graspers. The device is brought from lateral to medial around the esophagus in the same fashion as the Penrose drain was initially placed. The Penrose drain should be left in place, with the ends free, during insertion to aid in its passage through the retroesophageal tunnel. The free ends of the MSA device are then brought together, with care being taken not to capture loose tissue between the two joining magnets. Gentle agitation of the two magnets with a grasper prompts coupling. The Penrose drain is then removed, and the looped sutures are snipped free from the device, completing the procedure (Fig. 5).

Postoperative Care

Patients who undergo repair of a large hiatal hernia are admitted overnight. Other patients are routinely discharged home the day of surgery. All patients are sent home on a soft diet immediately after surgery, with a regular diet as tolerated. The diet of patients after MSA implantation is different and more important to long-term patient outcome and satisfaction than the diet after fundoplication. In the first 4 weeks after implantation, it is critical that MSA patients take frequent small meals of a soft or regular diet every 2 to 3 hours while awake to get the device to open and close, preventing it from becoming encapsulated in the closed position. Patients are told that this is physical therapy for the device in much the same way that a prosthetic knee needs to be exercised in the early postoperative period. These early and frequent small meals have seemingly decreased the incidence of long-term dysphagia.

RESULTS OF TREATMENT

Postoperative Complications

Immediate postoperative dysphagia is the most common side effect of MSA placement. Incidence and speed of resolution is reduced in patients who can take multiple (6) small meals per day for the first 4 weeks after surgery. If patients are unable to tolerate solid foods and are struggling with oral intake, a short course of steroids usually will help them get back to eating solid food and continuing the physical therapy of the device. We refrain from balloon dilation via endoscopy within the first 3 months, because this usually causes more inflammation and makes the dysphagia worse. If patients have persistent dysphagia after 3 months, dilating the area with a 15- to 18-mm balloon does seem to help.

Erosion, Persistent Dysphagia and Device Removal

Erosion occurs in 0.3% to 0.4% of patients. Erosions present with new-onset dysphagia 1 to 3 years after surgery, usually with 1 or 2 beads having eroded into the esophageal lumen, creating a contained perforation of the esophagus into the capsule surrounding the MSA device. Eroded devices can be removed endoscopically or with a combination of endoscopy and laparoscopy. No patient has needed an esophagectomy or gastrectomy due to device erosion.

Persistent dysphagia accounts for most of reported incidences of device removal. In the current series, between 2% to 6% of MSA devices require removal at follow up, out to 10 years in the longest series. Removal of the device is accomplished laparoscopically via exposure identical to that used for placement. An intense inflammatory capsule is present around the MSA device in the early postoperative period, but, by 8 weeks after surgery, this has begun to mature. The MSA device is located within the adhesive capsule around the esophagus, electrocautery is then used to expose the body of several beads anteriorly. The beads are made of titanium and do not transmit electrical current to underlying esophageal wall. Each bead to be torn grasped, retracted, and dissected free from the capsule. A single inter-bead wire is then cut with heavy shears, and the entire device is pulled free from its capsule in one piece and removed from the body. Fundoplication may then be accomplished in an immediate or staged fashion when the device is removed for persistent reflux. In our experience, fundoplication has not been needed to prevent reflux symptoms when the device is removed exclusively for dysphagia, likely owing to the inflammatory capsule alone often preventing recurrent acid reflux (Tatum).

Immediate Outcomes

The antireflux effects of the MSA procedure are immediate. Patients can be weaned from antireflux medications starting the day of surgery, with most patients being off of all pharmacologic therapy by 2 weeks after surgery. The importance of frequent oral intake in the 3 month period after surgery must be emphasized to patients to ensure good outcomes. Failure to induce frequent expansion of the MSA device with swallowing results in the MSA device becoming encapsulated in the contracted position, resulting in persistent dysphagia.

Long-Term Outcomes

Long term control of GERD symptoms is similar to the results after Nissen fundoplication in series extending nearly a decade since the adoption of the MSA into surgical practice (Ganz, 2016). Early results suggest that the MSA device may affect some regression of Barrett's esophagus at a rate similar to what has been experienced with Nissen fundoplication (Abraham, 2018). A randomized controlled trial by Bell and Lipham (2016) randomized patients with regurgitation symptoms on once daily proton pump inhibitor (PPI) to either twice daily PPI or MSA device implantation and found that 100% of patients had relief of regurgitation at 6 months compared with MSA vs only 10% of patients on PPI therapy alone, demonstrating that MSA is effective for not only the pain of reflux, but also the regurgitation that remains troubling to many patients on PPI therapy. Reflux control at 5-years' follow up has remained excellent—more than 84% of patients remain off of PPI, and moderate to severe regurgitation in 97% of patients before surgery remains low at 1.3% (Ganz, 2016). The repair of large hiatal hernia and placement of the MSA instead of performing a Nissen fundoplication has become widely accepted. Rates of hiatal hernia recurrence after repair accompanied by MSA device placement are at least equivalent to those after repair with fundoplication, with only a 4% recurrence at a median of 19 months in a recent series (Reiter, 2018).

CONCLUSION

The MSA device has not replaced fundoplication for patients with GERD, but it has provided a less invasive, durable alternative to Nissen fundoplication. It has also been shown to control reflux in patients with large hiatal hernias with an acceptably low recurrence rate. The advantages of MSA over the Nissen in the correct patient are a faster operative and recovery time, retention of the ability to belch or vomit, and the reversibility of an easily removable device that does not permanently alter gastric anatomy. The MSA is an acceptable alternative to Nissen fundoplication with what appears to be many advantages.

Management of Barrett's Esophagus

Anna Sophia Jackson, MD, and Brian C. [illegible], M.D., MHA, M.H.S., F.A.C.S., A.C.S.

DEFINITION OF BARRETT'S ESOPHAGUS AND TREATMENT OBJECTIVES

Barrett's esophagus (BE) is defined as the replacement of the normal squamous epithelium lining the distal esophagus with metaplastic columnar epithelium containing goblet cells. The contemporary definition of BE requires endoscopy, with biopsy demonstrating a visible segment of columnar epithelium and intestinal metaplasia with goblet cells (Fig. 1). BE is an acquired condition secondary to chronic esophageal injury and inflammation caused by both acidic and alkaline gastroesophageal reflux disease (GERD). It is conservatively estimated that 6% to 10% of GERD patients with GERD will develop BE, with a large majority of cases going unrecognized. BE is the major risk factor for esophageal adenocarcinoma (EAC), and management goals for patients with BE are directed at treating the underlying cause of BE (GERD), preventing progression of BE, and treatment of dysplastic BE before it transforms into EAC.

CLINICAL EFFECT AND FEATURES OF BARRETT'S ESOPHAGUS

The greatest clinical concern with BE is the risk of progression to EAC, a malignancy that has been rising in incidence over the past several decades. Many studies have shown that the presence of BE can

Immediate Outcomes

Management of Barrett's Esophagus

Anna Sophia Jackson, MD, and Brian E. Louie, MD, MHA, MPH, FRCSC, FACS

DEFINITION OF BARRETT'S ESOPHAGUS AND TREATMENT OBJECTIVES

Barrett's esophagus (BE) is defined as the replacement of the normal squamous epithelium lining the distal esophagus with metaplastic columnar epithelium containing goblet cells. The contemporary definition of BE requires endoscopy, with biopsy demonstrating a visible segment of columnar epithelium and intestinal metaplasia with goblet cells (Fig. 1). BE is an acquired condition secondary to chronic esophageal injury and inflammation caused by both acidic and alkaline gastroesophageal reflux disease (GERD). It is conservatively estimated that 6% to 10% of GERD patients with GERD will develop BE, with a large majority of cases going unrecognized. BE is the major risk factor for esophageal adenocarcinoma (EAC), and management goals for patients with BE are directed at treating the underlying cause of BE (GERD), preventing progression of BE, and treatment of dysplastic BE before it transforms into EAC.

CLINICAL EFFECT AND FEATURES OF BARRETT'S ESOPHAGUS

The greatest clinical concern with BE is the risk of progression to EAC, a malignancy that has been rising in incidence over the past several decades. Many studies have shown that the presence of BE can

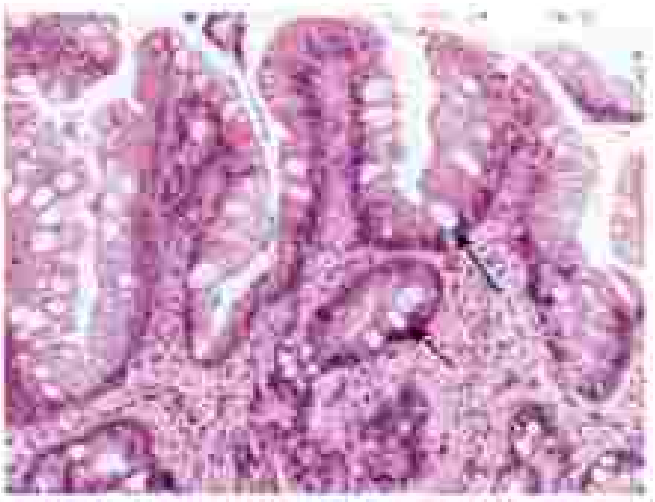

FIG. 1 Intestinal metaplasia with goblet cells present.

center at least a 40-fold increase in the risk for development of EAC compared with the general population, with some studies showing up to a 125-fold increase in risk. Despite the increased cancer risk, most patients do not progress to EAC, with an overall annual rate of neoplastic transformation estimated at 0.13% to 0.5%. In a study by Cameron and colleagues, the estimated median age of the development of BE is approximately 40 years; however, the mean age for the first endoscopic diagnosis of BE without carcinoma was 63 years. This demonstrates that BE may develop approximately 20 years before it is clinically recognized.

The natural progression of BE to carcinoma develops over time from nondysplastic columnar epithelium to dysplasia to carcinoma. Within the dysplastic phase, there is a progression from low-grade dysplasia (LGD) to high-grade dysplasia (HGD). LGD is differentiated from HGD by degree of architectural and cytologic distortions. There is much reported interobserver variability in diagnosing LGD versus HGD. The sequence of progression is driven by genetic and epigenetic events that eventually lead to a loss of genetic stability. The progression of BE to cancer is unpredictable, with a recent meta-analysis reporting that the overall risk of progression from HGD to EAC is 6% per patient per year.

Chronic exposure of the squamous-lined esophagus to both acid and duodenal secretions during reflux causes damage to the epithelium, inducing mucosal injury. With exposure to both acidic and alkaline gastroesophageal reflux activity alterations, the inflammatory cascade is initiated, promoting cellular proliferation and inducing genetic alterations and causing genetic destabilization through transcription factors, inflammatory cytokines, and other stimulators such as free radicals. The genetic alterations have been shown to correlate with the severity of GERD. In addition to chronic reflux, additional risk factors for the development of BE include family history, tobacco use, obesity, presence of hiatal hernia, white race, male gender, and age greater than 50 years.

SCREENING AND EVALUATION OF BARRETT'S ESOPHAGUS

Screening

Routine screening for BE of the general population is not recommended; however, based on duration and frequency of reflux combined with other risk factors, screening may be considered in high-risk patients based on current guidelines. A thorough history from patients helps elucidate the duration and frequency of their symptoms as well as additional risk factors they may have for the development of BE or EAC. The American College of Gastroenterology Clinical Guidelines recommend screening for BE with white light endoscopy in men with chronic (>5 years) and/or frequent (weekly or more) symptoms of GERD and two or more risk factors for BE or EAC including age greater than 50 years, white, elevated body mass index, history of smoking, and family history of BE or EAC. Given the substantially lower risk of EAC in females with chronic GERD, screening is not recommended; however, in individual cases of female patients, it can be considered based on risk factors.

Evaluation

On endoscopy, BE should be suspected when the columnar epithelium that appears salmon pink in color is noted proximal to the gastroesophageal junction (GEJ), which is defined endoscopically as the most proximal extent of the gastric folds (Fig. 2). The goal is to identify any areas of columnar replacement of the esophagus as well as any areas of irregularity within the columnar segments. For reporting purposes, BE is often divided into short or long segment with short segment BE defined as <3 cm; however, currently it is recommended to use the more objective Prague classification that defines the circumferential and maximal extent of BE. Measurements are taken from the proximal margin of the rugal folds during moderate insufflation to the proximal limit of the circumferential Barrett's segment (circumferential extent) and the longest tongue of Barrett's (maximal extent).

Biopsies of the distal esophagus are required during endoscopy regardless of whether BE is suspected or not. In my practice, biopsies are taken from the stomach, gastric cardia just below the GEJ, and above the GEJ, including all the columnar mucosa to the squamocolumnar junction. The purpose of gastric biopsies is to differentiate gastric intestinal metaplasia from Barrett's metaplasia. The Seattle Protocol is widely accepted as the standard of care in BE screening and surveillance and is used to detect dysplasia and EAC by obtaining four-quadrant biopsy samples at 1- to 2-cm intervals throughout the area of suspected BE. In addition, targeted biopsies of any other irregularities, including ulceration and raised areas, should be biopsied. The pathology should be reviewed by two pathologists, preferably with one having a gastrointestinal specialization, especially in the diagnosis of dysplasia.

Standard white light endoscopy can be enhanced for greater detection of BE by using chromoendoscopy. Traditionally, chromoendoscopy consisted of applying a chemical solution (Lugol's, methylene blue, and acetic acid have been described) onto the esophageal lining to enhance the visualization of both the mucosal surface and vascular patterns, highlighting mucosal irregularities. Although safe and inexpensive, its disadvantages include the use of a staining agent and high interobserver variability in the ability to identify abnormal areas. Most current-version endoscopes have an electronic version of chromoendoscopy that provides contrast enhancement of the mucosal surface without the need for dye by relying on optical filters applied to the spectrum of light. The most well-known of these is narrow band imaging (Olympus Medical Systems), but each endoscope manufacturer has its own postprocessing software system. A recent meta-analysis suggested that electronic chromoendoscopy may increase detection of dysplasia.

More recently, novel advanced imaging and sampling techniques have emerged that we have begun to incorporate into our practice to improve the accuracy of endoscopic surveillance and detection for BE. These include probe-based confocal laser endomicroscopy and wide area transepithelial sampling with three-dimensional analysis (WATS®; CDx Diagnostics). Probe-based confocal laser endomicroscopy (Mauna Kea Technologies) uses confocal concepts to capture microscopic images of tissue in vivo with the aid of a contrast agent—intravenous fluorescein. Probe-based confocal laser endomicroscopy allows for identification of intestinal metaplasia, dysplasia, and adenocarcinoma. WATS® uses a special abrasive brushing instrument to obtain tissue samples from a broad area of BE, so the very sampling more tissue than the Seattle Protocol alone. The tissue samples are then computer analyzed to identify the most suspicious

FIG. 1 Barrett's esophagus seen on endoscopy under both (A) white light endoscopy and (B) narrow band imaging.

TABLE 1 Risk Calculator for the Progression of Barrett's Esophagus

Risk Factor	Points Assigned	Score
Each 1-cm increase in the length of Barrett's esophagus	1 (to a maximum of 10)	0–10 points: low risk Annual risk of progression, 0.13%
Smoker or smoking history	5	11–20 points: intermediate risk Annual risk of progression, 0.73%
Male	9	>20 points: high risk
Diagnosis of low-grade dysplasia	11	Annual risk of progression, 2.1%

Modified from Parasa S, Vennalaganti S, Gaddam S, et al. Development and validation of a model to determine risk of progression of Barrett's esophagus to neoplasia. Gastroenterology. 2018;154(5):1282–1289.e2.

cells that are then reviewed by a pathologist. WATS[39] in combination with the Seattle Protocol has been shown in a multicenter prospective study to detect more cases of IMCD and neoplasia than the Seattle Protocol alone.

SURVEILLANCE OF BARRETT'S ESOPHAGUS

Once BE has been identified, a crucial step in management of patients with BE is surveillance of disease. Current guidelines recommend endoscopic surveillance intervals using the Seattle Protocol that vary with the presence and grade of dysplasia. After the diagnosis of BE is made on index endoscopy, we often will repeat the endoscopy 1 year after initial diagnosis to confirm the presence of BE and rule out dysplasia. For patients with BE without dysplasia, surveillance endoscopy should be performed every 3 to 5 years based on current guidelines. In our practice, however, surveillance for these patients ranges from 3 to 5 years, influenced by the length of BE (longer surveyed more frequently because the risk of developing EAC increases with length) and the initial grade of esophagitis (patients with grades C and D have a higher risk of developing BE) along with the other risk factors.

For patients indefinite for dysplasia on endoscopy, a repeat endoscopy should be performed 3 to 6 months after optimization of acid suppressive medications. If the indefinite for dysplasia diagnosis is confirmed, a surveillance endoscopy is recommended annually while indefinite for dysplasia. In the presence of LGD, surveillance is performed every 6 to 12 months. For those patients with HGD who do not undergo intervention, surveillance is recommended every 3 months. After intervention, continued surveillance is necessary. The nuances of surveillance after intervention are discussed in the sections that follow.

For counseling patients, a risk calculator has been developed that assigns points to risk factors to identify a patient at low, intermediate, or high risk of progression (Table 1). Although this risk model has not been externally validated, our Barrett's working group has been looking at how it can be used clinically to inform patients of their risk of progression and prognosis.

MANAGEMENT OF BARRETT'S ESOPHAGUS WITHOUT DYSPLASIA

In patients with nondysplastic BE, the principle treatment goal is to provide relief of the patient's GERD symptoms while protecting the esophageal mucosa and BE from progression to dysplasia from ongoing acid reflux injury. Medical therapy with proton pump inhibitors (PPIs) has been considered the first-line therapy for any patient with BE to control GERD. The American College of Gastroenterology Clinical Guidelines recommend patients with BE should receive once-daily PPI therapy for chemoprevention. Twice-daily dosing is not routinely needed unless necessitated by poor control of reflux symptoms or esophagitis. Medical therapy with PPIs treats esophagitis and therefore allows for more accurate surveillance of the esophagus. In a 2004 US

study by El-Serag and colleagues, 236 veterans with IM and no dysplasia at baseline were followed for 1470 patient-years. The study demonstrated a 75% reduction in the development of dysplasia in PPI users versus nonusers. Overall, PPIs are generally well tolerated by patients; however, the long-term safety of PPIs has been called into question.

Antireflux surgery is an alternative therapy when GERD symptoms are inadequately controlled with acid suppression medications and/or are an impairment to quality of life; however, many advocate for surgical intervention with an antireflux surgery earlier in the course of treatment given its proven effectiveness. Unlike medical therapy, antireflux surgery aims to address the underlying defects: the incompetent lower esophageal sphincter (LES) and hiatal hernia if present. If successful, this prevents reflux of all substances into the distal esophagus (see Surgical Considerations and Surgical Management of Barrett's Esophagus).

Patients will often ask if antireflux surgery will prevent the development of cancer; however, the concern for progression and the risk of cancer development is insufficient to recommend surgery to patients solely for these reasons. Similarly, the role or benefit of mucosal ablation with radiofrequency or other devices in unproven in patients with nondysplastic IM. It may have a role in patients with ultralong segment IM (>8 cm) to reduce the inferior complexity of appropriate four-quadrant surveillance biopsies every 1 to 2 cm. The simple approach with these patients is to counsel them about the need to provide excellent control of GERD regardless of whether the treatment is PPIs or surgery.

MANAGEMENT OF BARRETT'S ESOPHAGUS WITH LOW-GRADE DYSPLASIA

LGD is associated with an increased risk for progression to adenocarcinoma compared with nondysplastic IM. Given the high interobserver variability in diagnosing LGD in IM from inflammatory atypia, however, there is controversy on the best treatment when LGD is found on biopsy. Preferred societies, both gastroenterology and surgical, agree on the need for confirmation of LGD by two skilled pathologists. If patients are not already on a PPI, one should be started or the dose escalated if already prescribed one. After interventions to control the underlying reflux, a repeat endoscopy within 6 months to evaluate response to treatment is recommended. If there is resolution of LGD on surveillance biopsies, then patients can be maintained on PPI therapy. Alternatively, antireflux surgery with Nissen fundoplication can also be performed to control reflux. In a study by Rossi and colleagues, medical therapy with high-dose PPIs was compared with Nissen fundoplication to evaluate regression of LGD. Of the 19 patients treated with PPIs, 13 (63.2%) had regression of their LGD to IM without dysplasia, whereas 15 of 16 patients (93.8%) who received a Nissen had regression of LGD ($P = .03$).

If the diagnosis of LGD is persistent, endoscopic ablation therapy is recommended in the absence of mucosal abnormality. Although some argue for continued surveillance of patients with confirmed LGD, in a randomized clinical trial published in 2014, Phoa and colleagues demonstrated that radiofrequency ablation (RFA) resulted in a reduced risk of neoplastic progression over 3 years of follow-up compared with surveillance alone. After RFA is performed, patients require ongoing surveillance to detect any further progression or new lesions of dysplasia and a discussion about long-term management of their GERD with PPIs or antireflux surgery.

MANAGEMENT OF BARRETT'S ESOPHAGUS WITH HIGH-GRADE DYSPLASIA

The first step in management of patients with HGD is careful repeat endoscopy to map out the locations of any nodules or lesions such as ulcers within the columnar mucosa using both white light endoscopy and narrow band imaging. The additional use of chromoendoscopy can aid in the identification of any lesions within the mucosa. HGD is an indication for intervention in the vast majority of patients because of the high risk for progression to EAC.

Endoscopic mucosal resection should be used to excise small discrete mucosal nodules. Endoscopic mucosal resection is performed with a cap attached to the end of the endoscope. The lesion is suctioned into the cap and a rubber band applied to the base to create a "pseudopolyp" that can be snared and removed for pathologic assessment. A good specimen will include mucosa and submucosa with a clean base of muscle seen at the resection site. In lesions larger than 1 to 2 cm, endoscopic ultrasound should be used to evaluate the depth of invasion and presence of enlarged lymph nodes. If the lesion identified is small or there is no lesion, endoscopic ultrasound is not useful because the accuracy of T staging is poor.

Patients found to have HGD alone or adenocarcinoma confirmed at the mucosa level only (T1a) without lymphovascular invasion are candidates for endoscopic therapy to preserve the esophagus. Invasion into the submucosa (T1b), however, should lead to esophagectomy and lymph node dissection in most patients because of the increased likelihood of nodal metastases once the cancer reaches the submucosa. Patients undergoing esophageal preservation should have complete endoscopic resection of all raised lesions in one or more sessions 4 to 8 weeks apart until all dysplastic tissue has been eradicated. Even after complete endoscopic resection, a concomitant mucosal ablative procedure with RFA is frequently required to ensure complete eradication of disease because of the frequent multifocality of IM. RFA is performed at 8-week intervals until all the intestinal metaplasia has been eradicated.

After complete eradication of both dysplasia and intestinal metaplasia, ongoing surveillance is recommended every 3 months for the first year, every 6 months for the second year, and annually thereafter because there is a risk for recurrence or inadequately treated lesions. Furthermore, patients undergoing endoscopic therapy should be on maximum medical therapy (e.g., esomeprazole 40 mg twice daily) and long-term GERD control after endoscopic therapy either in the form of PPIs or antireflux surgery.

Esophagectomy in High-Grade Dysplasia

Although endoscopic treatments have become the standard of care, there is still a role for esophagectomy in the treatment of HGD. Advantages of esophagectomy include immediate disease eradication and no need for further surveillance; however, it carries the potential morbidity associated with the surgery. Operative mortality for esophagectomy in HGD and early tumors is low, at less than 1% at high-volume centers. Esophagectomy should be strongly considered in patients with the following characteristics:

- Poor prognostic risk factors of the lesion: large (>2 to 3 cm), lymphovascular invasion, multifocality
- Patient prefers surgery
- Unable to comply with the repeat endoscopic treatments and surveillance
- Inability to eradicate HGD and/or adenocarcinoma or progression of disease
- Failed ablation techniques
- End-stage esophageal function (from motility disorder, stricture, obstructed hiatal hernia)

For these patients, the best surgical approach is often a minimally invasive vagal-sparing esophagectomy that can eradicate disease while minimizing potential morbidity by sparing both vagal nerves (Figs. 3 and 4).

SURGICAL CONSIDERATIONS AND THE ROLE OF ANTIREFLUX SURGERY IN MANAGEMENT OF BARRETT'S

Patients with GERD and BE have been shown to have an increased amount of reflux compared with patients with GERD alone as well

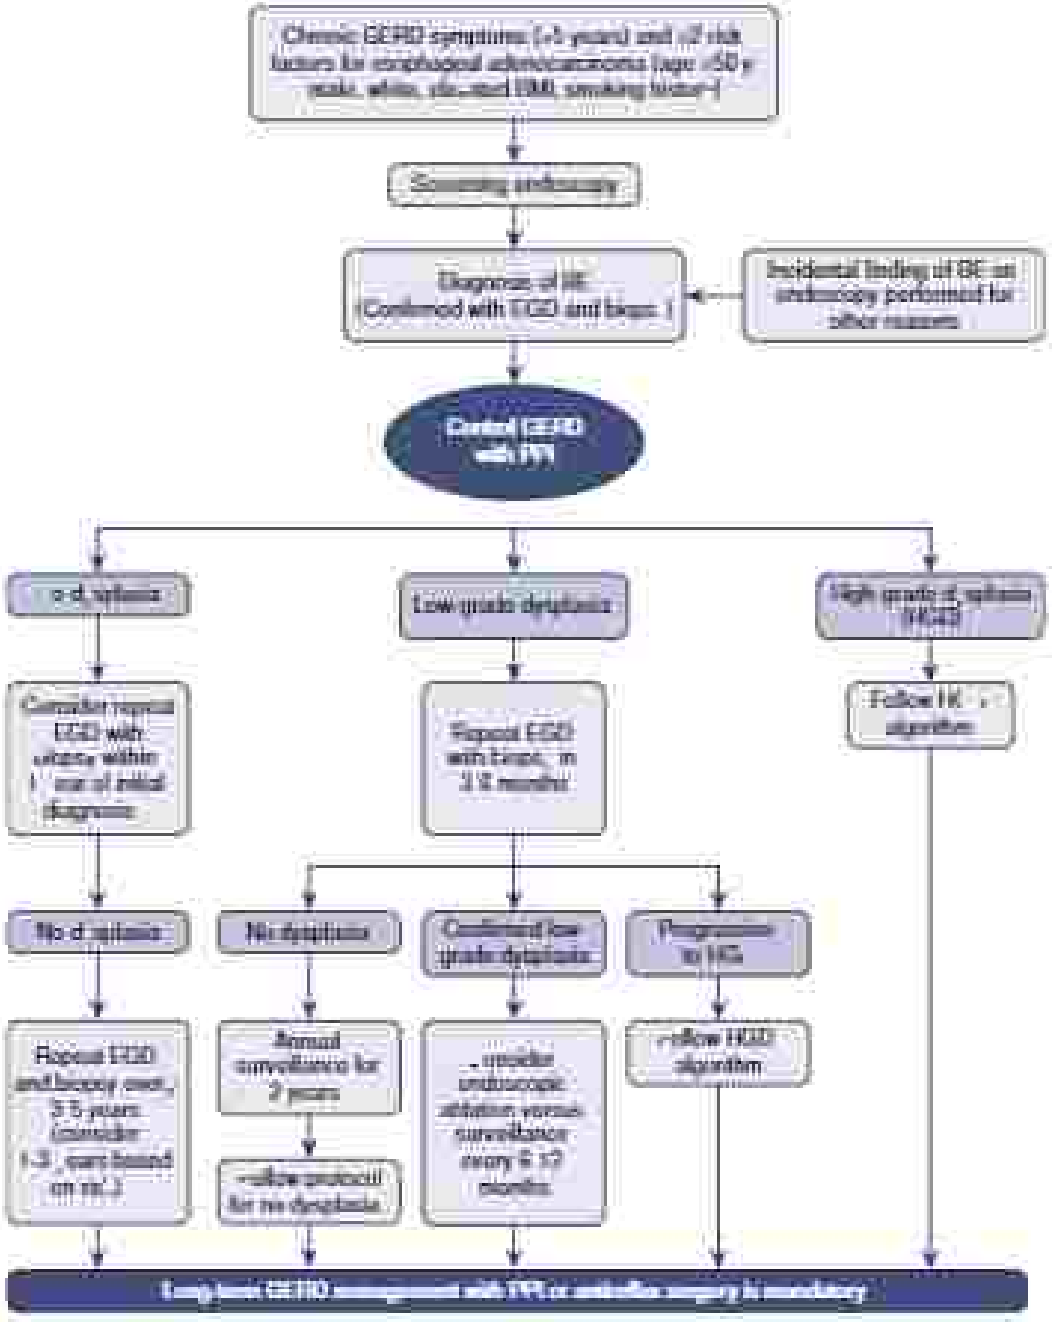

FIG. 3 Management of Barrett's esophagus. BE, Barrett's esophagus; BMI, body mass index; EGD, esophagogastroduodenoscopy; GERD, gastroesophageal reflux; PPI, proton pump inhibitor.

as a higher prevalence of incompetent LES, impaired esophageal motility, and hiatal hernias, making it difficult to control reflux with medical management alone. Antireflux surgery has several theoretical benefits in the management of GERD, including the control of both acid and bile pancreatic substrates that are contributing to the mucosal injury and therefore reducing inflammatory markers that are key in the development of BE including interleukin 8 and Cox-2. Furthermore, antireflux surgery aims to fix the incompetent LES and hiatal hernia if present. The complete reflux control can prevent progression of BE and even lead to regression and healing of the neoplastic mucosa, as shown in several studies. Oelschlager and colleagues assessed 189 patients treated with antireflux surgery for BE, of which 66 returned for endoscopic surveillance. At a median follow up of 30 months, 35% had complete regression of BE and only 3.3% had progression. Further, in a recent meta-analysis, Manner and colleagues found that antireflux surgery may prevent EAC better than medical therapy in patients with BE.

The esophageal injury sufficient to cause mucosal injury leading to BE can also cause edema, spasm, fibrosis, strictures, and shortening of the esophagus, leading to a more complex fundoplication. In addition, patients with BE more often have a hiatal hernia. These factors lead to a higher failure rate for fundoplication in the setting of BE at 10% to 20% at 3 to 5 years postoperatively (compared with 5% to 10% for those patients without BE). A failed fundoplication is a risk factor for disease progression because there is continued postoperative acid exposure to the distal esophagus. Careful selection of patients for fundoplication is critical and postoperative surveillance with serial endoscopies is mandatory.

For those patients considering antireflux surgery, further workup should include high resolution manometry and video esophagram

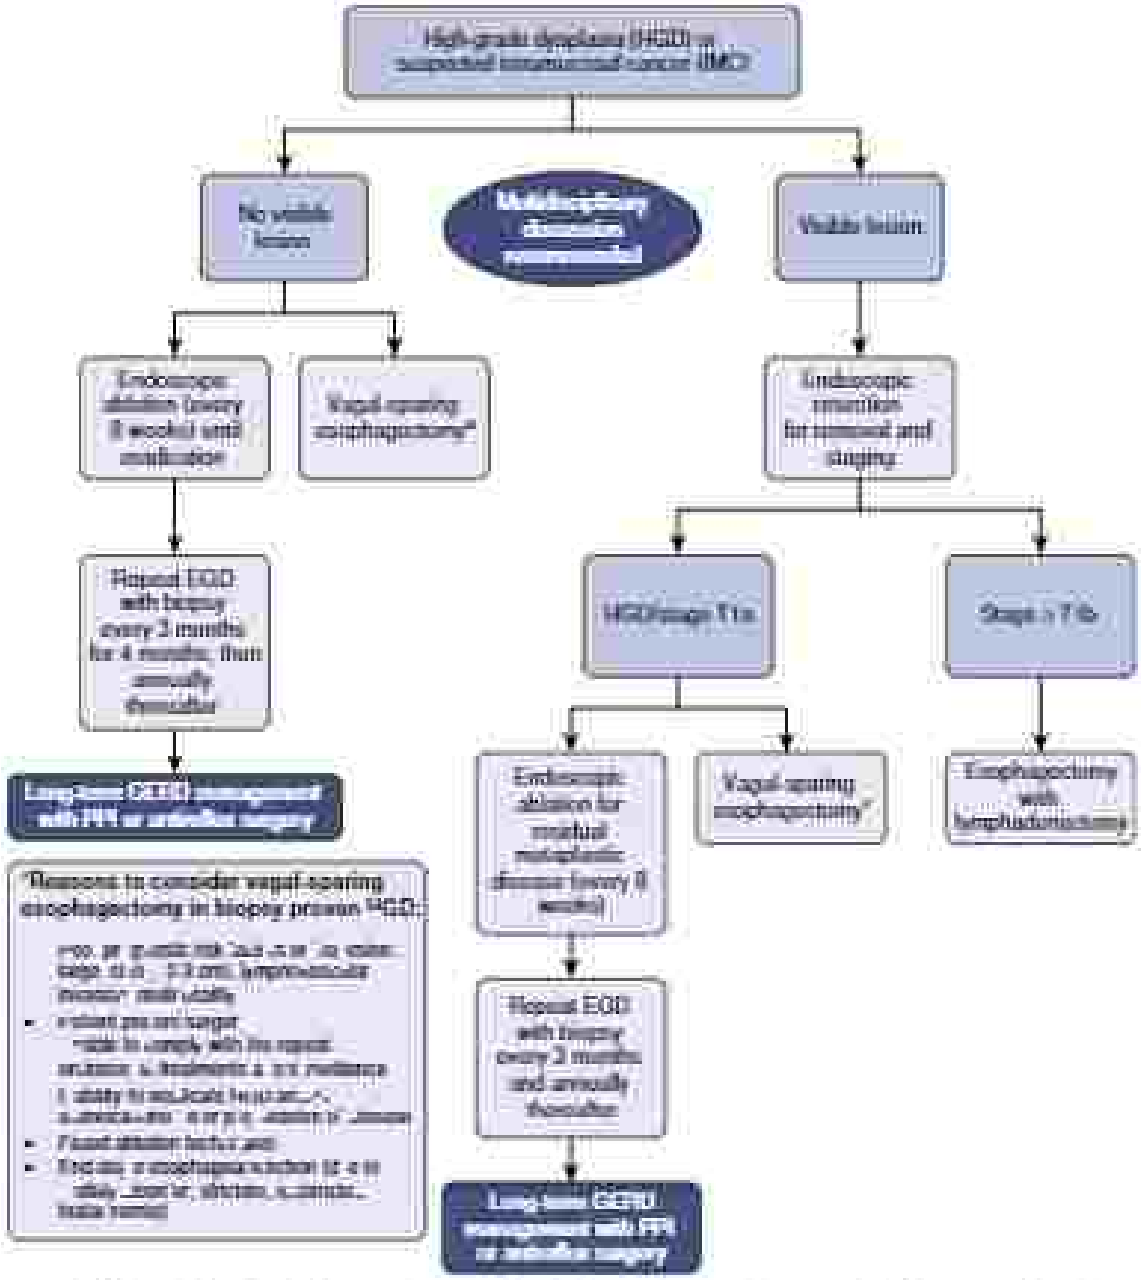

FIG. 4 Management of high-grade dysplasia and intramucosal cancer (IMC). EGD, esophagogastroduodenoscopy; GERD, gastroesophageal reflux; PPI, proton pump inhibitor.

We favor obtaining a pH test, not to diagnose GERD, but to prioritize baseline assessment of the patient's reflux. This allows comparison to any postfundoplication confirmatory testing that is performed. If esophageal dysmotility is a significant problem, a partial fundoplication can be performed to prevent postoperative problems with dysphagia; however, the efficacy of a partial fundoplication in patients with HG is questionable, with some studies suggesting decreased long-term control of reflux. Patients in this situation should be selected carefully and informed that they likely will need to remain on PPIs to ensure control of their GERD.

After intervention with RFA or endoscopic resection and surveillance of at least 1 year, our practice has been to have a discussion with the patients about long-term GERD control. Patients who remain incompletely controlled on PPI therapy with reasonable motility are considered for fundoplication. In a multicenter series, we demonstrated that fundoplication after endoscopic therapy results in similar durability and recurrence of HG when compared with patients managed with PPIs; however, fundoplication seemed to prevent further progression and the development of cancer.

CONCLUSION

Management of the patient with HG is intricately tethered to the treatment of the patient's underlying chronic GERD. When presenting this complex problem to the patient, it can often be broken down into two separate but related pathways: (1) treatment and subsequent surveillance of the Barrett's metaplasia and (2) treatment of the underlying GERD. Antireflux surgery can be beneficial to eradicate GERD symptoms and even induce regression of existing dysplasia and prevent progression. Patients must be carefully selected for surgery because those with HG are more likely to have a fundoplication failure and recurrence of hiatal hernia compared with those patients without HG; a failed antireflux surgery is a risk factor for the progression

of IM. Endoscopic treatments have transformed management of dysplastic Barrett's and now allow preservation of the esophagus in most patients, but esophagectomy continues to have a role in selected patients not amenable to or cured by endoscopic therapy.

Endoscopic Treatment of Barrett's Esophagus

Anne F. Ehlers, MD, MPH, and Brant K. Oelschlager, MD

Barrett's esophagus (BE) is a disease characterized by the gradual replacement of the normal stratified squamous epithelium of the esophagus with columnar, intestinal metaplasia (Fig. 1A, B) [1]. This transformation is due to chronic exposure to gastric contents, often within the context of gastroesophageal reflux disease (GERD). Patients at risk for BE are screened with endoscopy and biopsy. The major concern with BE is that it is a precursor lesion for esophageal adenocarcinoma (EAC), a disease with poor prognosis and poor long-term survival. In addition, EAC is a disease that continues to increase in incidence. Given this, identifying and eradicating BE before progression to adenocarcinoma is a top priority. In the past, patients with BE often were recommended for esophagectomy. More recently, evolving endoscopic techniques have replaced esophagectomy for many of these patients, allowing for eradication of BE with less morbidity and fewer complications.

SURVEILLANCE AND MANAGEMENT ALGORITHM

Screening

The primary risk factor for BE is longstanding GERD, along with male sex, age older than 50 years, and central obesity. Patients with GERD have a 10% to 15% risk of BE, increasing age and long segment BE (>3 cm) are risk factors for progression to dysplasia. Overall, the rate of progression from BE to esophageal adenocarcinoma is low, perhaps as low as 0.12% per year. Other evidence suggests that for patients with nondysplastic BE, the annual risk of progression to EAC is 0.33% per year among all patients with BE, and 0.19% per year among patients with short segment BE (<3 cm). For patients with low grade dysplasia (LGD), this risk increases to 0.5% per year. The risk increases substantially among those with high grade dysplasia (HGD), up to 19% in some studies. Early detection of invasive cancer is important because patients detected at an early stage have a much higher 5 year survival rate (80%–90%) compared with patients who present symptomatically with more advanced disease (10%–30%).

Identifying the most appropriate pool of patients for screening is an area of active debate, especially with the large number of adults who have GERD. Because only a minority of patients with GERD will ever develop BE, screening every patient with GERD is not cost-effective nor efficient. However, evidence suggests that surveillance of BE is associated with diagnosis of EAC at an earlier stage, which may be associated with improved outcomes. For these reasons, accurately identifying the population of patients with BE is critical. Current guidelines from the American College of Gastroenterology (ACG) recommend screening male patients with *five or more years* of GERD symptoms AND two or more risk factors for BE or EAC (age >50 years, white race, central obesity, history of smoking, family history of BE or EAC). Screening for female patients is generally not recommended, except for patients with multiple risk factors, as outlined previously.

Screening is generally undertaken using high resolution endoscopy with liberal use of narrow band imaging and biopsy, but as previously stated this can be very labor and time intensive. Several novel screening modalities have been proposed to reduce this burden. One alternative is transnasal esophagoscopy, which is an office based procedure that uses topical anesthetic to pass an endoscope through the nares and into the esophagus. Compared with traditional high resolution endoscopy, the image quality is reduced and the biopsies are smaller, but often are sufficient for histologic analysis to allow a diagnosis of BE to be made without a formal endoscopy. A second option for screening is the Cytosponge, which is a gelatin coated capsule attached to a string that is then swallowed by the patient. Once in the stomach, the gelatin coating dissolves leaving behind a sponge that is then retrieved by pulling on the string. As the sponge comes back through the esophagus, it picks up cells that can then be examined for abnormalities. It currently holds promise as a screening tool for BE but is not adequate to screen for EAC because transnasal esophagoscopy and Cytosponge are still relatively new, high resolution endoscopy is still the *gold standard for diagnosis of BE*.

Surveillance

Patients with confirmed BE in the absence of dysplasia or EAC should be regularly surveilled to detect disease progression. A challenge in the past has been lack of universal criteria for describing the extent of disease. To address this challenge, the Prague Criteria are a set of endoscopic data developed and validated by a working group specifically focused on esophagitis using standardized videos of endoscopies. The purpose was to improve on the previously used vague descriptions of "long" versus "short" segment disease, and to facilitate communication between providers. The Prague Criteria measure the extent of disease based on circumference and maximum extent (C&M) criteria, with C being the maximum circumferential extent of disease and M the maximum length, including any isolated tongues of disease.

Once a patient has been diagnosed with BE, the next step is to evaluate for any dysplasia or invasive cancer. The current recommendation is to evaluate the patient with high resolution or high definition white light endoscopy followed by meticulous inspection of the esophageal lumen, after both insufflation and desufflation, including inspection of the gastroesophageal junction in the retroflexed view. Some data suggest that longer inspection time is associated with better detection of dysplasia or EAC. Suspicious lesions such as erosions, ulcerations, nodules, plaques, and other mucosal or luminal abnormalities should be selectively sampled. Random biopsies are not recommended. Suspicious lesions in patients with known dysplasia are best removed via endoscopic mucosal resection (EMR), which will be described later in the chapter. Additionally, the ACG recommends against taking biopsies in areas of active, erosive esophagitis and instead to wait until the patient has been treated with antisecretory agents to allow the inflammation to subside.

Ongoing surveillance is dependent on the pathology determined at the time of biopsy. For patients who have BE without evidence of dysplasia, the recommendation is that they undergo repeat

of IM. Endoscopic treatments have transformed management of dysplastic Barrett's and now allow preservation of the esophagus in most patients, but esophagectomy continues to have a role in selected patients not amenable to or cured by endoscopic therapy.

Ongoing surveillance is dependent on the pathology determined at the time of biopsy. For patients who have BE without evidence of dysplasia, the recommendation is that they undergo repeat

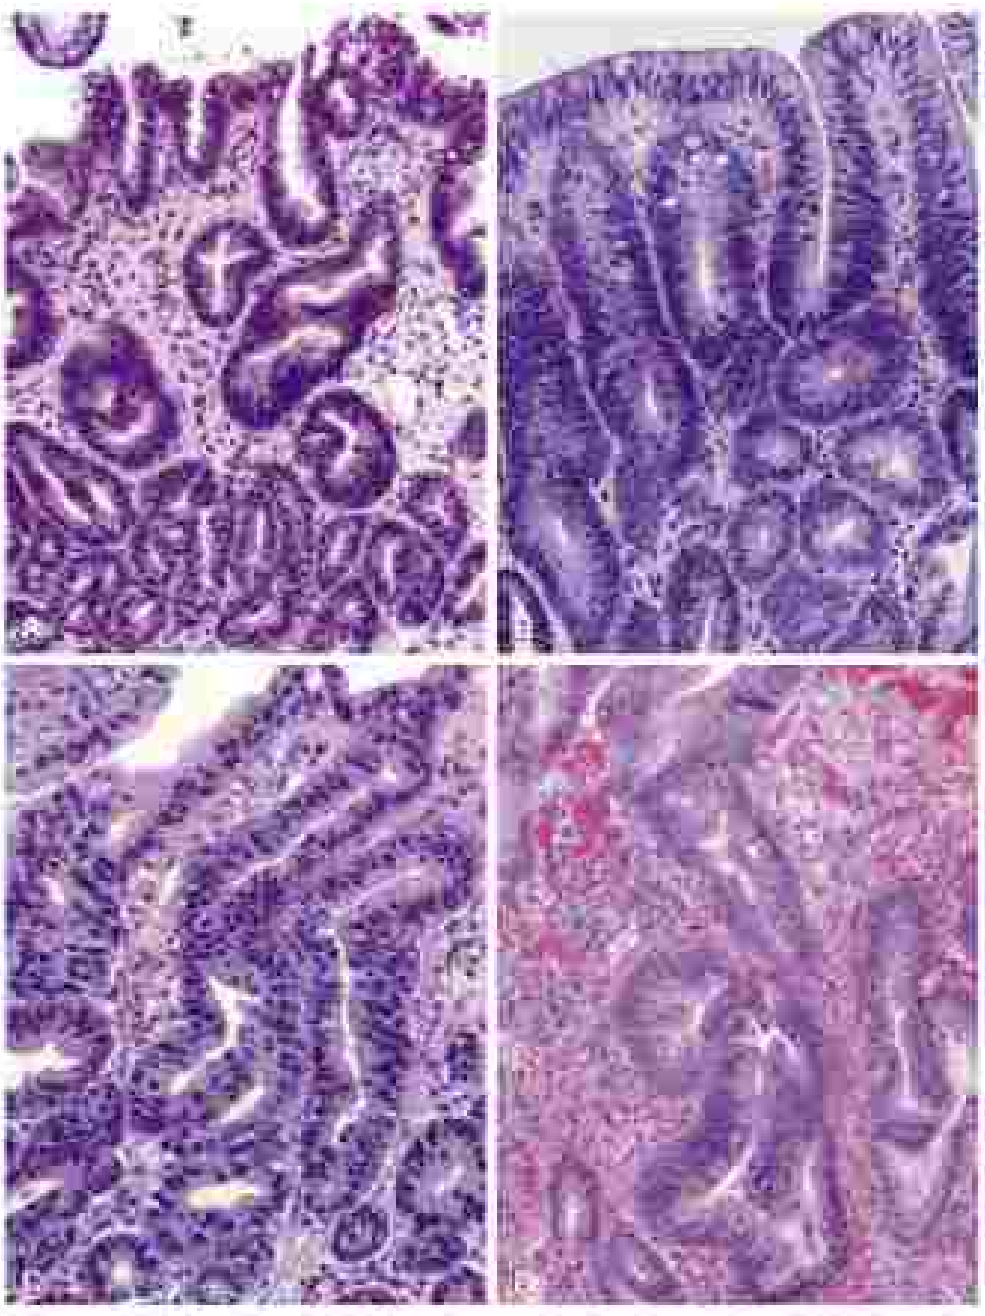

FIG. 1. Spectrum of dysplasia grading. (A) Negative for dysplasia. Although some nuclear hyperchromasia is present, it is limited to the normal proliferative zone with evidence of surface maturation. (B) Low-grade dysplasia shows basally oriented, hyperchromatic nuclei with pseudostratification. Crypt architecture is preserved. (C) High-grade dysplasia demonstrates prominent mitotic activity, enlarged nuclei, and loss of nuclear polarity with evidence of glandular crowding. (D) This lesion shows epithelial-lined papilla, reminiscent of that of low-grade dysplasia, in the deep glands. However, given the presence of surface maturation and the stromal changes suggestive of a reparative process, it is best classified as indefinite for dysplasia. *(From Hayes CJ, Travers CF, Mathews KS, Kaushik M, Aronis AG, Hagen JA, et al. Esophageal dysplasia: challenges. Semin Diagn Pathol. 2019;36(2):105–111.)*

endoscopic surveillance every 3 to 5 years, as described previously. In cases in which biopsies are inconclusive for dysplasia, patients should be placed on an acid suppression regimen for 3 to 6 months, after which repeat endoscopy should be performed. If the biopsies are still inconclusive at that time, repeat endoscopy should be performed 12 months later. If dysplasia is diagnosed (LGD or HGD), the biopsies should be reviewed by two separate pathologists, one of whom is an expert in gastrointestinal pathology because there is a high level of interobserver variability when it comes to dysplasia.

Once dysplasia is confirmed, the next steps depend on the degree of dysplasia. For LGD, endoscopic therapy is preferred for patients without significant comorbidity; however, repeat endoscopy at 12 months is acceptable in these cases. For HGD, endoscopic therapy is recommended except in the case of life limiting comorbid conditions. Patients with a diagnosed cancer should undergo further staging workup to determine if the cancer is resectable, and some early adenocarcinomas can be managed endoscopically. For certain young patients with long segment multifocal HGD, recurrent HGD, or

FIG. 3 Endoscopic image of Barrett's esophagus. The arrows mark the esophagogastric junction, which is identified endoscopically as the most proximal extent of the gastric folds. The mottled color and velvet-like texture of the Barrett's epithelium contrast sharply with the pale and glossy appearance of the esophageal squamous epithelium. Note that the Barrett's columnar epithelium extends well above the esophagogastric junction to the distal esophagus. (From Spechler SJ, Souza RF. Barrett's esophagus. In: Sleisenger and Fordtran's gastrointestinal and liver disease. Philadelphia: Elsevier; 2016.)

intramucosal cancer, surgery should be considered. A summary of the surveillance and treatment algorithm is provided in Figs. 2 and 4.

PRINCIPLES OF ENDOSCOPIC THERAPIES

The current evidence supports that endoscopic therapy should be used for patients with BE who have LGD, HGD, and for some patients with early intramucosal (T1a) EAC because the risk of lymph node metastasis is unacceptable for LGD and HGD and is low for intramucosal EAC. Endoscopic techniques work by either removing or halting development of invasive disease or destroying abnormal tissue (ablative techniques). The intestinal metaplasia is then replaced with normal appearing squamous epithelium (Fig. 3).

ENDOSCOPIC RESECTION TECHNIQUES

Endoscopic Mucosal Resection

EMR is a technique that allows removal of lesion within segments of BE for complete histologic analysis, including dysplasia and superficial T1a adenocarcinoma. It offers an advantage over ablative techniques because it allows for examination of tissue specimens, rather than just destroying them. The AGC recommends EMR as the initial treatment modality for patients with nodular BE. For patients without high-risk features (submucosal invasion, poor differentiation, or lymphatic/vascular invasion), EMR has 98.8% eradication rate of BE; in patients with high-risk features, the rate is 85.6%. For T1a tumors, EMR has a 91% to 98% eradication rate.

There are several methods used for EMR. In the cap assisted method, the endoscope is fitted with a transparent cap. Once located, the target lesion is sucked into the cap and a specialized electrocautery snare is used to resect the lesion. A submucosal injection can be

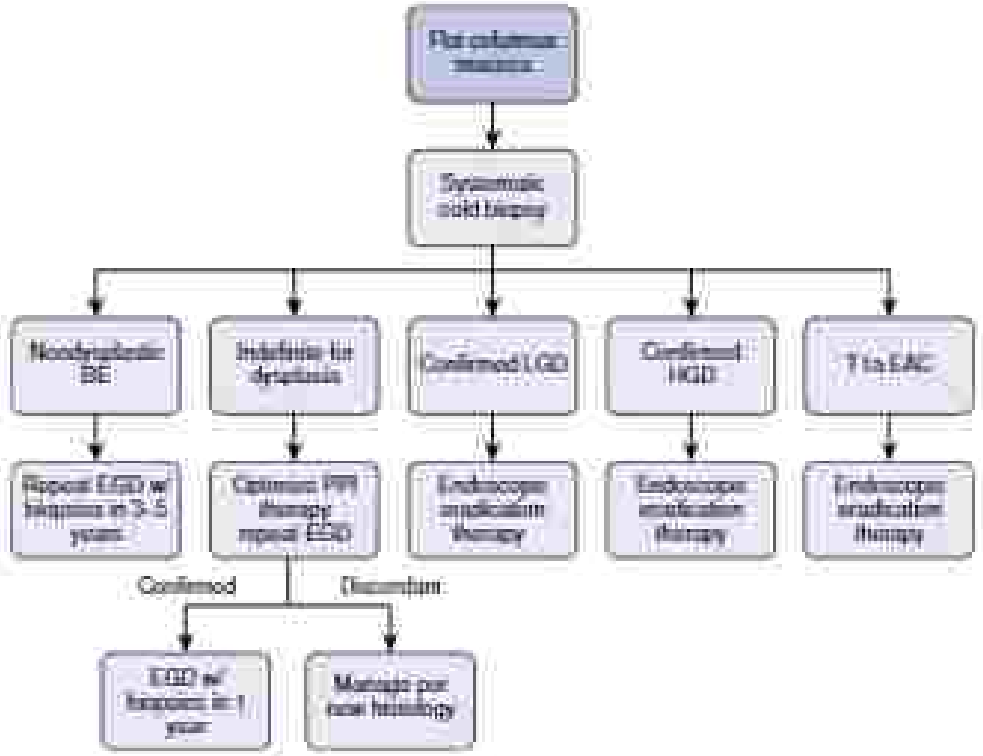

FIG. 2 Management of nonnodular Barrett's esophagus (BE). Although endoscopic eradication therapy is associated with a decreased rate of progression, surveillance upper endoscopy at 1-year intervals is an acceptable alternative. The algorithm assumes that the T1a esophageal adenocarcinoma (EAC) displays favorable characteristics for endoscopic therapy, including well-differentiated histology and lack of lymphovascular invasion. HGD, high-grade dysplasia; LGD, low-grade dysplasia; PPI, proton pump inhibitor. (From Shaheen NJ, Falk GW, Iyer PG, et al. ACG Clinical Guideline: Diagnosis and Management of Barrett's Esophagus. Am J Gastroenterol. 2016;111(1):30-50.)

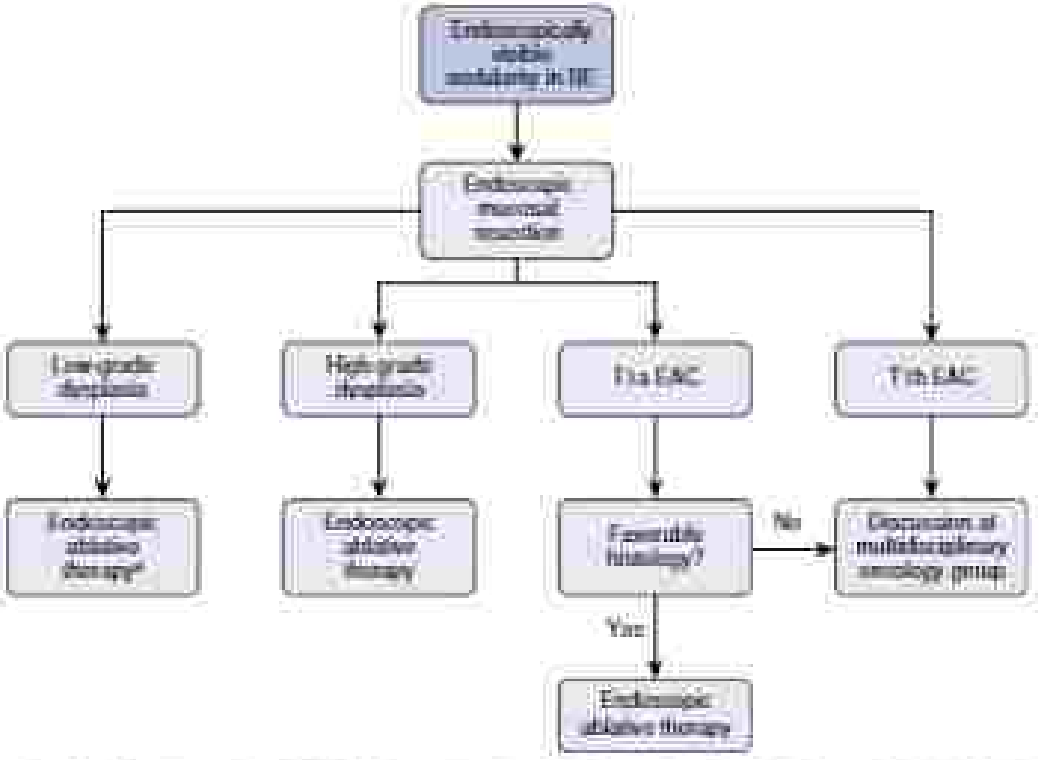

FIG. 4 Management of nodular Barrett's esophagus (BE). Note that aside from the clinical course of patients with low-grade dysplasia (LGD) managed by endoscopic surveillance following endoscopic mucosal resection (EMR), although this is an alternative treatment strategy. Endoscopic submucosal dissection is an alternative to EMR. Favorable histology consists of no lymphatic or vascular invasion and moderate to well-differentiated disease. EAC, esophageal adenocarcinoma. (From Wolfsen AJ, Gill GK, Iyer PG, et al. ACG Clinical Guideline: Diagnosis and Management of Barrett's Esophagus. Am J Gastroenterol. 2016;111:30-51.)

performed to facilitate this. In the ligation-assisted method, lesions are resected using a band ligation device attached to the tip of the endoscope. Once identified, the target lesion is again sucked into the endoscope and the band is applied around the lesion to create a pseudopolyp. Electrocautery is then used to remove the pseudopolyp. In the injection-assisted technique, the submucosal space is injected to lift the lesion and allow it to be snared and cut.

One of the primary side effects of EMR is esophageal stricture, which occurs in up to 40% of patients. Typically, these lesions can be managed with endoscopic dilation or stents. EMR is often used in conjunction with radiofrequency ablation (RFA) with good effect. In a recent systematic review, EMR alone had a 33.3% risk of stricture, 7.5% risk of bleeding, and 1.3% risk of perforation compared with 10.2%, 1.1%, and 0.2%, respectively, in patients undergoing EMR in conjunction with RFA.

Endoscopic Submucosal Dissection

Endoscopic submucosal dissection (ESD) is a technique that allows for complete, en bloc resection of suspicious lesions to allow for thorough histologic evaluation. When compared to EMR, it also allows for complete resection of lesions, rather than having to resect lesions in a piecemeal fashion, especially for larger lesions (>1.5–2 cm). The primary indication for ESD is resection of nodular lesions within a segment of BE to allow for complete histologic evaluation. Given the relative technical difficulty of this procedure, as well as the concern for significant adverse events, it is not as widely used. The ACG recommends that ESD only be performed in centers of clinical expertise.

The technique of ESD involves first marking the area of resection with coagulation. The submucosal space of the marked area is then injected with a saline solution to lift the area, and finally ESD resection knives are used to locate the muscularis and perform the submucosal dissection.

Most of the available data on ESD is from Europe or Asia, but a recent multicenter study performed in the United States showed that en bloc resection occurred in 95.2% of patients with a median resection size of 45 mm. Nearly half of patients required admission after the procedure, either for routine observation or for pain control. An R0 resection was achieved in 76.1%, and the overall cure rate was 69.6%. More than two-thirds of patients in this study were found to harbor EAC in the resected specimen, resulting in histologic upstaging in more than half of all patients. Adverse events occurred in 23.9% of patients, including bleeding (6.5%), perforation (2.2%), and esophageal stricture (15.2%). All adverse events were managed endoscopically.

These results were confirmed by a recent meta-analysis demonstrating that ESD has a 92.9% success rate of achieving en bloc resection, a 74.5% rate of achieving an R0 resection, and a 64.3% rate of achieving curative resection. Bleeding occurred in 1.8% of patients, and 1.5% of patients sustained esophageal perforation. Both the bleeding and perforation events were managed endoscopically. Overall esophageal stricture rate was 11.6%; these were managed with endoscopic dilation. The total rate of immediate and delayed adverse events was 4.9%.

ENDOSCOPIC ABLATION TECHNIQUE

Photodynamic Therapy

Photodynamic therapy (PDT) involves administration of a systemic photosensitizing agent that is taken up preferentially by neoplastic tissues. The photosensitizing agent then produces cytotoxicity after exposure to an appropriate wavelength and power of light, specific to the photosensitizing agent. The two most widely available photosensitizing agents are Photofrin and 5-aminolevulinic acid. Randomized trial data indicate that complete ablation of HGD can be achieved in 77% of patients with PDT, and 52% of patients had complete replacement of all BE tissue with normal squamous epithelium.

There is a relatively high complication rate associated with PDT. Because of its systemic administration, the photosensitizing agents can predispose to cutaneous photosensitivity similar to a sunburn to

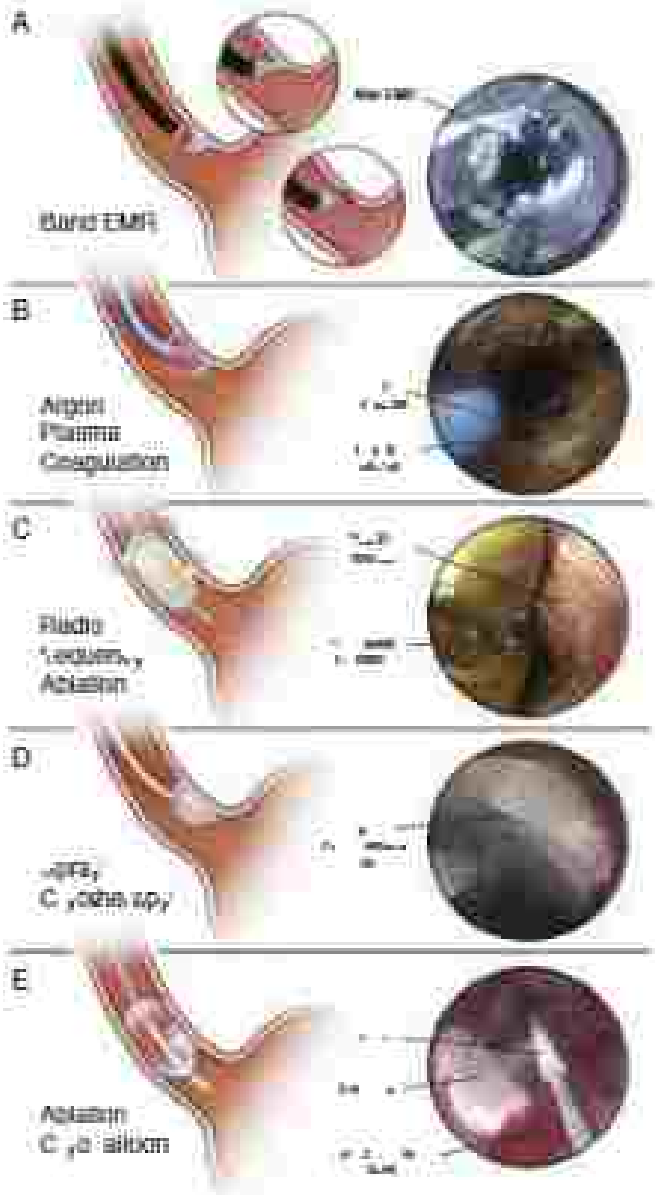

FIG. ... Endoscopic techniques for ablation of esophageal early neoplasia. (A) Band endoscopic mucosal resection involves suction and ligation (banding) of a target lesion, with or without prior submucosal injection, followed by resection using snare polypectomy technique. (B) Endoscopic photo shows the endoscopic view of the submucosa through the banding device after complete resection of well-differentiated adenocarcinoma. (B) Argon plasma coagulation (APC) involves conduction of heat energy with argon gas to the mucosa (arrow). Endoscopic image shows the APC catheter and white coagulation necrosis of treated BE mucosa (arrow). (C) Radiofrequency ablation (RFA) involves the application of a preset amount of heat energy (12 J) through electrodes on a circumferential (HALO 360) ablation catheter (arrow) inflated to make contact with the esophageal mucosa. Endoscopic image of post-RFA scarring. (D) Liquid nitrogen spray cryotherapy involves infusion of liquid nitrogen that expands to gas and freezes large areas of tissue to −196°C. The dosing of liquid nitrogen cryogen has varied from 15 to 30 seconds or less, followed by a thaw interval 4× seconds of thaw and repeated for three cycles. Endoscopic image of a nonconfluent island of ice on the esophageal mucosa. (E) The cryoballoon ablation system includes a portable handheld manual controller that delivers nitrous oxide gas into a low-pressure compliant, 30 mm, oval-shaped balloon at the end of a disposable balloon catheter passed through the endoscope channel. The balloon at the end of the catheter is inflated and simultaneously cooled by the gas expansion. The cryogen is directed toward a specific location by rotation of the diffuser. Endoscopic image shows the endoscopic view through the cryoballoon with a focal ice patch and thawed treated mucosa with post cryotherapy red color change (arrow). EMR, endoscopic mucosal resection. *(From di Pietro M, Canto MI, Fitzgerald RC. Endoscopic management of early adenocarcinoma and squamous cell carcinoma of the esophagus: screening, diagnosis, and therapy. Gastroenterology. 2018;154(2):421–436.)*

more than two-thirds of patients. Other complications include odynophagia, constipation, vomiting, retrosternal chest pain, dehydration, dysphagia, and stricture formation (up to 36% in some studies). This was the first effective ablation technique, but because of the relatively high complication rate, PDT is no longer widely used.

Argon Plasma Coagulation

Argon plasma coagulation (APC) uses a beam of argon gas to conduct an electrical current, resulting in a noncontact form of thermal electrocoagulation. The depth of necrosis is relatively shallow (2–3 mm) and can be useful in conditions such as IM that involve the mucosa. In

the initial randomized controlled trial (RCT) conducted by Ackroyd et al., after a median of three treatments, patients treated with APC achieved complete macroscopic ablation 60% of the time, with the remaining patients achieving a significant decrease in the size of their BE. At the 1 year follow up, 50% of patients had no macroscopic evidence of disease compared with only 12% in the surveillance group. At 5 year follow up, 70% of patients in the APC group had sustained at least a 50% reduction in the surface area of BE, and 40% had no histologic or macroscopic disease compared with only 25% and 15%, respectively, in the surveillance group.

There were no early complications, and long term complications included strictures that were managed with endoscopic dilation. Other reported complications include chest pain, odynophagia, ulceration, bleeding, perforation, and death. One advantage of APC is that the equipment is widely available and is relatively inexpensive. However, as noted in the RCTs, it often requires multiple treatments over time to achieve regression of disease.

Cryotherapy

Cryotherapy directly destroys tissue by freezing it, resulting in both immediate and delayed tissue destruction. There are several cryotherapy systems available, but the most widely studied is liquid nitrogen. In a retrospective study of patients treated with liquid nitrogen, Shaheen et al. found that after an average of four treatments, 97% of patients had resolution of HGD, 87% had resolution of intestinal dysplasia, and 77% had resolution of intestinal metaplasia. There were no serious complications, but 9% of patients developed strictures that were managed with endoscopic dilation.

At the 5 year follow up, 93% of patients had complete resolution of high grade dysplasia, 88% had resolution of dysplasia, and 72% had resolution of intestinal metaplasia, although some of these patients underwent "touch up" therapy after the initial round of treatment. As with other endoscopic methods of treatment, ongoing endoscopic surveillance is required.

One advantage of cryotherapy is that it can be used both as a first-line treatment for BE with dysplasia, and as a second-line treatment in patients who have failed other treatments. As with other therapies, however, it often requires multiple treatments to completely eradicate disease. In a recent review of liquid nitrogen cryotherapy, the complication rate ranged from 0% to 3% with the most frequent complication being pain requiring narcotics (10% of patients), followed by stricture requiring dilation (up to 9%), then bleeding and perforation.

Radiofrequency Ablation

The most commonly used ablative technique is RFA. Using either a balloon catheter or a focal catheter, a generator and a bipolar electrode array deliver a fixed amount of thermal energy, resulting in a uniform burn to a depth of 0.5 mm. RFA can be performed in the outpatient setting and is targeted as either a circumferential ablation (using the balloon catheter) or a focal ablation (using the focal catheter). Circumferential ablation is for circumferential segments of BE that are longer than 2 cm, whereas focal ablation is for shorter segments, or islands, of BE. After treatment, follow up is recommended in approximately 2 months, and often multiple sessions of RFA are required to achieve complete eradication of dysplasia, with close follow up following eradication.

In an RCT comparing RFA with sham endoscopy, complete eradication of HGD occurred in 90.5% of patients and complete eradication of IMD occurred in 81% of patients following RFA, compared with only 22% and 19% in the sham group, respectively. Among all patients, RFA completely eradicated evidence of intestinal metaplasia in 77.4%, compared with only 2.3% in the control group. All three results were statistically significant. There is a known rate of progression to esophageal cancer, and in this study 19% of patients with HGD progressed to cancer over a 1 year timeframe. At 3 year follow up these results were found to be durable: complete eradication of dysplasia occurred in 90% of patients, and complete eradication of intestinal metaplasia occurred in 97% of patients; results were similar at 5 year follow up.

The primary side effects of RFA are chest pain and dysphagia lasting up to 8 days, and strictures occur in up to 8% of patients. Bleeding is rare. No deaths have been reported following RFA. RFA is the preferred therapy for nonnodular BE.

CONCLUSION

The management of BE continues to evolve as new technology and more effective treatments become available. Compared with esophagectomy, endoscopic techniques have the advantage of being less invasive with lower complications; however, in all cases, it is important to ensure that the correct technique is being used, which requires a baseline understanding of each technique. In general, patients with nodular disease should have this removed, and patients with early esophageal cancer should be referred for discussion at a multidisciplinary cancer group or tumor board to discuss alternative therapies to endoscopic ones.

Management of Paraesophageal Hiatal Hernia

Francisco Schlottmann, MD, MPH, and Marco G. Patti, MD

Hiatal hernias result from a widening of the diaphragmatic esophageal hiatus and a weakening of the phrenoesophageal membrane. Consequently, the stomach and other intraabdominal organs may herniate through the diaphragmatic hiatus into the mediastinum. The incidence of these hernias in the general population is unclear because many patients are asymptomatic and how the hernia diagnosed incidentally in the context of chest or abdominal imaging for unrelated conditions. Other patients, however, present with a wide range of symptoms, and potentially lethal complications such as volvulus, strangulation, incarceration, and perforation.

Hiatal hernias are subclassified into four types:

- Type I: The esophagogastric junction (EGJ) herniates above the diaphragm into the mediastinum ("sliding hernia").
- Type II: A portion of the stomach is herniated into the mediastinum alongside a normally positioned (i.e., intraabdominal) EGJ.

the initial randomized controlled trial (RCT) conducted by Ackroyd et al., after a median of three treatments, patients treated with APC achieved complete macroscopic ablation 60% of the time, with the remaining patients achieving a significant decrease in the size of their BE. At the 1 year follow up, 50% of patients had no macroscopic evidence of disease compared with only 12% in the surveillance group. Management of Paraesophageal Hiatal Hernia

Francisco Schlottmann, MD, MPH, and Marco G. Patti, MD

Hiatal hernias result from a widening of the diaphragmatic esophageal hiatus and a weakening of the phrenoesophageal membrane. Consequently, the stomach and other intraabdominal organs may herniate through the diaphragmatic hiatus into the mediastinum. The incidence of these hernias in the general population is unclear because many patients are asymptomatic and how the hernia diagnosed incidentally in the context of chest or abdominal imaging for unrelated conditions. Other patients, however, present with a wide range of symptoms, and potentially lethal complications such as volvulus, strangulation, incarceration, and perforation.

Hiatal hernias are subclassified into four types:

- Type I: The esophagogastric junction (EGJ) herniates above the diaphragm into the mediastinum ("sliding hernia").
- Type II: A portion of the stomach is herniated into the mediastinum alongside a normally positioned (i.e., intraabdominal) EGJ.

- Type III. The GEJ is above the hiatus and a portion of the stomach is folded alongside the esophagus.
- Type IV. An intra-abdominal organ other than the stomach is additionally herniated through the hiatus.

Type I hernias are the most common form of hiatal hernia and account for up to 95% of the total prevalence. Type II, III, and IV hernias are together termed paraesophageal hernias (PEHs) and combined account for the remaining 5% of hiatal hernias.

SURGICAL INDICATION

Historically, surgical repair has been advocated in all patients with PEH, even when asymptomatic. In recent years, nonsurgical management has proven to be a better alternative to elective surgery in asymptomatic or minimally symptomatic patients; thus surgical treatment is now considered mainly for symptomatic PEH.

Associated symptoms can include heartburn, regurgitation, postprandial epigastric or chest pain, dysphagia, vomiting, weight loss, dyspnea, and anemia. Symptomatic patients without prohibitive operative risk should undergo laparoscopic repair.

PREOPERATIVE EVALUATION

In addition to a thorough history and physical evaluation, several tests are needed preoperatively to determine the anatomy and physiology of the esophagus and stomach.

Barium esophagram. This study is critical for the diagnosis of PEH and description of its anatomy. The ability to distinguish between different hernia types helps determine the complexity of the operation (Fig. 1).

Upper endoscopy. Endoscopy is important to rule out malignancy and determine the presence of esophagitis, Barrett's esophagus, gastritis, Cameron ulcers, and/or peptic ulcer disease.

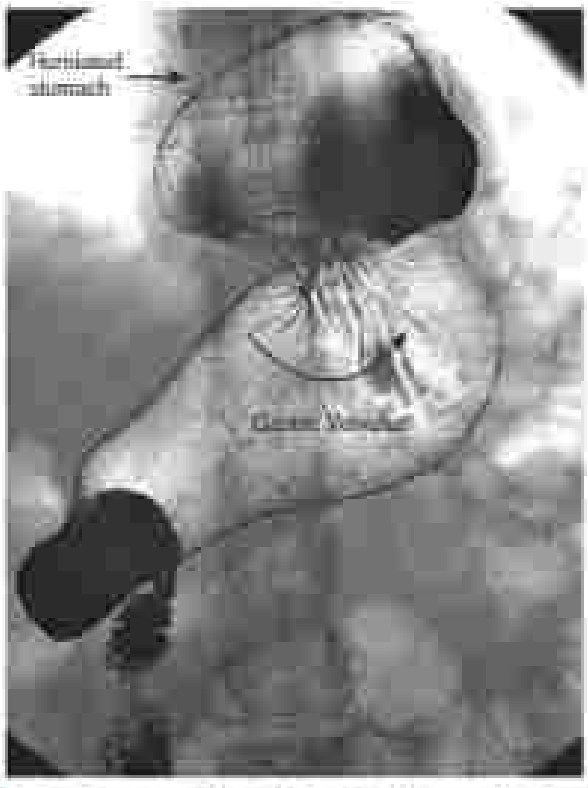

FIG. 1 Barium esophagram showing a large paraesophageal hernia with a gastric volvulus.

Abdominal and chest computed tomography scan. This test will add additional information if the presence of a type IV hernia is suspected (Fig. 2).

Esophageal manometry. Patients with PEH often have abnormal esophageal motility. In patients with complete upper third or severely impaired peristalsis, we tailor our operation and perform a partial fundoplication. If the manometry is technically unfeasible or the patient cannot tolerate the catheter, a partial fundoplication should also be performed.

Although patients with PEH may have pathologic reflux, obtaining a pH monitoring study does not add significant information preoperatively. The operation will alter the physiology of the GEJ and a fundoplication to prevent reflux will be performed regardless of the results of the study.

Cardiopulmonary risk assessment and related tests are performed on a case by case basis, particularly because these patients are often elderly.

SURGICAL TECHNIQUE

Traditionally, PEH repair required either a laparotomy or thoracotomy, which was accompanied by the morbidity associated with these approaches. Since its introduction, laparoscopic repair has been shown to be superior to other approaches in terms of improved postoperative outcomes; therefore, the vast majority of our patients are managed with a laparoscopic approach.

Positioning of the Patient

After induction of general endotracheal anesthesia, an orogastric tube is inserted to keep the stomach decompressed. The patient is positioned supine in low lithotomy position with the lower extremities extended on stirrups, with knees flexed 20 to 30 degrees. To avoid sliding because of the steep reverse Trendelenburg position used during the entire procedure, a bean bag is inflated to create a "saddle" under the perineum. Pneumatic compression stockings and subcutaneous heparin are always used as prophylaxis against deep vein thrombosis (particularly important as the increased abdominal pressure secondary to the pneumoperitoneum and the steep Trendelenburg position decrease venous return). The surgeon stands between the patient's legs, and the first and second assistants on the left and right side of the operating table, respectively.

Trocar Placement

Five 10-mm ports are used for the procedure: one for the camera, two for the operating surgeon, one for the assistant, and one for the liver retractor. The first port is usually placed in the midline about 14 cm below the xiphoid process; it can be also placed slightly to the left of the midline to be in line with the esophagus. This port is used for insertion of the scope. The second port is placed in the left midclavicular line at the same level of port 1 and is used for the insertion of a Babcock clamp for traction, a grasper to hold the Penrose drain while surrounding the esophagus, or for devices used to divide the short gastric vessels. The third port is placed in the right midclavicular line at the same level of the other two ports and is used for the liver retractor. The fourth and fifth ports are placed under the right and left costal margins so that their axes and the camera form an angle of about 120 degrees. These ports are used for the insertion of dissecting and suturing instruments (Fig. 3).

Troubleshooting

Extreme care must be taken when positioning the first port in the supraumbilical area because the site is just above the aorta and its bifurcation. We recommend using an optical trocar to obtain access after achieving a pneumoperitoneum of 15 mm Hg with a Veress needle. In addition, a common mistake is to place the trocars too low. This can make the operation more challenging (e.g., difficult to take down the proximal short gastric vessels and perform the mediastinal dissection).

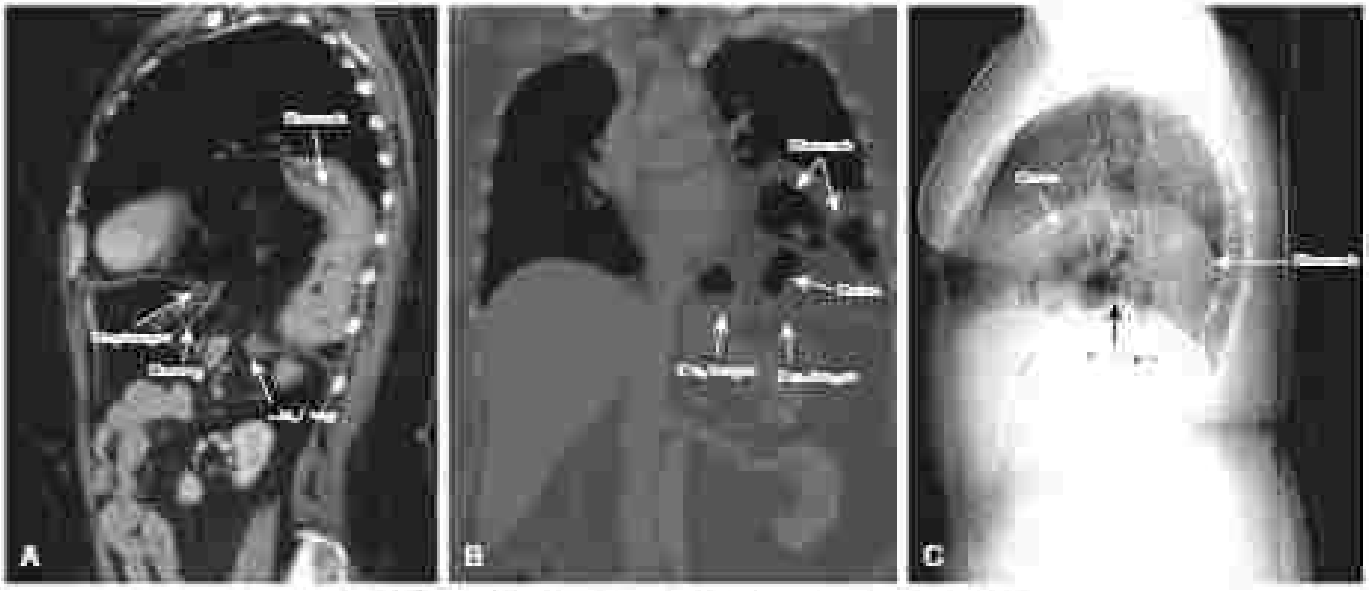

FIG. 2 Computed tomography scans showing a type IV paraesophageal hernia.

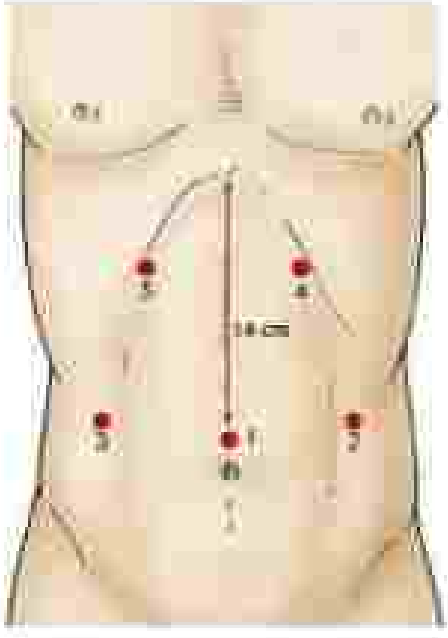

FIG. 3 Port placement for laparoscopic paraesophageal hernia repair. (From Patti MG, Feo CV, Arcerito M, Fisichella PM, Way LW. Laparoscopic paraesophageal hernia repair. J Am Coll Surg. 2000;191(3):331.)

Dissection and Reduction of Hernia Sac

After the initial abdominal exploration, an attempt is made to reduce the stomach. This is done by gently pulling the herniated stomach out of the posterior mediastinum down into the abdomen using a Babcock clamp. Excessive force should be avoided during this initial maneuver to prevent gastric injury or even perforation. The dissection is safely started along the greater curvature (left crus approach), the short gastric vessels are divided, and the left pillar of the crus is reached. Then, the hernia sac is incised at the junction with the left crus and an anterior and lateral mobilization of the esophagus is performed. Once the initial dissection from the left has been completed and more stomach is reduced, the gastrohepatic ligament is opened toward the right pillar of the crus and the esophagus is further dissected in the posterior mediastinum. A posterior window behind the esophagus is created and a Penrose drain is placed around the esophagus incorporating both the anterior and posterior vagus nerves. The hernia sac is then freed from mediastinal adhesions by blunt dissection. If the correct plane has been entered, the hernia sac should separate relatively easily, revealing the mediastinal pleura laterally, pericardium anteriorly, and aorta posteriorly. We do not routinely resect the entire sac, but rather transect it at the level of the esophageal hiatus to identify the esophagogastric junction.

Troubleshooting

Opposite to most of the surgical operations, in patients with PEH, we start along the greater curvature of the stomach by dividing the short gastric vessels. This approach reduces the risk of injury to a replaced or accessory left hepatic artery that can occur if the dissection is started over the gastrohepatic ligament. This resultant bleeding may be difficult to control if the proximal stump of the artery retracts above the diaphragm into the mediastinum. During blunt dissection of the hernia sac, tears in the pleura on either side can occur. The anesthesiologist should be informed, and in case of capnothorax that results in hypotension or increased airways pressure, the reduction in insufflation pressure usually corrects these abnormalities.

Esophageal mobilization and Lengthening

The mediastinal dissection is extended proximally to leave at least 3 cm of esophagus below the diaphragm. This limits the risk of recurrence and returns the EGJ to its most physiologic location. After extended mobilization of the esophagus in the posterior mediastinum, the presence of a short esophagus is rare. Therefore, esophageal lengthening procedures (e.g., stapled wedge gastroplasty) are seldom used.

Troubleshooting

While measuring the length of the esophagus below the diaphragm, it is critical to avoid caudal traction on the stomach because this can falsely lengthen the intraabdominal segment of the esophagus.

Closure of the Esophageal Hiatus

Retraction of the esophagus upward and toward the patient's left with the Penrose drain provides proper exposure. The closure of the

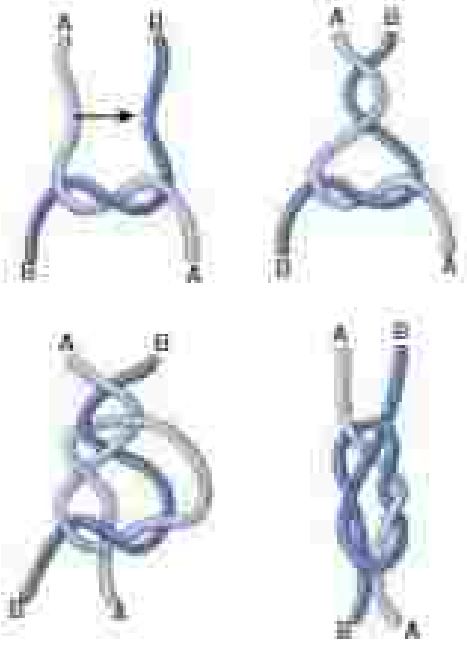

FIG. 4 Intracorporeal suture knot. (From Patti MG, Feo CV, Arcerito M, et al. Laparoscopic paraesophageal hernia repair. J Am Coll Surg. 2000;191(1):70–77.)

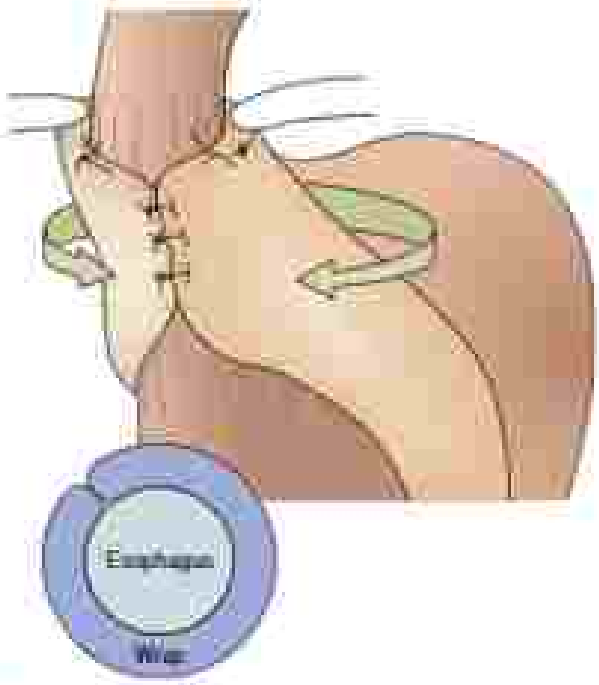

FIG. 5 Crural repair and total 360-degree fundoplication. (From Townsend CM, Beauchamp RD, Evers BM, et al. Sabiston Textbook of Surgery. 20th edition. Philadelphia: Elsevier; 2017.)

hiatus starts with the approximation of the right and left pillar of the crus behind the esophagus with interrupted nonabsorbable sutures. Because the hiatus is often very large, the closure of the crura can be under tension. The placement of the first stitch is critical because it decreases the tension and facilitates the placement of subsequent stitches. This first stitch is placed about 1 cm posterior to the esophagus and is secured with an extracorporeal jamming knot ("Capitan knot" in nautical terminology) to overcome tension (Fig. 4). Subsequent stitches are placed below the first one. Often only posterior sutures are necessary. Sometimes, however, one or two additional stitches anterior to the esophagus are needed to further narrow the hiatus. If there is considerable tension placed on the closure, a relaxing incision on the right hemidiaphragm (incision just lateral to the right crus) can help to approximate the right crus with the left one. If this is performed, a mesh patch over the resulting diaphragmatic defect is needed.

With the development and wide application of mesh placement for tension-free repair of inguinal and incisional hernias, many surgeons believed that the use of mesh for laparoscopic PHH repair would reduce recurrence rate. These beliefs were supported by two randomized trials that reported a significant reduction in recurrence rates by using synthetic mesh in hiatal hernia repairs. However, serious complications because of mesh erosion into the esophagus and even the aorta became a serious concern and brought the development of biological meshes with absorbable material. Interestingly, a randomized trial showed a significant reduction of the 6-month recurrence rate with the use of a biologic prosthesis as compared to cruroplasty alone (9% vs 24%). The same group, however, reported later a similar 5-year recurrence rate between the two groups (54% vs 50%). Based on the current evidence and our experience, the use of mesh is not routinely recommended and should be reserved for patients in whom a tension-free cruroplasty cannot be achieved.

Troubleshooting

Care must be taken with the inferior vena cava and aorta when placing the stitches. The crura should not be too tight, and a clear grasper should slide easily between the esophagus and the crura. The bougie should not be placed during this part of the procedure because it interferes with exposure and suturing.

Fundoplication

Once the hiatus is closed, the fundoplication is the last step of the procedure. The rationale for a fundoplication includes the following: (1) it increases the resting pressure of the lower esophageal sphincter, (2) it corrects gastroesophageal reflux, if present preoperatively, (3) it prevents the development of postoperative reflux secondary to the extensive dissection, and (4) it works as a gastropexy anchoring the stomach below the diaphragm.

The stomach is passed behind the esophagus and a three-dimensional maneuver is performed to verify sufficient fundic mobilization and to avoid having part of the gastric fundus above the wrap. For a total 360-degree fundoplication, a 56F bougie is inserted down the esophagus into the stomach to prevent postoperative dysphagia. The gastric fundus is then pulled under the esophagus with two graspers, and the left and right sides of the fundus are wrapped above the esophagogastric junction. A Babcock clamp is used to hold the two sides of the fundus during the placement of the first stitch. A 360-degree fundoplication is created by placing three stitches of nonabsorbable material at 1-cm intervals to approximate the right and left side of the fundoplication. The length of the anterior portion of the fundoplication should be approximately 2 cm (Fig. 5).

The partial posterior 240-degree fundoplication (Toupet fundoplication) is created by placing six stitches of nonabsorbable material. The right and left sides of the fundus are separately sutured to the right and left side of the esophagus, leaving 120 degrees of the anterior esophageal wall uncovered (Fig. 6).

Troubleshooting

The wrap should not be under tension. Essentially, if the wrap remains in the right side after pulling the fundus under the esophagus and does not retract back to the left, then it is floppy and suturing can be performed. If tension is still present after these maneuvers, a partial fundoplication is preferred.

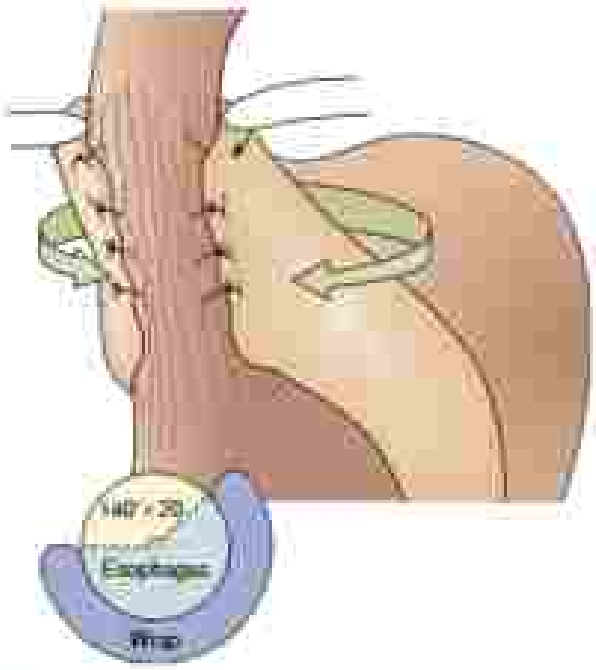

FIG. 6 Crural repair and partial posterior fundoplication. (From Townsend et al: Sabiston Textbook of Surgery, 20th edition. Philadelphia: Elsevier, 2017.)

POSTOPERATIVE CARE

Patients are typically extubated immediately after completion of the operation and the orogastric tube is pulled out. Patients are fed the morning after the procedure with clear liquids and then a soft diet. They are usually discharged after 24 to 48 hours and are instructed to avoid meat, bread, and carbonated beverages for the following 2 weeks. The time to full recovery ranges between 2 and 3 weeks.

OUTCOMES

The laparoscopic PEH repair has proven to be a durable repair with excellent long-term symptomatic relief. Although a high recurrence rate has been reported, in most cases it consists of small sliding hiatal hernias seen on follow-up radiographic imaging without any clinical significance.

MANAGEMENT OF ZENKER'S DIVERTICULUM

Derek T. Moore, MD, John B. Romanelli, MD, FACS, and Katie S. Nason, MD, MPH

Zenker's diverticulum is a rare disorder that is the end result of chronically increased hypopharyngeal pressure, which creates a pulsion diverticulum by pushing the hypopharyngeal mucosa through Killian's triangle at the junction of the hypopharynx and the esophagus. Over time, the diverticulum enlarges and symptoms develop. Killian's triangle is an area of weakness between the thyropharyngeus muscles, which constrict the pharynx, and the cricopharyngeus, which acts as the upper esophageal sphincter. This impaired relaxation of the cricopharyngeus is opposed by the pulsion forces of the pharyngeal constrictors, thus creating Zenker's diverticulum. Occurring in approximately 2 of every 100,000 people, the pathology was first described by Abraham Ludlow in 1769, but is named after German pathologist Friedrich Albert von Zenker, who published a case series of 28 patients in 1877.

CLINICAL FEATURES

Zenker's diverticulum most commonly presents in patients in their seventh and eighth decades as dysphagia, but is also associated with regurgitation of undigested food, choking, cough, aspiration, halitosis, weight loss, and hoarseness. Etiology of these symptoms may stem either from incomplete relaxation of the upper esophageal sphincter or external esophageal compression by the diverticulum. Hematemesis, obstruction, or acute change in symptoms may signal malignancy in the diverticulum. Ulcers can also develop and may be a source of significant bleeding. In some patients, a neck mass may be palpable. In these patients, palpation of the mass may induce Boyce's sign, which is a rumbling or gurgling sense made by movement of gas and liquid (borborygmus) and may help to identify the swelling as a diverticulum rather than a cyst or other mass like structure.

The degree of dysphagia is typically quantified with a dysphagia scale such as the Dakkak and Bennett score (Table 1). This can be obtained in the preoperative setting and used to monitor symptoms for progression and postoperatively to determine degree of symptom relief. Initial symptom assessment should also include a comprehensive assessment of associated symptoms. As the diverticulum enlarges, dysphagia worsens. Weight loss and malnutrition are a common complaint, occurring in up to 20% of patients. Supplemental

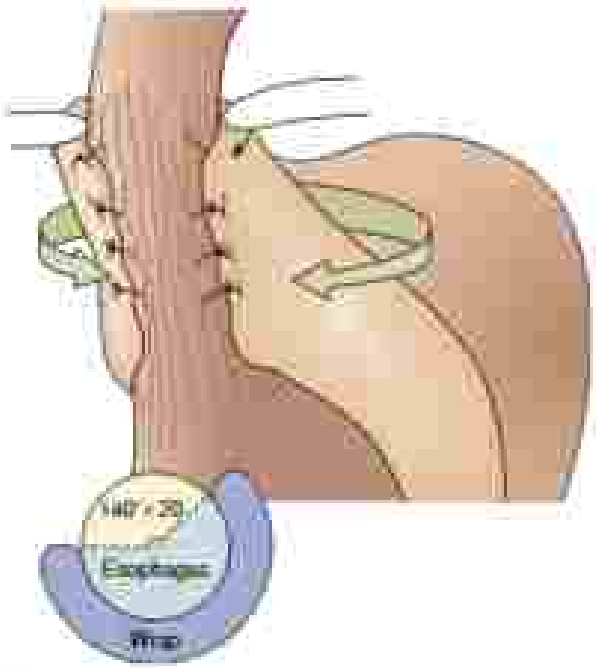

FIG. 6 Crural repair and partial posterior fundoplication. (From Townsend et al: Sabiston Textbook of Surgery, 20th edition. Philadelphia: Elsevier 2017.)

POSTOPERATIVE CARE

Patients are typically extubated immediately after completion of the operation and the orogastric tube is pulled out. Patients are fed the morning after the procedure with clear liquids and then a soft diet. They are usually discharged after 24 to 48 hours and are instructed to avoid meat, bread, and carbonated beverages for the following 2 weeks. The time to full recovery ranges between 2 and 3 weeks.

OUTCOMES

The laparoscopic PEH repair has proven to be a durable repair with excellent long-term symptomatic relief. Although a high recurrence rate has been reported, in most cases it consists of small sliding hiatal hernias seen on follow-up radiographic imaging without any clinical significance.

nutrition may be needed, including enteral feeding via a feeding tube in cases of severe malnutrition before operative intervention to prevent wound healing complications (Table 2).

DIAGNOSIS

Diagnosis of Zenker's diverticulum includes history and physical examination followed by radiographic assessment with either a contrast esophagram or computed tomography scan imaging of the neck. On contrast esophagram, Zenker's diverticulum is seen as an outpouching at the upper esophagus just proximal to the cricopharyngeus muscle (Fig. 1). In some cases, a cricopharyngeal bar or "stricture" may be noted. The esophagram allows the surgeon to note the presence of the diverticulum, measure size, and assess for mucosal lining abnormalities that may influence the choice of treatment. Computed tomography imaging will typically show a cystic mass adjacent to the hypopharynx with air and/or fluid. Subsequent evaluation with flexible endoscopy is often performed, but is not necessary if prior imaging shows a definitive diverticulum without mucosal abnormalities. There is some evidence that gastroesophageal reflux disease contributes to the development of hypertension of the upper esophageal sphincter in this population, so aggressive management of reflux with lifestyle modification and antireflux medications is warranted. Additional testing with manometry can provide useful information with regard to esophageal motility but must be approached cautiously because the catheter can perforate the diverticulum if the proceduralist is not aware of the patient's anatomy and attempts to force the catheter. Coiling of the catheter in the diverticulum is also a frequent problem.

SURGICAL TREATMENT

The options for surgical management currently include both transoral endoscopic and transcervical open approaches (Table 3). Regardless of the surgical approach, the primary tenet of repair is to relieve the area of high pressure created by impaired relaxation of the cricopharyngeus muscle by performing a complete cricopharyngeal myotomy.

FIG. 1 Contrast esophagram showing outpouching of the hypopharynx just proximal to the cricopharyngeus muscle.

TABLE 3 Summary of Operative Techniques for Management of Zenker's Diverticulum

Technique	Description
Open diverticulectomy with myotomy	Excision of diverticulum with myotomy of the cricopharyngeus muscle
Open diverticulopexy with myotomy	Mobilization of the diverticulum with suture fixation above the neck of the diverticulum to the prevertebral fascia with myotomy of the cricopharyngeus muscle
Open myotomy alone	Myotomy of the cricopharyngeus muscle
Endoscopic diverticulotomy (rigid or flexible)	Transoral endoscopic division of cricopharyngeus muscle and the septum between the diverticulum and esophagus using electrocautery, laser, or stapler

failure to address this obstruction distal to the diverticulum will result in incomplete relief of symptoms and increase the likelihood of complications, such as a leak, at the site of the repair.

OPEN TRANSCERVICAL SURGICAL TREATMENT

Open surgical therapy was first performed by Wheeler in 1886, and was long considered the gold standard for treatment of Zenker's diverticulum. There are many approaches to open surgery that have

been developed over time, with the most common approach via a left cervical incision. Dissection is performed through the platysma down to the medial border of the sternocleidomastoid and carotid sheath. These are retracted laterally to expose the esophagus and diverticulum. A left-sided incision is always used, regardless of the location of the diverticulum because the cervical esophagus is positioned slightly off midline toward the left, behind the trachea at this level. Once the base of the diverticulum is exposed, the cricopharyngeus is divided completely, taking care to address all muscle fibers and to expose the underlying esophageal mucosa. Once all fibers have been divided for a complete myotomy, the diverticulum is either resected or undergoes diverticulopexy, depending on the anatomy and safety. Diverticulectomy is performed using a stapler across the base of the diverticulum, which is exposed by carefully separating the mucosa from the surrounding musculature. In some cases, the diverticulum can be sharply dissected and oversewn, but this is less commonly done. Other surgical options include performing a diverticulopexy by suturing the apex of the diverticulum to the prevertebral fascia to a nondependent location or invaginating the diverticulum and oversewing the neck to prevent recurrence. The advantage of performing a diverticulectomy is elimination of the small risk of diverticular carcinoma and complete elimination of the pouch, where food and liquid might otherwise be retained. The advantage of diverticulopexy and invagination is the decreased risk of a postoperative leak as neither approach violates the hypopharyngeal mucosa. Open surgical treatment of Zenker's diverticulum has become significantly less common but may still be indicated in extremely large or small diverticula because they present the most challenges to endoscopic treatment.

ENDOSCOPIC TREATMENT

Endoscopic treatment for Zenker's diverticulum has become the most common approach to surgical therapy over the past decade, with equivalent success rates and less invasive technique. Endoscopic approaches include rigid endoscopy and flexible endoscopy.

Rigid Endoscopic Treatment

First described in 1917 by Mosher, followed by the introduction of the rigid endoscope, stapler and Weerda diverticulascope (Fig. 2), rigid endoscopic stapled diverticulotomy became the minimally invasive standard of care in treatment of Zenker's diverticulum. The endoscopic approach offers comparable success rates while reducing postoperative pain and length of hospitalization. This approach capitalizes on the dependent positioning of most diverticula, which track along the esophagus and thus have a shared septum. The septum includes the esophageal mucosa and the underlying cricopharyngeus muscle and the dependent wall of the diverticulum externally. After induction of general anesthesia, the patient must be positioned with the neck fully extended. The Weerda diverticulascope is then inserted with one blade on each side the diverticular septum. Many surgeons use a laparoscopic or endoscopic suturing device to place a stay suture at the apex of the septum to provide traction (Fig. 3). An endoscopic stapler is modified by shaving off the nail of the anvil to allow the full length of the cutting portion of the stapler to be used in dividing the septum. The endoscopic stapler is then inserted with the jaws across the septum. The cartridge is placed in the esophagus, and the anvil is placed in the diverticulum. The stapler is then fired, which both divides the septum (including the cricopharyngeus muscle) and staples the cut edges.

Results with this procedure have been excellent. A recent systematic review by Yuan and colleagues included 1900 patients from 44 studies undergoing rigid endoscopy with stapling for management of Zenker's diverticulum. The overall complication rate was 7.1%, with a mortality rate of 0.3%. The most common complications included dental injuries (2%), esophageal mucosal damage (1.6%), and perforations (1.6%). Complications were increased in patients with larger diverticula requiring multiple staple loads. A limitation to the rigid endoscopic approach is a relatively high rate of abandonment, typically because of small diverticula. This was reported as 7.2% in one series (Leong et al.). Historically, diverticula smaller than 2 to 3 cm have not been amenable to stapling, but the use of the stay suture facilitates anchoring of the stapler to the diverticular pouch, although care must be taken not to perforate the diverticulum.

Alternatives to stapling of the septum include division with cautery using monopolar (as described by Dohlman et al.) or bipolar energy devices, as well as carbon dioxide laser. The risk of this method is potential failure of coagulation of the mucosal edges, but these may be approximated with clips. Systematic reviews of the publications reporting outcomes using the Dohlman technique show an overall complication rate of 7.8%, with a 0.2% mortality rate. Review of the carbon dioxide laser technique demonstrated an overall complication rate of 9.3%, with an identical mortality rate of 0.2% by comparison.

Flexible Endoscopic Treatment

Flexible endoscopic therapy for Zenker's diverticulum, first introduced in 1995, has become increasingly common over the past decade. Similar to the rigid endoscopic approach, the procedure is a diverticulotomy and not a diverticulectomy. It offers the significant advantage of not requiring neck extension, which is helpful for elderly patients in whom extension can be limited. Further, it can be performed under conscious sedation, so it is especially useful for patients who have significant surgical comorbidities limiting general

FIG. 2 Weerda diverticulascope.

anesthesia. Although some authors describe the use of a rigid diverticuloscope, a simple endoscopic cap can also be used to open the esophageal and diverticular lumens to expose the diverticular septum. Often, a nasogastric tube or a guidewire is placed in the true esophageal lumen to help differentiate it from the false lumen (the diverticulum).

A major advantage to the flexible endoscopic technique is that it allows direct visualization of the cricopharyngeal muscle. One possible reason for recurrences or failure with a stapled or laser technique is that it can be difficult to ascertain if the muscle is completely divided. In the flexible endoscopic approach, the mucosa is opened first, exposing the muscle (Fig. 4A, C). The muscle is then completely divided until no further muscle fibers are visible without tunneling into the esophageal wall (Fig. 4D). With advancements in technology, multiple tools can then be used through or alongside of the flexible endoscope to incise the diverticular septum, such as hook knife cautery endoscopic shears, argon plasma coagulation, needle knife cautery, sling bridle knife, the dutch cutter knife, carbon dioxide laser, and the thulium laser. At the conclusion of the mucosal and muscular diversion, endoscopic clips are deployed to close the mucosa (Fig. 4E, F).

Across multiple studies, this approach has shown to be an effective and less invasive modality of treatment. Two recent review articles aggregated the results of multiple published series with both prospective and retrospective trials from around the globe. Composite clinical success rate (defined as complete resolution or significant improvement in symptoms) was 87.9% (Jain et al.) in one study and 91% (Ishaq et al.) in another. Of patients who failed initial treatment and elected for repeat flexible endoscopic therapy, 91.2% had subsequent clinical success. Outcomes were not stratified by diverticular size in all but one study. One prospective cohort study did find that diverticula larger than 50 mm led to increased clinical failure rates. Complication rates for the flexible endoscopic approach are low; in one series, there were reported rates of cervical emphysema (6.7%), perforation (1.8%), and bleeding (3.1%) (Yuan et al.).

CONCLUSION

The treatment of Zenker's diverticulum has undergone a true paradigm shift from dominance of open surgery to transoral endoscopic techniques as they have become more universally accepted as safe and effective. Meta-analysis by Albers and colleagues showed significant decrease in length of procedure and hospital stay and lower complication rates after endoscopic treatment, whereas open surgical therapy resulted in lower recurrence rates.

Endoscopic treatment itself has evolved significantly, with flexible endoscopy becoming significantly more prevalent in the past decade. Investigation is still under way comparing rigid with flexible techniques because there are no definitive randomized trials distinguishing superiority of one technique. Each modality is operator dependent, and outcomes are very likely to be related to the comfort of the surgeon using either the Weerda scope or flexible endoscope.

As technology continues to advance, the treatment of Zenker's will almost certainly continue to evolve. The variety of tools already available allows us to tailor our treatment to individual patients and diverticula, and as surgeons it is important for us to be facile with multiple modes of therapy to properly treat Zenker's in its different iterations.

Achalasia of the Esophagus

Eric W. Etzkill, MD, MPH, and Stephen C. Yang, MD

Achalasia, defined as the failure or incomplete relaxation of the lower esophageal sphincter (LES) with accompanying esophageal body aperistalsis in the absence of mechanical obstruction, is the most common type of esophageal motility disorder. It has an incidence of 1 to 100,000 people, with a prevalence of 10 to 100,000. There is no difference in gender prevalence between the ages of 30 and 60 years. The primary cause of achalasia remains undetermined, but it is believed to arise from degeneration of inhibitory ganglion cells in the myenteric plexus of the LES and esophageal body. Factors associated with an increased risk of achalasia include viral neurodegenerative disorders, Chagas syndrome, type 1 diabetes mellitus, hypothyroidism, and autoimmune conditions such as Sjögren's syndrome, systemic lupus erythematosus, and uveitis. Familial cases are rare.

A diagnosis of achalasia should be suspected in patients with dysphagia to both solids and liquids that does not resolve despite the use of proton pump inhibitors. If left untreated, achalasia is a progressive disease that may advance to megaesophagus and is associated with an increased risk of esophageal squamous cell carcinoma.

Although no standardized criteria exist to determine severity of disease, the diameter and configuration of the esophagus within the thoracic cavity are generally considered the two primary factors. The Eckardt scale (Table 1) is one scale frequently used to assess disease severity and efficacy to therapy. Clinical stages of 0 to 4 are assigned based on the sum of the symptom scores, corresponding to 0 to 1, 2 to 3, 4 to 6, and more than 6, respectively. Stages 0 and 1 are associated with remission of the disease, whereas stages II and III represent treatment failure. Qualitatively, severe achalasia is defined as an esophageal diameter greater than 6 cm, and stage achalasia includes the distal angulation, a sigmoid or tortuous esophagus greater than 6 cm diameter, or megaesophagus greater than 10 cm in diameter. Roughly 2% to 15% of people with achalasia progress to end stage achalasia, are generally resistant to initial endoscopic and surgical treatments and ultimately require an esophagectomy.

DIAGNOSIS

More than 90% of patients with achalasia first present with dysphagia to both solids and liquids as the primary symptom. The majority also present with regurgitation of undigested food, which occurs most frequently while recumbent at night. They also may have additional symptoms of gastroesophageal reflux, chest pain, epigastric pain, weight loss, cough, hoarseness, wheezing, and a sore throat. This may result in a misdiagnosis of gastroesophageal reflux disease (GERD) and delay appropriate diagnosis and treatment. Additional disorders in the differential diagnosis include esophageal rings, webs, or strictures, peptic ulcer strictures, esophagitis, other esophageal motility disorders, prior fundoplication or bariatric surgery, malignancy causing intrinsic obstruction or extrinsic compression, paraesophageal achalasia, and systemic disorders, including sarcoidosis and amyloidosis. Aside from possible weight loss, there are generally no physical examination findings associated with achalasia.

TABLE 1 Eckardt Clinical Scoring System for Achalasia

	Symptom			
Score	Weight Loss (kg)	Dysphagia	Retrosternal Pain	Regurgitation
0	None	None	None	None
1	≤5	Occasional	Occasional	Occasional
2	5-10	Daily	Daily	Daily
3	>10	Each meal	Each meal	Each meal

Final score is the sum of all four components, range 0–12.

Esophageal Function Tests

The diagnosis of esophageal achalasia is established with a combination of esophageal function tests. Initially barium esophagography (preferably with a video component), esophagogastroduodenoscopy (EGD), or both are required to exclude extrinsic or intrinsic mechanical obstruction due to malignancy. If the patient's clinical history or EGD findings raise suspicion for malignancy an endoscopic ultrasound (EUS) should be performed. Esophageal manometry followed by 24-hour pH monitoring are used to confirm the suspicion.

Barium Esophagogram

After initial screening test for dysphagia, patients should undergo radiographic evaluation with a barium esophagogram to evaluate esophageal emptying and assess gastroesophageal junction morphology. A video or cine technique may allow real-time assessment of motility disorders and assess esophageal emptying. Although this modality helps to confirm the diagnosis of achalasia, it is not sensitive enough to diagnose it alone. Classically the "bird beak" appearance with tapering at the GEJ is found. Additional findings include an epiphrenic diverticulum, sigmoidal esophageal dilation, retained food products, delayed emptying, and a decrease or absence of gastric air bubbles. These findings can assist in ruling out other esophageal disorders with similar presentations to achalasia, including pseudoachalasia due to malignant obstruction or infiltration. In addition to diagnosis, esophagrams are also used to assess esophageal emptying after any intervention.

Esophagogastroduodenoscopy

EGD allows for direct visualization, excluding mechanical obstruction, confirming other structural abnormalities such as diverticula, and ascertaining tissue biopsies. Although nearly one half of all patients with achalasia will have a normal EGD, findings consistent with achalasia include retained saliva or food products in the absence of mechanical obstruction, a hirsutism or dilated esophagus, inflamed mucosa, a thickened LES with a tapered configuration, a thickened GEJ, and exaggerated abnormal contractions. Although EGD findings alone are not sufficient for the diagnosis of achalasia, they are used to support its diagnosis.

Esophageal Manometry

Esophageal manometry remains the gold standard for diagnosing achalasia, irrespective of findings from other modalities. The classic findings diagnostic of achalasia include aperistalsis and a failure of LES relaxation with swallowing.

Once mechanical obstruction is excluded, patients should undergo esophageal manometry, preferably using a high-resolution system because it can simultaneously assess upper and lower esophageal sphincters and the entire length of the esophagus, compared to 5-cm intervals with traditional manometry. The functional assessment allows for the classification of achalasia into one of three types based on esophageal pressure topography (Fig. 1).

During manometry a pressure-sensing device placed through the nose down the esophagus and into the stomach is used to measure pressure throughout the esophagus and the LES, thereby studying

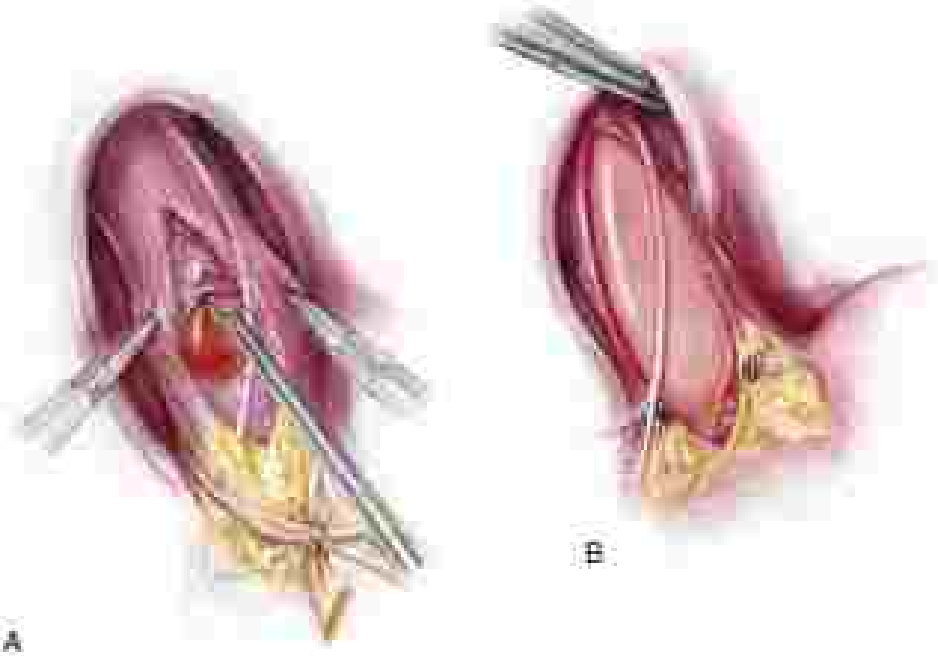

FIG. 1 Laparoscopic Heller myotomy. (A) Elevation and division of the submucosal esophagus plane. (B) Muscle fibers are separated from underlying mucosa until at least 50% of the mucosal circumference is exposed. (*Courtesy Cleveland Clinic Foundation Staff Members: From Cameron JL, Sandborn C. Atlas of Gastrointestinal Surgery, vol. 1. 2nd ed. Hamilton, ON: BC Decker Inc; 2007.*)

esophageal contractile strength and coordination. A diagnosis of achalasia is confirmed by the required combination of incomplete LES relaxation and aperistalsis in the absence of mechanical obstruction on high-resolution manometry. With conventional manometry, failure of LES relaxation is defined as a mean fall in resting pressure to a nadir greater than 8 mm Hg above gastric pressure. Aperistalsis is defined by an absence of contraction or the presence of simultaneous contractions with amplitudes less than 40 mm Hg in the distal two-thirds of the esophagus. With high-resolution manometry, impaired LES relaxation is defined by a mean 4-second integrated resting pressure (IRP) 15 mm Hg or more over ten swallows. Aperistalsis is characterized by lack of contractions or pressurization throughout the esophagus. Additional findings that support the diagnosis of achalasia but are not required include increased baseline LES pressure greater than 45 mm Hg, increased esophageal body baseline pressure, simultaneous nonperistaltic contractions, and a complete LES relaxation to gastric baseline of less than 4 seconds' duration.

Endoscopic Ultrasound

Endoscopic Ultrasound (EUS) is used to exclude pseudoachalasia, due to an extraluminal or infiltrating mass in patients with a strong suspicion for malignancy. Clinical factors that raise suspicion for malignancy include increased age, unexplained weight loss, and aggressive symptom onset. Endoscopic findings supporting malignancy include extrinsic compression, more severe outflow obstruction with increased GEJ resistance compared to that observed with achalasia, and mucosal ulceration. Fine needle aspiration can be performed with EUS to support the diagnosis of achalasia, which would include thickened inner circular muscular layer of the LES.

CLASSIFICATION

The use of high-resolution manometry has allowed for a greater understanding of and more focused treatments for achalasia. There are three primary types of achalasia based on high-resolution manometric findings, according to the Chicago Classification of Esophageal Motility Disorders v3.0. All three types have in common impaired LES relaxation, quantified by an IRP greater than 15 mm Hg, as well as aperistalsis. Definitions and criteria are listed in Table 2.

Vigorous Achalasia

Vigorous achalasia is a subtype of achalasia with clinical and manometric features of both achalasia and diffuse esophageal spasm. Its diagnosis is confirmed with manometry, which demonstrates simultaneous, repetitive, distalize high amplitude contractions or premature peristalsis with contractions greater than 40 mm Hg in the absence of coordinated LES relaxation, in contrast to low amplitude contractions seen with classic achalasia.

TREATMENT

Achalasia is a chronic, incurable, progressive disease. As such, treatment is aimed at reducing the hypertonicity of the LES and improving or resolving symptoms by improving esophageal emptying and preventing further dilation. Treatment for esophageal achalasia can be categorized into pharmacologic, surgical, and endoscopic procedures, which are all intended to reduce the tone of the LES. Although most patients experience improvement in swallowing and other symptoms after treatment, peristalsis remains abnormal, and esophageal function never fully recovers. Risks associated with treatment include the progression to sigmoesophagus or end-stage achalasia, as well as esophageal squamous cell carcinoma.

Initial surgical and endoscopic treatments for achalasia in patients deemed good surgical candidates include pneumatic dilation, laparoscopic myotomy, and peroral endoscopic myotomy (POEM). Each of these methods has been shown to be equally effective, and choice of treatment often is based on type of achalasia, patient preference, and physician or institutional expertise.

Pneumatic Dilation

For patients who do not wish to undergo surgery or in whom initial surgical management has failed, pneumatic dilation (PD) is an effective first-line nonsurgical therapy. The risk of perforation is lower than

TABLE 2 Summary of Chicago Classification of Motility Disorders v3.0: Characteristics and Treatment Options for Achalasia

	Type 1: Classic Achalasia (10% of Patients)	Type 2: Achalasia With Pressurization (~15% of Patients)	Type 3: Spastic Achalasia (10% of Patients)
Barium swallow			
Manometry findings	High IRP Absent peristalsis Absent contractile activity	Normal IRP Simultaneous, normal-amplitude pressurization Absent peristalsis Absent contractile activity	High IRP Absent peristalsis ≥2 spastic contractions with or without periods of compartmentalized pressurization
High-resolution manometry			Response to Therapy	Intermediate response	Most responsive Least likely to require further treatment within 12 months	Least responsive Botox ineffective Most likely to need multiple interventions Surgical myotomy more effective than POEM

IRP, integrated resting pressure; POEM, peroral endoscopic myotomy.
Modified from Kahrilas PJ, et al. Classification of achalasia [types 1 to 3]. [illegible] 2015;[illegible]:144.

with a myotomy, and 50% to 90% of patients experience symptomatic relief. Although the rate of perforation is lower, PD should only be recommended to patients who would also be surgical candidates and where surgical intervention is available because the possibility of perforation may necessitate surgical repair. Roughly one third of all patients will have recurrent symptoms requiring repeat PD within 5 years. Factors that increase the likelihood of successful outcomes with PD include age greater than 45 years, female sex, pendulation LES pressure less than 10 mm Hg, and type II achalasia.

During PD, the lumen of the LES is dilated using a nonlatex, opaque polyethylene pneumatic balloon on a flexible catheter under fluoroscopic or endoscopic guidance over a guidewire. A handheld manometer is used to inflate the balloon (30–40 mm) to a pressure of 7 to 15 psi and held for 15 to 60 seconds. This allows for dilation and disruption of the circular muscle layer of the LES. Dilation is usually started with a 30 mm balloon and serially increased using larger-diameter balloons according to treatment response and symptom severity. Greater improvement in symptoms is generally seen with the use of larger diameter balloons.

At the conclusion of the procedure, patients should undergo esophagography first with a water soluble contrast followed by barium contrast, if negative, to rule out perforation. If perforation is expected, computed tomography scanning should be performed to look for free air. If a perforation is confirmed, an endoscopically placed covered stent should be placed across the defect. Patients should also be instructed to seek immediate medical attention if they experience severe chest pain within several days of undergoing PD because this may be the first indication of a delayed perforation, a potentially catastrophic complication. Additional complications include esophagitis, hematoma, and gastroesophageal reflux disease, which occur in 15% to 30% of patients and frequently require acid-suppressing therapy.

Peroral Endoscopic Myotomy

POEM has emerged over the past several years as an effective endoscopic approach to treating achalasia as well as other esophageal motility disorders. This therapy uses ESD to perform a surgical myotomy. Indications for POEM as a minimally invasive treatment include patients who are surgical candidates but do not wish to undergo surgery or those for whom prior medical or surgical treatments, including PD and laparoscopic myotomy, have failed. POEM is safe and well tolerated and is associated with lower complications, shorter hospital stays, and quicker recovery compared with laparoscopic myotomy. Although long-term data have yet to emerge, POEM has been demonstrated to be equivalent to PD and surgical myotomy in the short term, with more than 90% of patients reporting improvement in symptoms. As such, this method has become the preferred modality in several institutions, especially in morbidly obese patients or those who have undergone previous surgeries in whom laparoscopic myotomy could be technically challenging.

Before undergoing POEM, patients should be prescribed proton pump and swallow for at least 5 days due to the high incidence of candida esophagitis associated with retained food in patients with achalasia. They should be placed on a clear liquid diet for 2 days before the procedure. POEM is performed in the operating room with the patient under general anesthesia. The patient should be positioned supine and receive perioperative first-generation cephalosporin and fluconazole before induction. Endoscopy with CO_2 insufflation is first used to identify the location of the anatomic GEJ. Methylene blue mixed with saline is then injected into the submucosal plane 15 cm proximal to the GEJ, creating a cushion to decrease the risk of esophageal perforation. Epinephrine is avoided due to potential ischemic damage caused by vasoconstriction. A 1.5- to 2-cm longitudinal incision is then made to the mucosa on the anterior wall of the esophagus, at the 1 o'clock position. This allows access into the submucosal space. A gastroscope with a transparent cap is then introduced into the submucosal space, and a submucosal tunnel of at least 3 cm is created, traversing significant bridging vessels with coagulation. The myotomy is begun 2 cm distal to the distal end of the mucosotomy, and the plane between the inner circular and outer longitudinal muscle is identified. From here, a myotomy of the circular layer is performed, extending distally to the gastric cardia for 2 to 3 cm or until large submucosal gastric vessels are identified. The endoscope is then passed back through the esophageal lumen to evaluate the myotomy and determine its adequacy by passing the scope through the GEJ. Once hemostasis is achieved, gentamicin in 20 mL normal saline is instilled into the submucosal tunnel, and the mucosal incision is closed with either endoscopic sutures or clips.

Patients should undergo esophagography the day after the procedure to evaluate for obstruction or leak. If negative, the patient should be started on a clear liquid diet and acid suppressive therapy. Six months after the procedure, the patient should undergo evaluation with esophageal pH testing to evaluate for reflux.

Complications associated with POEM include mucosal perforation, pneumothorax, pneumomediastinum, pneumoperitoneum, subcutaneous emphysema, and pleural effusions. Although POEM does not involve dividing the phrenoesophageal membrane or altering the angle of His, the intrinsic antireflux barrier should be preserved, and one would not expect increased rates of gastroesophageal reflux after POEM. However, studies indicate that the post-POEM reflux rate is similar to that seen with PD or surgical myotomy without partial fundoplication. Long-term outcomes, including durability of symptom improvement and reflux control, are currently unknown.

Laparoscopic Surgical Myotomy (Heller Myotomy)

Laparoscopic Heller myotomy (LHM) with partial fundoplication, first developed as a minimally invasive alternative to the traditional open anterior myotomy and later the Ombredanne myotomy, remains the gold standard for the treatment for achalasia over the past 3 decades. The goal of the myotomy is to completely open the LES and relieve dysphagia.

The LHM provides initial symptomatic relief from dysphagia in approximately 90% of patients for type I and II achalasia and 50% for type III achalasia while decreasing the rates of postoperative reflux. Compared with the open myotomy procedure, LHM is associated with decreased postoperative pain, shorter hospital stays, and earlier return to function.

LHM is indicated as a first-line treatment for all surgical candidates with achalasia willing to undergo surgery, or in those who have failed PD. The operation consists of dividing the muscles of the LES, followed by a fundoplication to decrease postsurgical reflux. Partial fundoplication is favored over total fundoplication because this reduces treatment failure. The two primary complications of the surgery are mucosal perforation and GERD.

The patient should be placed in the supine, split-legged position on the operating table with adequate footboard and padding to prevent sliding during the steep reverse Trendelenburg position that is commonly used. A rapid sequence induction may be performed due to potential risk of aspiration related to retained esophageal contents. Endoscopy is then performed to evaluate for any residual food particles in the esophagus, as well as to copiously irrigate and clean the esophagus to allow for a complete endoscopic evaluation. The endoscope is also used to locate the exact site of GEJ obstruction using illumination and insufflation. The endoscope is left in place to allow for endoscopic assessment throughout the operation.

With the primary surgeon between the patient's legs and the assistant to the patient's left, abdominal access is gained by either the Hasson cutdown technique or with a Veress needle system inserted into the left paramedian location two thirds down between the xiphoid and umbilicus. This will be the site of the 10 mm 30 degree laparoscope. Alternatively, a Veress needle could be used to insufflate the

abdomen initially, especially if the patient has had prior abdominal surgeries. The remaining trocars are placed under direct visualization and include a 10-mm port to the left midclavicular line approximately 2 cm below the costal margin, a 5-mm trocar to the right of the falciform ligament 2 cm below the costal margin, and a 5-mm trocar to the right of the xiphoid used to hold a Nathanson liver retractor for holding the left lateral segment away from the hiatus.

After the trocars are placed, the gastric fat pad is retracted inferiorly and laterally. The gastrohepatic ligament is opened, and the upper aspect of the right crural arch, as well as the phrenoesophageal ligament, are identified. The phrenoesophageal membrane is incised at the 10 o'clock position along the crural arc and extended clockwise over the anterior esophagus over to the left side of the crural arch. The most superior short gastric branches are divided to allow for sufficient mobilization of the upper fundus and identification of the GEJ and angle of His for eventual fundoplication. The hiatus is then evaluated for a hernia, and, if not present, the posterior attachments are left intact. If a hiatal hernia is identified, circumferential dissection around the hiatus is performed, and a posterior window is developed between the posterior vagus and esophagus. A Penrose drain is then passed through this window to facilitate traction for further circumferential dissection into the lower mediastinum. The gastrocolic fat pad is then dissected off the anterior surface of the stomach from left to right, exposing the surface for the myotomy.

To both minimize oozing and separate the muscular wall from the submucosa thereby facilitating identification of the proper plane for dissection and myotomy, normal saline instilled with 0.5% epinephrine is injected into the muscular wall of the distal esophagus, GEJ, and cardia of the stomach in the area of the anticipated myotomy.

The myotomy is then begun 2 cm proximal to the GEJ with sharp dissection or low-voltage diathermy (Fig. 1). The circular muscle is elevated and divided until the submucosal plane is identified. In this plane the myotomy is extended 5 cm proximal to the GEJ and distally 2.5 cm onto the gastric cardia, or until large veins of the transverse submucosal plexus are encountered. The muscle fibers are then separated from the underlying mucosa on either side of the myotomy until at least 50% of the mucosal circumference is exposed.

Extreme caution is required when extending the myotomy from the distal esophagus to the GEJ and cardia of the stomach because of the potentially extremely thin muscular wall and increased risk of perforation here. Once the myotomy is complete, the endoscope is used to confirm the integrity of the mucosa and adequacy of the myotomy. An underwater seal test with saline instilled around the myotomy and endoscopic insufflation is performed to verify the absence of leak. The adequacy of the myotomy is assessed by obliteration of the rugnae mucosa at the site of distraction, as well as easy entry of the endoscope into the stomach. Transillumination can be used to identify any bands of muscle that remain, which can then be divided.

Next, a partial fundoplication is performed to cover the myotomy and create a low-pressure valve, thereby decreasing the risk of postoperative reflux. Importantly, a complete fundoplication (Nissen) is not recommended because this results in significant obstruction to esophageal emptying and is thus counterproductive to the myotomy. Either an anterior (Dor) or partial posterior (Toupet) fundoplication can be performed, depending on surgeon preference and degree of posterior dissection performed during the operation. Some evidence suggests that the Dor fundoplication is associated with a significantly higher percentage of postoperative reflux at 6 months compared with the Toupet fundoplication, although there appear to be no differences in symptoms.

For the Dor fundoplication, the greater curvature of the stomach 2 cm distal to the anatomic GEJ is sutured to the left crus at the 2 o'clock position. The cut edge of the myotomy should be incorporated into this suture to accentuate the angle of His. From here, subsequent sutures should be taken along the greater curvature at 2 cm intervals and sutured to the hiatus from left to right, folding the anterior surface of the stomach over the myotomy. The fundus is then sutured to the right crus of the myotomy and the right crura at the 11 o'clock position. Finally, the mobilized fundus is sutured to the superior portion of the arcuate ligament, resulting in the fundus being in contact with the anterior esophagus. The esophagoscope is inserted into the stomach during this suturing to prevent esophageal obstruction.

With the partial posterior Toupet fundoplication, the gastric fundus is passed from left to right through the retroesophageal space. The fundoplication is aligned to the esophagus, and the bilateral triangulation sutures between the mobilized fundus, myotomy, and crural arc at the 11 and 12 o'clock positions. The fundus is then grasped and mobilized from left to right and sutured to the right crus to drape over the esophagomyotomy.

After either the Dor or Toupet fundoplication, esophagoscopy is performed after completion of the procedure to confirm adequacy of the myotomy, the integrity of the fundoplication, and to evaluate for any mucosal perforations. An esophagogram is obtained on postoperative day 1, and, if negative, the patient is started on a clear liquid diet and discharged on a soft diet for 2 weeks. Importantly, after myotomy, patients should be counseled to thoroughly chew food, swallow small bites, and avoid lying flat because this increases the risk of aspiration.

Transthoracic Myotomy

Transthoracic approaches to esophagomyotomy, including the left thoracoscopic myotomy, have largely been abandoned and are now almost exclusively reserved for patients in whom laparoscopic or abdominal approaches are not feasible. Difficulties with the thoracoscopic approach include the need for a Heller fundoplication to reduce reflux, difficulty extending the myotomy onto the gastric wall, patient intolerance to single lung ventilation, and longer postoperative stay and worse postoperative pain because of chest tube management and the thoracic incision. However, some centers prefer thoracic myotomy because, unlike with LHM, it allows control of the esophagus, cardia, and stomach but does not alter the normal anatomic interrelationship of these organs and surrounding structures.

After carotid intubation with a single-lumen endotracheal tube, an esophagoscopy is performed to visualize, clear, and clean the esophagus. A dual-lumen endotracheal tube, or bronchus blocker, is then placed to allow for single lung ventilation of the right lung and atelectasis of the left lung to facilitate esophageal dissection. The esophagoscope is left in place for transillumination and insufflation as necessary.

The patient is then placed in a right lateral decubitus position. A lateral muscle sparing minithoracotomy incision at the seventh intercostal space is the incision we frequently perform. The inferior pulmonary ligament is then divided to allow access to the distal esophagus. The esophagus is dissected from the level of the inferior pulmonary ligament to the anterior pericostal membrane. With the esophagoscope in place for alternatively a 50 Maloney dilator) within the esophagus, the esophagus is then encircled with a Penrose drain, with care taken to avoid injury to vagal nerve trunks. The pericostal reflection is then incised, the crural opening is expanded, and the most cephalad short gastric arcades are ligated. The GEJ and gastric cardia are then identified. Saline with 0.5% epinephrine is injected into the muscular wall of the distal esophagus and GEJ, reducing oozing and allowing for separation of the muscular wall from the submucosa. The esophagomyotomy is then performed in a similar fashion as with the LHM (Fig. 2A). A Belsey fundoplication is then performed to reduce reflux (Fig. 2B). A chest tube connected to an underwater seal drainage system is placed. The postoperative management, including barium esophagogram and clear liquid diet with advancement, is similar to that taken for the LHM.

Esophagectomy

Despite symptomatic improvement with therapy, some patients may continue to experience ongoing incomplete esophageal emptying, resulting in progression to end stage disease and its associated complications. Diagnostic findings suggestive of end stage achalasia with barium esophagram include sigmoid esophagus with a tortuous, dilated course, megaesophagus, and pulsion diverticula.

Although severe or end stage achalasia was traditionally an indication for a partial esophagectomy because of the thought that the esophagus would never be able to adequately empty even with a myotomy, recent data suggest that surgical or endoscopic myotomies can improve symptoms in the overwhelming majority of patients. Partial esophagectomy with interposition is now generally indicated for the treatment of end stage achalasia and best reserved for patients who are refractory to all other treatments or who have another concomitant esophageal pathology for whom esophagectomy is indicated. In patients who are poor surgical candidates, refractory, and end stage achalasia can be managed with endoscopic botulinum toxin injection into the LES or with pharmacotherapy as described above.

PHARMACOTHERAPY

For patients who are deemed poor surgical candidates or who need temporary treatments while awaiting more definitive therapy, less effective but accepted treatment options include pharmacotherapy such as calcium channel blockers, long acting nitrates, isosorbide dinitrate, phosphodiesterase 5 inhibitors, or the injection of botulinum toxin into the LES endoscopically. Pharmacotherapy, the least effective option, is generally limited by its short duration of action, incomplete relief of symptoms, poor absorption, adverse effects, intolerance, and decreased efficacy with prolonged use. The most commonly used class of medical therapy is calcium channel blockers, most commonly nifedipine. They work by inhibiting LES muscle contraction and resting pressure. Nitrates are also commonly used and increase nitric oxide concentration in the smooth muscle of the LES, increasing cyclic adenosine monophosphate levels and resulting in muscle relaxation. Phosphodiesterase 5 inhibitors such as sildenafil inhibit cyclic guanosine monophosphate degradation, thus reducing muscle contraction.

Botulinum toxin therapy is generally indicated for patients who are not surgical candidates or have refractory symptoms after myotomy or PD. It is not indicated for type III achalasia. It is associated with an approximately 50% decrease in LES baseline pressure. At least four quadrants of the LES should be injected during EGD, just proximal to the squamocolumnar junction. Repeated injections every 6 to 24 months are frequently necessitated because relapse of symptoms is common with this therapy. Some evidence suggests that patients older than 65 years and those with lower LES (less than 50% of the upper reference limit) may experience a longer duration of symptom improvement with botulinum toxin. Complications associated with botulinum toxin include inflammatory or allergic reactions, chest pain, mediastinitis, and mucosal ulceration.

POSTTREATMENT MONITORING

Patients with achalasia should undergo ongoing monitoring after treatment to evaluate symptom improvement and esophageal emptying. Although patients may experience improvement in symptoms, esophageal emptying may continue to be impaired, thus increasing the risk of disease progression and associated complications. Barium esophagograms and manometry are the most common methods of monitoring. In addition to monitoring all patients with achalasia for the development of end stage achalasia or esophageal squamous cell carcinoma, these tools can help identify patients who require closer follow up because of increased risk of disease progression. Endoscopic surveillance is currently not routinely recommended, although some experts recommend monitoring with EGD every 3 years starting 10 years after the initial diagnosis of achalasia.

SUMMARY

Achalasia is a relatively rare disorder but represents the most common esophageal motility disorder. As the age of the United States population increases, surgeons will likely encounter more patients with achalasia due to its increasing prevalence and incidence with age. Many treatment options exist, and a proposed algorithm is shown in Fig. 3, based on the current quality of evidence and updated guidelines from numerous organizations. Choices of therapies should be guided by patients' demographics and preferences, and local institutional expertise.

MANAGEMENT OF DISORDERS OF ESOPHAGEAL MOTILITY

T. Robert Qa'jah, MD, MSc, and Mark [illegible]atis, MD, FACS

Disorders of esophageal motility present a diagnostic and therapeutic challenge to gastroenterologists and surgeons. Achalasia, the most prevalent and best understood of these disorders, is addressed under "Management of Achalasia of the Esophagus" elsewhere in this textbook. Nonachalasia esophageal motility disorders are less prevalent, incompletely understood, and often difficult to treat. The optimal classification schema for this group of disorders is a work in progress. Management strategies are also controversial, and there is no universally accepted standard of care. In this chapter, we attempt to guide the surgeon in a review of nonachalasia esophageal motility disorders and the application of their most current classification, with recommendations for management based on recent data.

PRESENTATION

Patients with disorders of esophageal motility may present with chest pain, dysphagia, regurgitation, heartburn, globus sensation, upper respiratory complaints, or some combination of these. Because these symptoms are nonspecific and esophageal motility disorders are rare, workup for other life-threatening conditions is necessary. Cardiovascular and pulmonary causes usually have been ruled out already in the patient with chest pain before referral to the surgeon. A negative cardiac workup is reassurance enough for some patients who may be able to conservatively manage mild symptoms. Anxiety, depression, somatoform disorders, and other psychiatric diagnoses are more

Management of Disorders of Esophageal Motility

T. Robert Qasim, MD, MSc, and Mark Kuhn, MD, FACS

Disorders of esophageal motility present a diagnostic and therapeutic challenge to gastroenterologists and surgeons. Achalasia, the most prevalent and best understood of these disorders, is addressed under "Management of Achalasia of the Esophagus" elsewhere in this textbook. Nonachalasia esophageal motility disorders are less prevalent, incompletely understood, and often difficult to treat. The optimal classification schema for this group of disorders is a work in progress. Management strategies are also controversial, and there is no universally accepted standard of care. In this chapter, we attempt to guide the surgeon in a review of nonachalasia esophageal motility disorders and the application of their most current classification, with recommendations for management based on recent data.

PRESENTATION

Patients with disorders of esophageal motility may present with chest pain, dysphagia, regurgitation, heartburn, globus sensation, upper respiratory complaints, or some combination of these. Because these symptoms are nonspecific and esophageal motility disorders are rare, workup for other life-threatening conditions is necessary. Cardiovascular and pulmonary causes usually have been ruled out already in the patient with chest pain before referral to the surgeon. A negative cardiac workup is reassurance enough for some patients who may be able to conservatively manage mild symptoms. Anxiety, depression, somatoform disorders, and other psychiatric diagnoses are more

common in the population of patients with esophageal motility disorders, thus a psychiatric history is an important part of the evaluation.

Gastroesophageal reflux disease (GERD) is another common cause of noncardiac chest pain. A trial of a proton pump inhibitor (PPI) is warranted, and, if troublesome symptoms persist, further diagnostic testing should be carried out. Concerning associated symptoms, such as dysphagia with weight loss, should heighten the suspicion for a mechanical or malignant process and prompt expedient and careful evaluation.

DIAGNOSTIC TESTING

All patients evaluated for esophageal motility disorders must undergo a comprehensive diagnostic workup. This includes a contrast esophagram to help visualize anatomy, esophageal length, and the presence of a diaphragmatic hernia or esophageal diverticulum. A pH study with or without impedance is important to identify GERD, which may be the primary or contributing cause of symptoms. Endoscopic evaluation with biopsy is also mandatory to identify Barrett's esophagus, malignancy, pepsin stricture or esophagitis related to acid exposure, eosinophilia, or infection. In the absence of mechanical obstruction or mucosal abnormalities, esophageal motility is evaluated next by manometry.

High-resolution manometry (HRM) with esophageal pressure topography (EPT) is the preferred method to evaluate for esophageal motility. HRM precisely defines esophageal contractile function, peristalsis, and bolus transit when impedance evaluation is included. Compared with conventional manometry, study acquisition is faster, more comfortable, and better tolerated by patients. For technicians and physicians, the topography contour plots increase diagnostic yield provide an intuitive visual presentation of anatomic and physiologic characteristics.

CLASSIFICATION OF DISEASE

Classifying esophageal motility disorders is an evolving process. Definitions of disease phenotype have changed over time, with improvements in diagnostic technology and better understanding of the clinical importance of various manometric patterns. In 2003, Richter systematically classified esophageal motility disorders using conventional manometric criteria. Using HRM, Khatibu and colleagues redefined this scheme in 2008 with the first edition of the Chicago Classification of esophageal motility disorders. The Chicago Classification is currently in its third edition (CC v3.0), which introduced to simplify and clarify recognition of EPT patterns and physiologic metrics to better define clinically relevant phenotypes of esophageal dysmotility. CC v3.0 classifies the various manometric entities as *Esophagogastric outflow obstruction, Major disorders of peristalsis*, or *Minor disorders of peristalsis* (Fig. 1). Manometric findings that do not meet criteria for these categories are considered normal. The most recent CC v3.0 has increased the number of normal findings when compared with CC v2.0 and augmented the relevance of abnormal findings. This chapter reviews nonachalasia disorders of esophageal motility according to the hierarchic analysis of the most current version of the Chicago Classification.

Esophagogastric Outflow Obstruction

Esophagogastric junction outflow obstruction (EGJOO) may be the result of intrinsic or extrinsic pathology, which highlights the

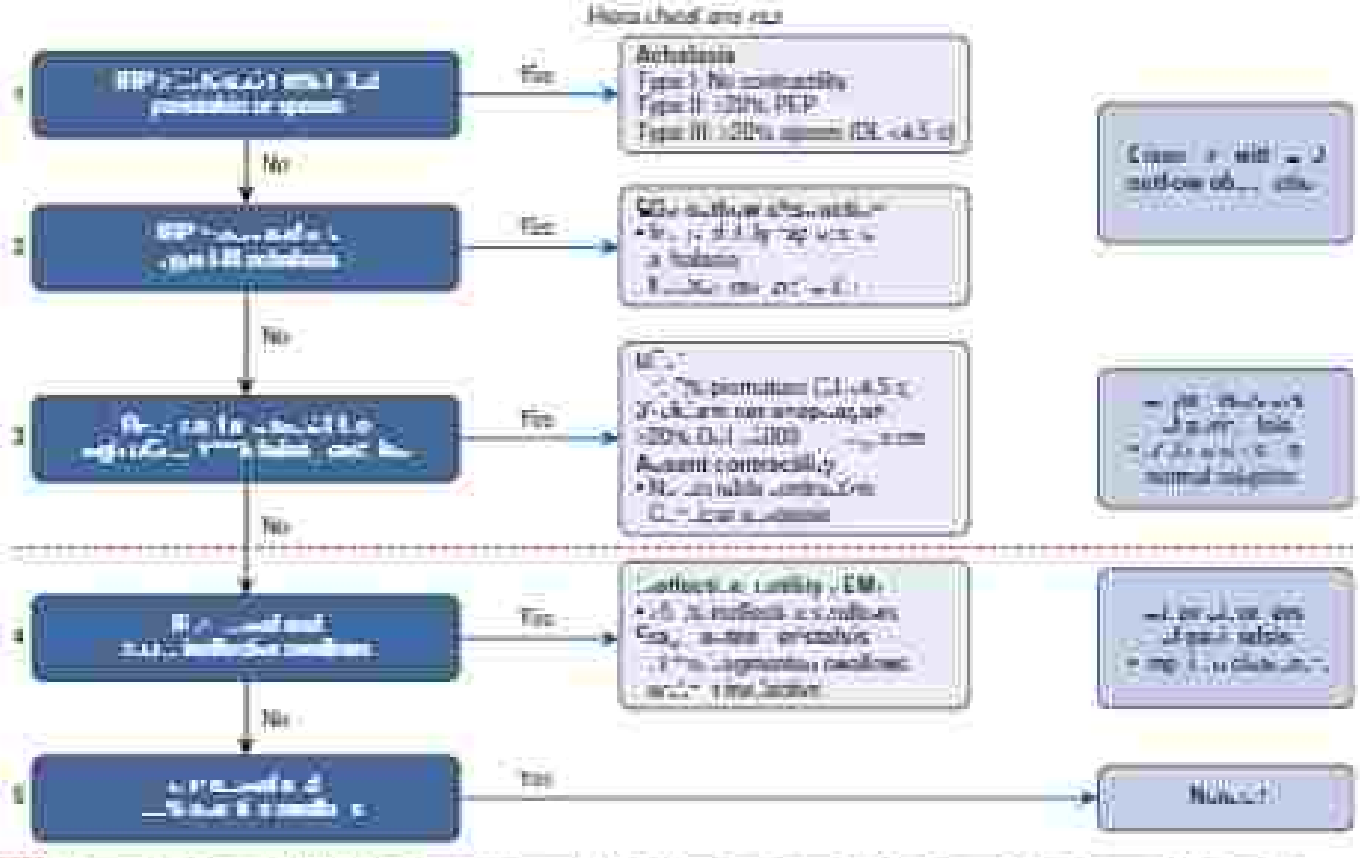

FIG. 1 Chicago Classification v3.0. DL, Distal contractile integral; DES, distal esophageal spasm; EGJ, esophagogastric junction; IRP, integrated relaxation pressure; PEP, pan-esophageal pressurization; ↑, upper limit normal. *From Kahrilas PJ, Bredenoord AJ, Fox M, et al. The Chicago Classification of esophageal motility disorders, v3.0. Neurogastroenterol Motil. 2015;27:160–174.*

importance of the comprehensive esophageal workup. Distal ulcers, peptic stricture, stiff esophageal body resulting from scarring or radiation, prior surgical interventions, paraesophageal resulting from malignancy or vascular obstruction from a dilated aortic arch are potential sources of mechanical outflow obstruction (Fig. 2A). Prominent vascular artifact on manometry or a history suggestive of malignancy should prompt adjunct evaluation with endoscopic ultrasonography (EUS) or computed tomography. In a retrospective study, findings on selective EUS altered clinical management in as many as 15% of concerning cases. When other mechanical causes of esophagogastric outflow obstruction and achalasia have been ruled out, idiopathic cases remain. This is identified by incomplete relaxation of the EGJ, currently defined by HRM as elevated integrated relaxation pressure in the setting of preserved peristalsis (Fig. 2B), differentiating EGJOO from achalasia.

It is hypothesized that EGJOO may represent an incompletely expressed or precursor variant of achalasia, but this has not been verified in large numbers of patients. There are few data specific to this new entity since it has been redefined in CC v3.0. Cases previously classified as hypertensive lower esophageal sphincter (HTLES) by older versions of the Chicago Classification would most likely meet criteria for EGJOO. Interestingly, patients diagnosed with HTLES were found to have paradoxically elevated esophageal acid exposure about 25% of the time, despite relative EGJ obstruction. Therefore treatment of patients in this group should be tailored based on symptoms. PPIs should be considered if GERD is the major complaint. If dysphagia without abnormal esophageal acid exposure is identified, then medications directed to esophageal smooth muscle relaxation can be attempted. Endoscopic pneumatic dilation (PD) or botulinum toxin (Botox) injections are moderately effective options for relief of obstructive symptoms. Surgical therapy may be indicated in cases of severe or refractory symptoms. Esophageal myotomy, fundoplication, or a combination of the two can be tailored to the patient's symptoms and objective pathophysiology. Antireflux surgery without myotomy has been found to achieve good long term results for patients with reflux and mild EGJOO caused by acid induced spasm and inflammation, although preoperative dysphagia was found to predict a higher rate of failure. With dysphagia as the primary symptom, and other tested or normal esophageal acid exposure, laparoscopic Heller myotomy with partial fundoplication and peroral endoscopic myotomy (POEM) have been used successfully to describe such as EGJOO that do not affect the esophageal body. Abdominal approaches for surgery are favored over thoracic because adequate proximal dissection is possible without accessing the thoracic cavity. Abdominal fundoplication options also offer greater symptom relief and generally are considered less technically challenging.

Major Esophageal Motility Disorders

This group of disorders is defined by manometric parameters that are always associated with symptoms. Distal esophageal spasm (DES), also frequently referred to as *diffuse esophageal spasm*, is sometimes grouped with nutcracker esophagus or hypercontractile esophagus and achalasia type III as hypercontractile or "spastic" motility disorders. Patients with DES are symptomatic with chest pain, dysphagia, or regurgitation resulting from spastic contractions. The cause of DES is believed to be an impaired neurologic inhibitory pathway, allowing premature esophageal smooth muscle contractions. This disorder may overlap with or progress to achalasia. Rapid contractions previously categorized as DES by conventional manometry have been found to be nonspecific. With HRM these rapid contractions sometimes are identified in patients with EGJOO, GERD, and even in normal control subjects and therefore are no longer used to define DES. DES currently is defined by premature contractions in more than 20% of swallows. This is indicated on HRM as a low distal latency, a truncated interval between initiation and deceleration of pressure (Fig. 3A). Barium esophagram classically shows a corkscrew pattern of simultaneous contractions, although this pattern is actually

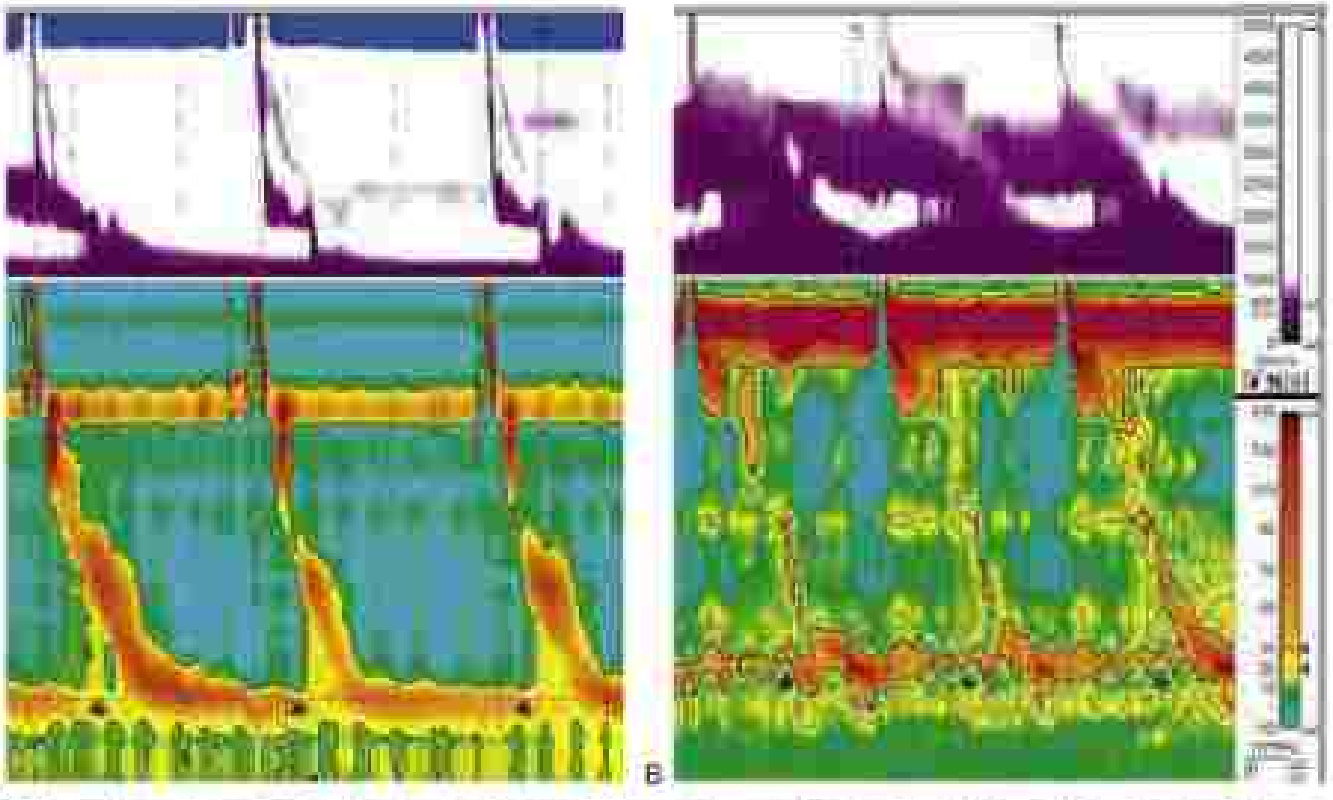

FIG. 2 Esophagogastric junction (EGJ) outflow obstruction. Note the high-pressure, increasing EGJ (see *dot*). (*A*) In this case caused by a hiatal hernia. (*B*) idiopathic, in the setting of ineffective motility and incomplete bolus clearance. *(Courtesy Ikr Gregori Clair.)*

uncommon and not required for diagnosis (Fig. 3B). Treatment options for IHS vary. Patients initially may benefit from reassurance with dietary and behavioral modifications or pharmacologic therapy. Persistent cases may require endoscopic intervention with PD or fistula, or surgical myotomy of variable length. Surgical approaches are discussed in more detail in the treatment section of this chapter.

Jackhammer esophagus was named to describe extreme hypercontractility and avoid confusion with IHS. This disorder's cause is believed to be excessive cholinergic drive, causing asynchronous contractions of circular and longitudinal muscle. Jackhammer is defined manometrically by at least two swallows with significant hypercontractile vigor as measured by a distal contractile integral (DCI) exceeding 8000 mm Hg • s • cm (Fig. 6A). The hypercontractile segment may involve the esophageal body or may be limited to the esophagogastric junction, with IRP relaxation pressure usually in the upper limit of normal.

Patients with jackhammer esophagus are consistently symptomatic with chest pain, dysphagia, or regurgitation. This differentiates jackhammer by CC v3.0 criteria from nutcracker esophagus, defined as hypercontractile peristalsis with DCI between 5000 to 8000 mm Hg • s • cm (Fig. 4B). Although some patients with DCI in this range are symptomatic, some symptom-free control patients also fall into this range. For this reason, the clinical relevance of nutcracker esophagus has been questioned. Some patients previously meeting criteria for nutcracker esophagus by manometry will now be classified as "normal" by CC v3.0, and the effect of that change has yet to be determined. Since CC v3.0 was published, few cases reports have been made specifically for management of jackhammer esophagus, so further study of outcomes for this hypercontractile group will be required with time. Treatment is aimed at controlling spasm and can include dietary and behavioral modification, pharmacologic therapy, or endoscopic or surgical treatments, which are subsequently discussed.

Absent contractility is another new clinical entity under CC v3.0. This disorder is defined by HRM with hypocontractility and failed peristalsis in 100% of swallows in the setting of an IRP with normal relaxation pressure. Premature hypocontractile swallows with failed peristalsis are grouped here. In cases with borderline DCI relaxation and evidence of esophageal pressurization, achalasia should be considered and the patient managed accordingly.

Systemic sclerosis (scleroderma) falls into the absent contractility category (Fig. 5). This figure demonstrates complete hypocontraction of esophageal smooth muscle, with preserved skeletal muscle contraction in the upper esophageal sphincter and diaphragm. Therapeutic options specific to diminished esophageal motility are limited, so treatment is directed primarily at the underlying systemic disorder, as well as relief of symptoms. Unfortunately, no specific pharmacologic therapy improves contractility and function of esophageal smooth muscle. Prokinetic agents are fraught with side effects and are primarily avoided. GERD has been identified frequently in these patients and should be treated aggressively with PPIs. Antireflux surgery can be considered carefully for refractory GERD cases in this setting but should be approached with caution at the risk of exacerbating dysphagia. Because connective tissue disorders such as scleroderma also can affect gastric motility, one should be aware that GERD symptoms may be a result of overflow reflux and should not be treated by fundoplication alone. A small retrospective review of scleroderma patients treated with fundoplication or Roux-en-Y gastric bypass (RYGBP) revealed improvement in control of reflux and dysphagia in the RYGBP group compared with fundoplication. In very carefully selected cases, RYGBP may be considered for primary management of refractory GERD in scleroderma. Less invasive endoscopic procedures such as suture plication or radiofrequency ablation may be more appealing for GERD in such fragile patients but are less effective at reducing reflux.

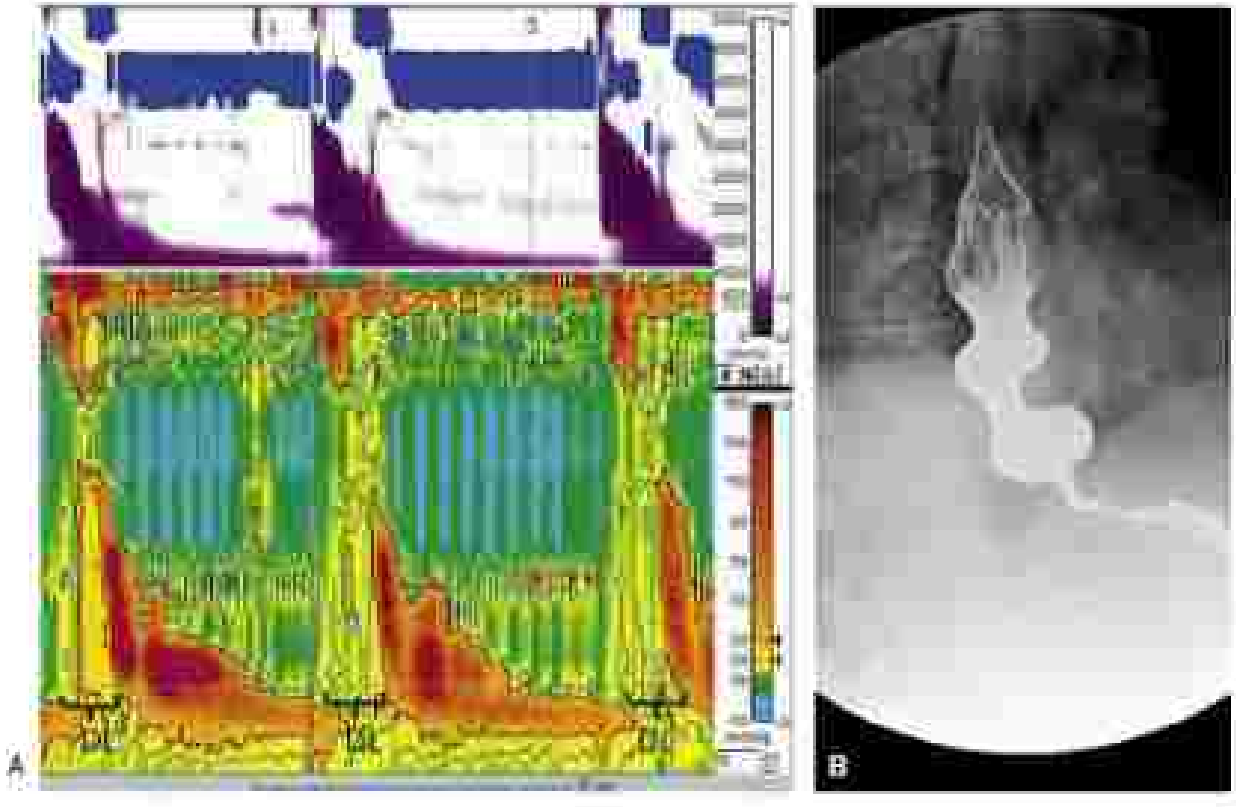

FIG. 3. Distal esophageal spasm. (A) Premature contractions with low distal integrity (normal between initiation and contraction of peristalsis). (B) Esophagogram with corkscrew pattern of simultaneous tertiary esophageal body contractions. (Courtesy The Oregon Clinic.)

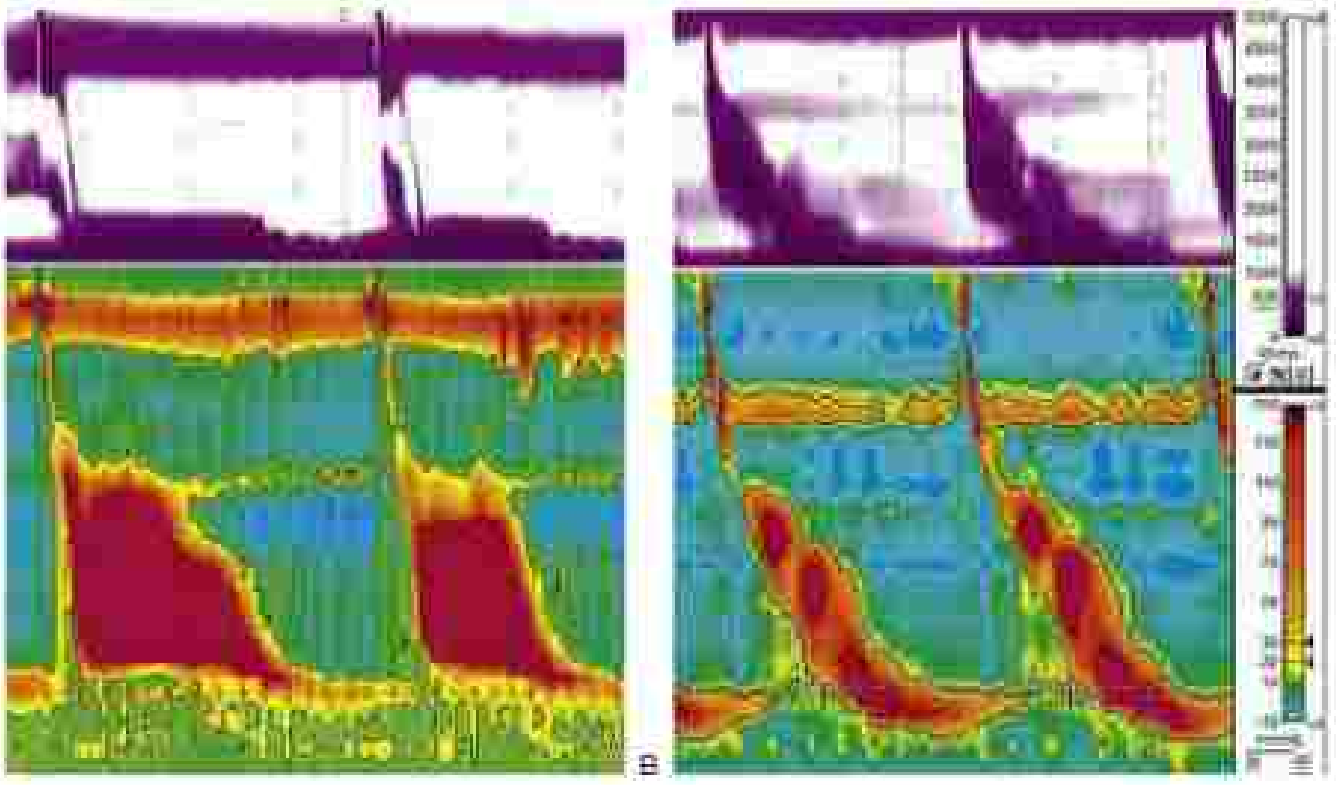

FIG. 4 (Hypercontractile disorder) (A) Jackhammer esophagus. Extremely elevated contractile vigor (DCI in this case ranged from 12,000 to 30,000) (B) Nutcracker esophagus. Periodic vigorous contractions with DCI 5000 to 8000. DCI, Distal contractile integral. (Courtesy Dr. Ginger Chen.)

Minor Esophageal Motility Disorders

Patients with minor motility disorders often have minimal symptoms and require fewer interventions over time, and, as such, the prognosis of these patients is overall better than for those with major esophageal motility disorders. Ineffective esophageal motility (IEM) is a minor esophageal motility disorder defined by a significant number of weak or failed swallows. Presentation may include heartburn and regurgitation with or without dysphagia, and symptoms tend to be mild. GERD often plays a significant role in the underlying cause of IEM because many of these patients are found to have underlying abnormal esophageal acid exposure. IEM is defined by HRM criteria as at least 50% of swallows with low or absent contractile vigor, indicated by DCI less than 450 mm Hg × s × cm (Fig. 4A). Interestingly, symptom-free healthy patients may also exhibit a manometric pattern consistent with IEM. In the patient with IEM, the manometry technician may elect to perform additional provocative testing with multiple repetitive swallow (MRS) assessment. Definitive inhibition of the esophageal body and EGJ occurs during MRS, usually followed by augmented esophageal contraction vigor and improved bolus transit. Augmented contraction with MRS may be reassuring to the physician who is considering an antireflux procedure to treat underlying GERD while avoiding iatrogenic postoperative dysphagia. When MRS does not augment subsequent contraction, it is predictive of late dysphagia after fundoplication. Although evidence would indicate that there is a relatively low risk of postoperative dysphagia with Nissen fundoplication for patients with IEM, many surgeons choose to carefully tailor a partial fundoplication to avoid the risk of postoperative dysphagia. Clinical implications of MRS findings in this setting have yet to be defined clearly and require further study because these provocative maneuvers are used more frequently with HRM.

Therapeutic options are limited for IEM patients. Because many, if not most, IEM cases are related to chronic reflux disease, correction of GERD may result in correction of the motility disorder. Reassurance along with dietary and behavioral modifications may be helpful. As in other motility disorders, prokinetic drugs generally are not recommended. Low dose antidepressants, especially tricyclic antidepressants or trazodone, may reduce functional chest discomfort, heartburn, and globus sensation but may not be effective for dysphagia.

Fragmented peristalsis is the final minor disorder of esophageal motility. It is defined manometrically by at least 50% of swallows with fragmented contractions, with a distal to peristaltic contraction of at least 5 cm, with preserved overall contraction vigor not meeting criteria for IEM (Fig. 4B). Outside of GC v3.0, no specific reports on this newly defined disorder have been made, and its clinical relevance is yet to be defined.

NONOPERATIVE MANAGEMENT

The main goals of any treatment for patients with esophageal motility disorders include reduction of chest pain and dysphagia. Treatment is focused on reducing spasm, GERD, and outflow obstruction to facilitate esophageal emptying. Reassurance alone can be beneficial. Reassurance not only helps to relieve anxiety but also has been shown to reduce severity of chest pain and frequency of healthcare use.

Dietary and Behavioral Modifications

Dietary and behavioral modifications can be very helpful for avoiding chest pain or dysphagia. These modifications include sitting upright and allowing plenty of time for meals, taking small bites, chewing thoroughly, and taking sips of liquid between bites. Foods such as bread, meat, and rice are notorious for worsening dysphagia and should be ingested with caution or minimized. Extremely hot or cold foods can exacerbate esophageal spasm. Chewing soft or liquefied foods can be helpful during symptom flares.

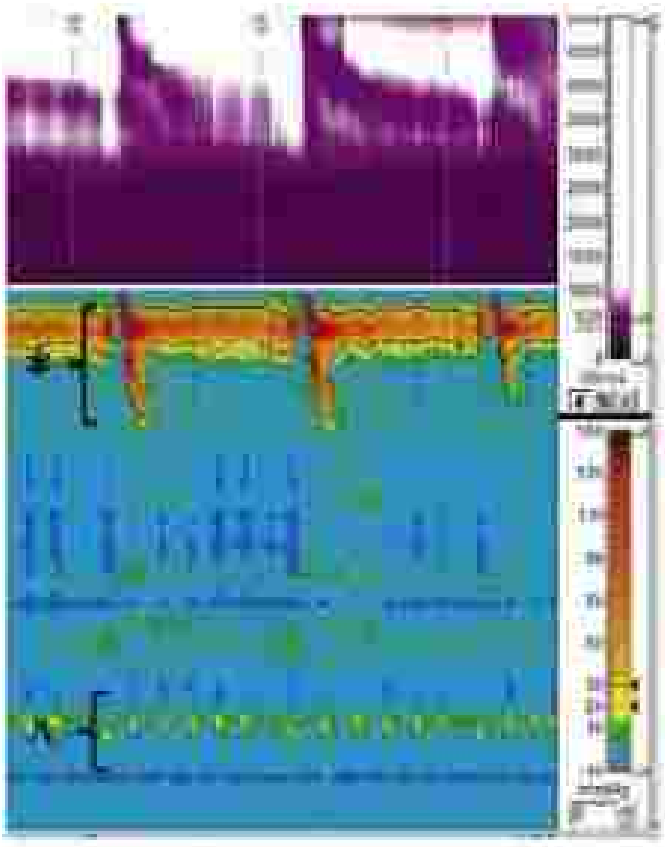

FIG. 5 Absent contractility. This is a case of scleroderma with complete hypomotility of esophageal smooth muscle, total preserved function of skeletal muscle of the upper esophageal sphincter (asterisk) and diaphragm (arrowheads). (Courtesy Per Gregersen, Chile.)

Pharmacologic Therapy

Before pharmacologic therapy is initiated, it is important to carefully review the patient's home medications and minimize those that affect esophageal motility. PPI in particular is associated with chronic opioid use and has been shown to improve with opioid cessation. A few classes of drugs have been used with some success in providing symptomatic relief of esophageal spasm. Smooth muscle relaxing agents (nitrates or calcium channel blockers) taken 15 minutes before meals may provide some symptomatic relief in spastic or hypercontractile disorders, including DES, some cases of EGJOO, and achalasia-esophagus. Phosphodiesterase 5 inhibitors such as sildenafil, which acts by blocking degradation of nitric oxide, also can be effective. These drugs may be tolerated poorly because of lightheadedness, headache, or other side effects, and tachyphylaxis has been noted. Cost of sildenafil may be prohibitive, and effects of daily long-term use of this agent in various populations of patients are unknown. Low dose antidepressants, including tricyclic agents and trazodone, may provide pain modulation and anxiety relief for noncardiac chest pain. As previously discussed, CSRD is frequently part of the clinical syndrome of esophageal dysmotility, although its role in pathogenesis is not understood completely. A trial of PPIs is warranted and may help reduce inflammation, pain, and spasm related to abnormal esophageal acid exposure.

Endoscopic Therapy

Pneumatic dilation (PD) has been used to treat spastic esophageal motility disorders affecting the EGJ, including EGJOO, DES, and nutcracker esophagus, with variable success. In small studies, 26% to 70% of DES and nutcracker patients had good response with PD, although there is concern that some of these cases may have been classified more accurately as achalasia. From the achalasia literature, there is a known risk of perforation with pneumatic dilation in the range of about 2% to 5% of cases performed by expert endoscopists. This rate of perforation is unacceptable to many endoscopists, who no longer use PD as first line therapy.

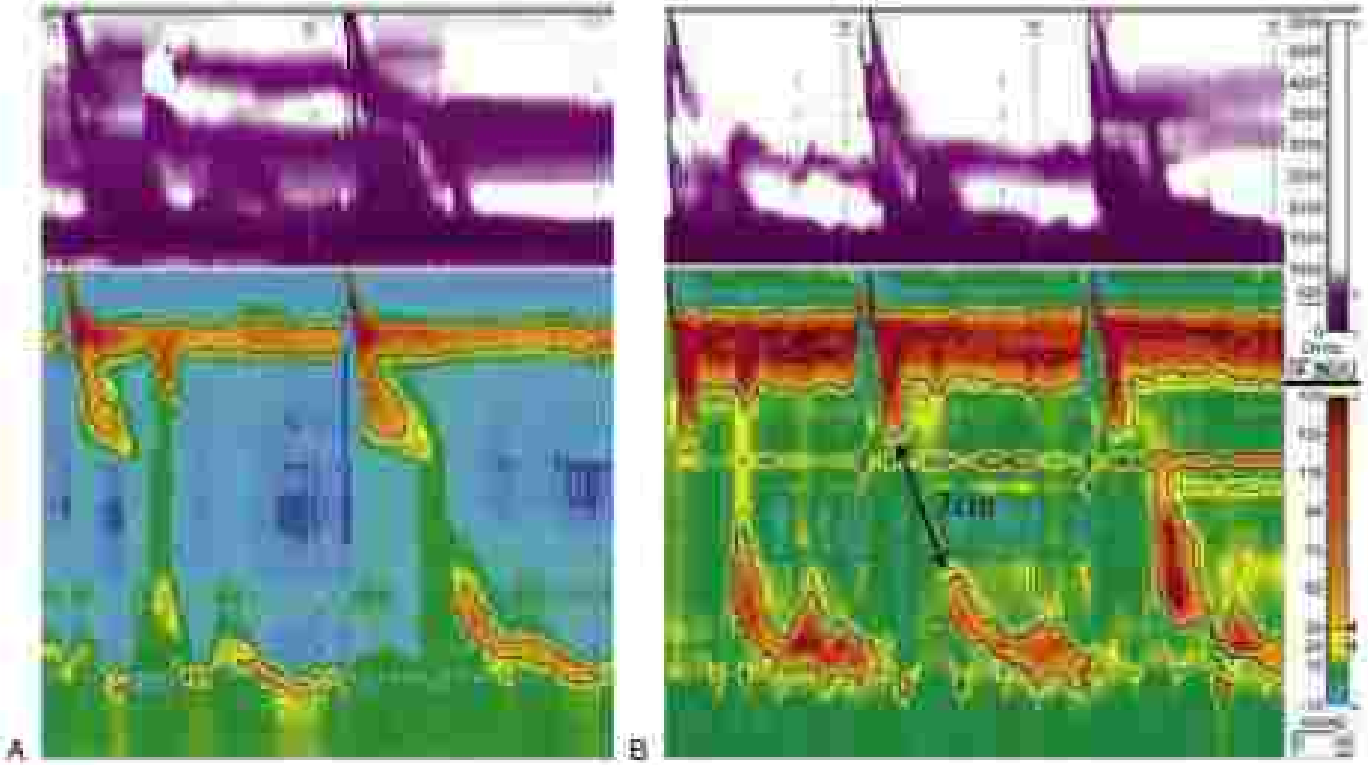

FIG. 6 Minor disorders of peristalsis. (A) Ineffective esophageal motility, weak peristalsis (DCI <450). (B) Fragmented peristalsis (Large breaks | 5 cm) with preserved contractile vigor (DCI ~450). DCI, distal contractile integral. (Courtesy Per Gregersen, Chile.)

Endoscopic injection of botulinum toxin (Botox) may be temporarily effective in relief of spasm in HOBO, DES, or jackhammer disorders. The technique for administration of botulinum toxin has not been standardized; some report injection of the EGJ alone and others include the esophageal body. Botox to the esophageal body may be helpful in cases such as DES or jackhammer, although it is uncertain exactly where and how much drug should be injected. Infection is an uncommon but serious risk of Botox injections. One death resulting from mediastinitis has been reported in a DES case treated with Botox, although other serious adverse events have been rare. Endoscopists may elect to use EUS to guide positioning and depth of injections into the thinner walled esophageal body. In small studies of patients with HOBO and DES, successful relief of symptoms with botulinum toxin injections was achieved in more than 50% of patients at 6 months, with further improvement from serial or alternate treatments thereafter. This was comparable to efficacy in achalasia. Fall off of symptom relief is present in each of these disorders with time, which may require repeat treatments or escalation to surgical intervention. Preexistent symptoms and spastic features may predict early recurrence of symptoms. Botulinum toxin before surgical myotomy has been noted to increase difficulty in identifying and maintaining the proper dissection plane. Prior Botox is not a contraindication to surgery and is sometimes useful as a trial to determine if a patient may respond well to surgical myotomy. Long term studies are not available evaluating the efficacy of repeated botulinum toxin injection for spasm.

SURGICAL MANAGEMENT

Surgical therapy is an option for nonachalasia esophageal motility disorders, but optimal timing and approach are controversial. Surgery generally has been reserved for medically refractory cases because outcomes are variable, sometimes unpredictable, and may be associated with surgical morbidity. As mentioned before, EGJ patients with GERD, whether they also have dysphagia, tolerate antireflux surgery well, and treatment of the reflux often corrects the motility disorder as well. Classically, these patients have a partial fundoplication, most commonly a 270-degree posterior wrap (Fig. 7). Nissen fundoplication also has been shown to be well tolerated in this setting; however, a full wrap should be reserved for EGJ patients with minimal symptoms of dysphagia before surgery. Endoluminal antireflux procedures such as Stretta radiofrequency or transoral incisionless fundoplication, which provide less aggressive valve reconstruction, also may be good options for these patients.

Data on surgical outcomes for EGJOO, DES, and hypercontractile disorders are limited to a few series, mostly small and nonrandomized over the last 50 years. As diagnostic modalities have improved and disease classifications have evolved, these data become even more difficult to interpret. In general, outcomes for surgery are better for relief of chest pain and dysphagia compared with medical or endoscopic therapies. In DES, which is the most frequently studied esophageal motility disorder aside from achalasia, good symptomatic outcomes are reported in about 70% of cases treated with surgical myotomy via an abdominal or thoracic approach at highly skilled centers. These outcomes are notably less successful than those for surgical myotomy for achalasia, so surgery often is reserved as a last resort for patients with nonachalasia motility disorders. Therefore many of these patients endure long courses of medical or endoscopic therapy because there is no clear definition of "medical failure."

Surgical techniques for esophageal myotomy are varied. Traditional open surgery largely has been replaced by minimally invasive techniques, and now endoscopic options are available. Length of the esophageal body myotomy, inclusion of the EGJ in the myotomy, and addition of a concomitant antireflux procedure are variable from surgeon to surgeon. Previous authors in this text have recommended a long thoracic myotomy for the treatment of DES or other esophageal body motility disorders and have described the technique in detail (Fig. 8). Thoracic access allows myotomy extension for the full length of the esophageal body, which is not possible with laparoscopic Heller myotomy. However, thoracic myotomy has the disadvantage of requiring single lung ventilation, chest tube placement, and typically a longer length of stay. The thoracic approach is complicated further if the surgeon desires a fundoplication or extended gastric myotomy.

FIG. 7 Completed laparoscopic 270-degree posterior fundoplication.

POEM offers several advantages for esophageal myotomy and is preferred as a less invasive technique for patients with hypercontractile/spastic esophageal motility disorders. This natural orifice transluminal endoscopic surgery procedure is completely endoscopic and intraluminal. It provides the ability to tailor the length and location of the myotomy with ease because the entire affected esophageal body and EGJ are accessible. POEM allows the surgeon to produce a selective circular myotomy and avoids the risk of vagus nerve injury or disruption of the diaphragmatic crural component of the EGJ. Single lung ventilation, lateral or prone positioning, and chest tubes are not required. Moreover, postoperative pain is usually minimal.

POEM was first applied clinically for achalasia by Inoue in 2008, and since then more than 4000 cases have been performed worldwide with an excellent safety profile and good clinical results, mostly for patients with achalasia. Until recently, studies of POEM for nonachalasia esophageal motility disorders included only a few adult cases and have not always been stratified by subtype. POEM is also used for spastic esophageal disorders such as DES, jackhammer esophagus, and EGJ outflow obstruction (including cases of sigmoider esophagus and EGJ 0.8 as classified before CC v3.0) with good results. POEM has reported success rates of more than 80% for these disorders with relatively low morbidity at expert centers. In a recent meta-analysis by Khan et al, examining the clinical success of POEM in spastic esophageal disorders including type III spastic achalasia, DES and sigmoid esophagus, 179 patients were pooled for analysis from 8 observational studies. Clinical success for all types of spastic esophageal disorders was 87%. Although these studies are small, they suggest comparable outcomes for extended POEM with low morbidity as compared with traditional open or laparoscopic/thoracoscopic approaches for extended esophageal myotomy.

There is controversy about whether myotomy for esophageal body motility disorders should be extended through the EGJ. Given the subsequent weakening of peristalsis after esophageal body myotomy, it is recommended to extend the myotomy through the EGJ onto the stomach to prevent refluxing outflow obstruction and postoperative

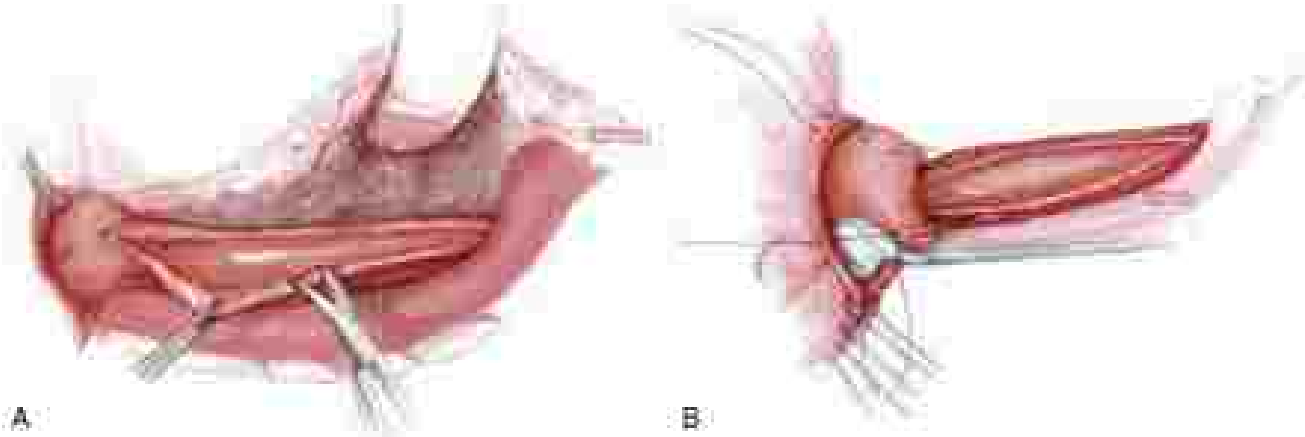

FIG. 8 (A) Thoracic myotomy and (B) distal myotomy. (*Courtesy Carmen Scalise, from Carmen JF, Scalise C, Atlas of Gastrointestinal Surgery, vol 1, 2nd ed. Hudson OH: People's Medical Publishing; 2007.*)

dysphagia, even in the setting of a normally relaxing EGJ. POEM myotomy length should be tailored based on HRM topography and endoscopic measurement of the high pressure zone and has been extended proximally anywhere between 6 and 25 cm above the gastric cardia in such cases. POEM with variable length of myotomy was comparable to other surgical techniques for relief of dysphagia and chest pain and had low morbidity.

A disadvantage of POEM is the requisite learning curve, which is about 20 cases for experienced endoscopists as demonstrated by Kurian and colleagues. GERD is also a long-term risk of POEM, currently with a 20% to 80% risk based on cumulative data. This is in fact comparable to Heller myotomy with partial fundoplication, which has a postoperative rate of GERD between 20% and 62%, depending on the fundoplication technique. Postoperative GERD is asymptomatic in half of patients, so routine follow-up pH testing or endoscopy is prudent. Patients identified with GERD have been treated successfully with PPIs with avoidance of long-term sequelae of reflux. Because the POEM results in a low rate of clinically significant leak or stricture and has been shown to be safe and effective in revision after Heller myotomy, Botox, and pneumatic dilation, POEM does not preclude subsequent endoscopic, laparoscopic, or thoracoscopic procedures should they be required. Due to these benefits, extended myotomy by POEM should be the preferred approach for primary spastic motility disorders requiring intervention.

OPERATIVE TECHNIQUE

Previous chapters in this and other texts have described esophageal myotomy with or without fundoplication via abdominal and thoracic approaches, so these are not repeated in detail here.

POEM is performed in the operating room under general anesthesia. The procedure requires a high definition endoscope for optimal visualization and CO_2 insufflation because it has a better safety profile than room air. The patient is placed in the supine position to allow access to the abdomen or chest. For a few days before the procedure, patients are given a Nystatin rinse prophylactically to clear any *Candida* esophagitis related to esophageal stasis and allowed only a liquid diet for 1 day to allow clearance of retained food. A preoperative antibiotic is administered, as well as a single preoperative dose of intravenous steroid to prevent development of mucosal edema.

Upper endoscopy is performed to evaluate the anatomy, rule out *Candida* spp., and clear any fluid or food debris within the esophagus before proceeding. EndoFLIP (endoscopic functional luminal imaging probe) is used to measure baseline esophageal diameter, pressure, cross sectional area, distensibility, and compliance. An overtube is used for distal myotomy to stabilize the scope from overlonging. No overtube is used for extended myotomy. The gastric wall is tattooed with indigo carmine 2 cm distal to the EGJ in the anterior position along the lesser curvature, marking the target for the distal extent of the myotomy. The location and extent of the myotomy and mucosotomy are calculated based on careful evaluation of the preoperative manometry and intraoperative evaluation of the high pressure zone. An angled dissecting cap is attached to the high definition endoscope to facilitate dissection and visualization. A mucosal lift is created with injectable saline with dilute indigo carmine in the anterior esophagus 2 to 4 cm proximal to the proximal extent of the planned myotomy (Fig. 9).

An endoscopic cautery knife is used to create a 1.5-cm longitudinal mucosal incision to expose the submucosa. Using the dissecting cap, the surgeon advances the endoscope through the mucosotomy and into the submucosal plane. Once inside, spray cautery and serial injections of lifting solution are used to create a submucosal tunnel, separating the mucosa from the circular muscle. Visible vessels are coagulated with the dissecting knife or grasped with hot biopsy forceps. The submucosal tunnel is extended distally across the GEJ and onto the gastric wall until the distal darker blue tattoo is reached.

Once satisfied with the extent of the tunnel, the endoscope is brought back, and the myotomy is created by selectively dividing the circular muscle layer. The thin longitudinal muscle layer is left intact whenever possible. Full-thickness breaches of the muscle are usually not critical as the submucosal adventitial tissue is left intact. The myotomy is extended across the EGJ and into the proximal gastric wall. During the procedure, exiting the tunnel to deflate insufflated gas from the stomach may be required to relieve gastric distension. Capnoperitoneum may develop in up to 30% of cases; it is often minor and self-limited but is evacuated easily with a Veress needle if abdominal overdistension or respiratory compromise develops.

After the myotomy is completed, the surgeon withdraws the endoscope, checking for hemostasis. Completion endoscopy identifies any inadvertent mucosal injuries, which are treated with endoscopic clips. The EndoFLIP catheter is replaced, and measurements are compared with those obtained before surgery to ensure adequacy of the myotomy before closure. Endoscopic clips then are used to close the proximal mucosotomy in a longitudinal fashion from distal to proximal.

Postoperative Care

The patient is kept NPO overnight, and a routine contrast esophagogram is obtained on the first postoperative day. If no leaks or obstruction are identified, the patient is allowed clear liquids and crushed medications. The patient may be discharged on postoperative day 1 if liquids are tolerated and should maintain a pure-consistency diet for 1 week to avoid disruption of the mucosal closure clips. In most cases, postoperative pain is minimal and usually does not require narcotics.

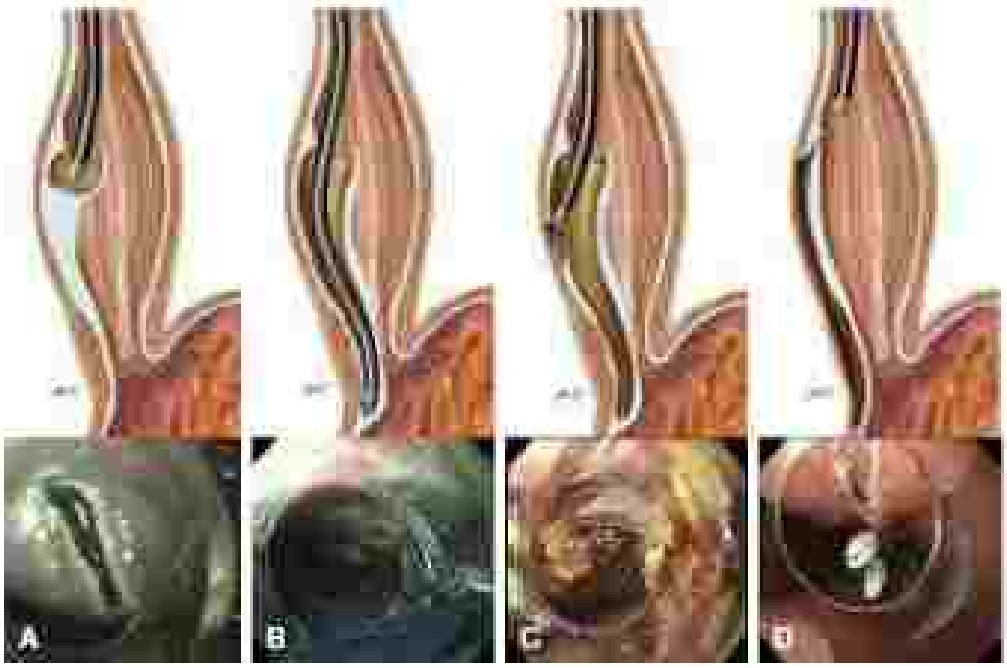

FIG. 9 Per oral endoscopic myotomy. (A) Entry into submucosal plane. (B) Creation of submucosal tunnel (mucosa is intact at circular muscle at superior). (C) Myotomy of circular muscle. (D) Closure of mucosal entry site with clips. (From Inoue H, Sato H, Ikeda H, et al. Per-oral endoscopic myotomy: a series of 500 patients. J Am Coll Surg 2015;221:256–264.)

Complications

Acute postoperative complications can include barotrauma bleeding, mucosal leak or dehiscence, or mediastinitis. No deaths have been reported. Bleeding may require transfusion and repeat endoscopy to achieve hemostasis. Mucosal leaks or dehiscence may heal with conservative management but often require repeat endoscopy and repair with additional clips or suturing. Mediastinitis is treated with antibiotics and may require percutaneous or surgical drainage. Post procedure adverse events in the meta analysis reported by Khan et al for all types of spastic esophageal disorders were 14%. Most of the adverse events (74%) were managed conservatively. Five patients required prolonged hospitalization and/or an intervention for pneumothorax, pulmonary embolism, capnoperitoneum, or bleeding.

CONCLUSION

There is work to be done to the realm of neurohalasia esophageal motility disorders as HRM diagnostics and treatment options evolve. To achieve the best possible outcome, therapeutic options should be considered carefully and individually tailored. Patients should be advised on expectations because treatment outcomes are somewhat unpredictable and may be disappointing in some cases. POEM is a promising, minimally invasive treatment option for hypercontractile and spastic disorders and perhaps will be considered as an early surgical intervention rather than salvage therapy, given its relative success and safety profile. For hypermotility disorders associated with GERD, partial fundoplications remain the gold standard, although Nissen fundoplication also has been shown to be well tolerated in all but the most extreme cases. There also may be a role for newer endoscopic antireflux procedures, although there are insufficient data at this time to define their application for these relatively rare disorders.

ACKNOWLEDGMENT

We acknowledge Lee L. Swanstrom, MD, and Kristin Wilson Bonds, MD, for their comprehensive chapter content in the previous edition of this text.

Management of Esophageal Cancer

Filippo Filicori, MD, and Lee L. Swanström, MD, FACS, FASGE, FRCSEng

The conceptual approach to esophageal cancer has changed significantly over the past few decades. New treatment modalities have significantly improved the outcomes in this patient population. As an example, neoadjuvant therapy has considerably improved outcomes for patients with advanced locoregional disease; however, the benefits of neoadjuvant treatment in patients with more limited locoregional spread has yet to be proven. Because nodal involvement is the best predictor of long-term survival and an important guide for therapeutic approaches, a thorough staging is mandatory for all esophageal cancers, along with a determination of the functional status of the patient. Another disruptive advance is that of endoscopic resection (ER) of early cancers and premalignant lesions. This has been proven to be a valuable diagnostic and therapeutic tool and is increasingly used as a first-line approach to superficial neoplasms. These changes in treatment algorithms, coupled with decreasing operative morbidity, improved oncologic yields of recent surgical approaches, and enhanced screening and surveillance algorithms for early cancers are the underlying reasons for the improved survival we have witnessed in the last few decades.

STAGING

Staging of esophageal cancers is most often by the TNM classification, which evaluates the local tumor (T), the regional lymph nodes (N) and the distant sites of metastasis (M). Over the past decade, the importance of the number of involved lymph nodes has been recognized and incorporated into the seventh and eighth editions of the American Joint Committee on Cancer (AJCC) Staging System (Table 1 and Figs. 1 to 3). This classification is based on the risk-adjusted random survival factor analysis of data generated from 22,654 patients who were treated with esophagectomy alone or esophagectomy with preoperative neoadjuvant and/or postoperative adjuvant therapy. The eighth edition of the AJCC classification distinguishes three N categories based on the number of lymph nodes involved. The most recent classification also presents separate staging for the clinical, pathologic (pTNM), and postneoadjuvant pathologic groups to increase clarity of treatment algorithms. In addition, pT1 cancers have been further subcategorized in pT1a and pT1b, which allows for a more tailored surgical approach given the higher risk for pT1b lesions to have nodal spread and, by implication, local recurrence after endoscopic treatment. Furthermore, cancers of the esophagogastric junction that have their epicenters within the proximal 2 cm of the gastric cardia (previously classified as Siewert types I and II) are now staged as esophageal cancers. Those with epicenters more than 2 cm distal to the esophagogastric junction (previously classified as Siewert type III), even if the esophagus is involved, are staged as stomach cancers and therefore treated following the gastric cancer guidelines (Fig. 4). Staging should proceed in a methodical fashion to accurately determine the TNM status of the patient and better advise as to the best treatment options.

ESOPHAGOGASTRODUODENOSCOPY AND BIOPSY

Endoscopy and tissue biopsy are the first steps in surgical staging. The location of the tumor, length, extent of circumferential involvement, and presence of associated Barrett's esophagus according to Prague criteria should be accurately recorded. Traditional endoscopic biopsy is the preferred approach for large lesions and those that are suspected of being locally aggressive. Narrow band imaging and newer imaging techniques that allow for real-time detection of dysplastic or neoplastic mucosal, such as confocal laser microscopy or optical coherence tomography, should be used liberally to increase the diagnostic yield of the biopsies. Because ER allows accurate pathologic T staging, it is recommended as a first diagnostic/therapeutic approach for all superficial lesions and especially those that are less than 2 cm and those appearing nodular or ulcerated. Consistent use of ER makes mistaging the depth of invasion of T1a and T1b lesions uncommon. ER techniques are described later in the chapter. When the lesion invades the submucosal layer or if the resection margin is positive, other methods such as endoscopic ultrasound (EUS) can be used to determine the T stage.

EUS is the only tool that allows the clinician to directly visualize the depth of invasion of a neoplasm. Despite technological improvements, T mistaging is still common and occurs in as many as 20% of cases, especially in those with T1 and T2 cancers. Specifically, a recent meta-analysis has shown that EUS accuracy for T1 cancers was 83.5%, 75% for T2 cancers, 89% for T3 cancers, and 89% for T4 cancers. EUS can provide information regarding N status with an accuracy of 77% to 84%, a number that can rise to 95% when this technique is coupled with fine needle aspiration. There is little information on the accuracy of EUS clinical N staging using the AJCC eighth edition staging system. Overall, EUS is a valuable tool when the tumor is too large or deep for endoscopic mucosal resection (EMR) or when EMR yields indeterminate results or positive margins.

CROSS-SECTIONAL IMAGING

Computed tomography (CT) has for a long time been the primary diagnostic imaging modality to determine N and M stage. It is of the utmost importance to rule out metastatic disease, which is present in 35% of the patients at diagnosis. More recently, fused positron emission tomography (PET) CT studies have improved diagnostic performance by combining anatomic and metabolic information. The radiotracer 2-[18F] fluoro-2-deoxy-D-glucose has been reported to accumulate in 92% to 100% of esophageal cancers. Unfortunately, FDG-PET lacks sufficient specificity to determine T staging; other modalities, described previously, are more suitable for the purpose of accurately staging local invasion. Data suggest that PET CT increases accuracy when compared with FDG-PET alone when evaluating N status (92% vs 84%). FDG-PET has also been shown to be more accurate compared with CT to determine the presence of M disease (94% vs 63%). In addition, PET CT also allows detection of the metabolic response of a tumor to neoadjuvant treatment, which has been correlated with survival in several studies. Overall PET CT appears to allow better staging providing additional information in 23% of cases when compared with CT alone. PET CT is therefore the preferred imaging modality in patient with advanced locoregional disease for both initial staging and to determine response to neoadjuvant treatment.

TREATMENT ALGORITHMS

Treatment recommendations are ideally made after joint consultation by a multidisciplinary team including surgical, radiation and medical oncologists, gastroenterologists, radiologists, and pathologists. National Comprehensive Cancer Network guidelines were recently updated in 2018 for both esophageal adenocarcinoma and squamous cell carcinoma and contain several new recommendations compared with their previous versions (Figs. 5 and 6).

TisN0M0, T1aN0M0, and T1bN0M0

Superficial esophageal adenocarcinomas are often cured by resection alone, whether using endoscopic techniques or esophagectomy.

TABLE 1. Staging of Esophageal Cancer, AJCC Manual, 8th Edition

Category	Criteria
T CATEGORY	
TX	Tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia, defined as malignant cells confined by the basement membrane
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa
T1a*	Tumor invades the lamina propria or muscularis mucosae
T1b*	Tumor invades the submucosa
T2	Tumor invades the muscularis propria
T3	Tumor invades the adventitia
T4	Tumor invades adjacent structures
T4a*	Tumor invades the pleura, pericardium, azygos vein, diaphragm, or peritoneum
T4b*	Tumor invades other adjacent structures, such as the aorta, vertebral body, or trachea
N CATEGORY	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis to 1–2 regional lymph nodes
N2	Metastasis to 3–6 regional lymph nodes
N3	Metastasis to ≥7 regional lymph nodes
M category	
M0	No distant metastasis
M1	Distant metastasis
ADENOCARCINOMA G CATEGORY	
GX	Differentiation cannot be assessed
G1	Well differentiated, with >95% of the tumor composed of well-formed glands
G2	Moderately differentiated, with 50%–95% of the tumor showing gland formation
G3*	Poorly differentiated, with tumors composed of neat and sheets of cells with <50% of the tumor demonstrating glandular formation
SQUAMOUS CELL CARCINOMA G CATEGORY	
GX	Differentiation cannot be assessed
G1	Well differentiated, with prominent keratinization with pearl formation and a minor component of nonkeratinizing basaloid-like cells, tumor cells arranged in sheets, and mitotic counts low
G2	Moderately differentiated, with variable histologic features ranging from parakeratotic to poorly keratinizing features and pearl formation generally absent
G3*	Poorly differentiated, consisting predominantly of basaloid-like cells forming large and small nests with frequent central necrosis and with the nests consisting of sheets or processes. The arrangements of tumor cells that are occasionally punctuated by small numbers of parakeratotic or keratinizing cells
SQUAMOUS CELL CARCINOMA L CATEGORY†	
LX	Location unknown

A tumor with stage Tis by definition does not extend beyond the basal membrane and therefore can be treated by endoscopic means such as ER. Radiofrequency ablation (RFA) and cryoablation can also be used on flat lesions but lack the advantage of providing a surgical specimen that might guide further treatment. T1a tumors invade through the basal membrane and into the superficial submucosal space. Local resection is therefore potentially curative. These neoplasms do have a 2% potential to harbor metastases to the regional lymph nodes, but because this is near the operative mortality of surgical resection, it is universally considered the preferable option. Sampling errors might also occur and metachronous neoplasms can potentially surround the biopsied areas and therefore these patients require both endoscopic and radiologic continued surveillance. If the carcinoma is penetrating the muscularis mucosae (T1b), the rate of lymphatic infiltration increases in correlation with the depth of infiltration in the submucosa. The overall chance of nodal spread is directly correlated with the depth of invasion of the three submucosal layers (sm1, sm2, and sm3), tumor differentiation, and presence of lymphovascular invasion (LVI). LVI is the most important prognostic determinant of outcome for locally resected early stage cancer. Risk of nodal involvement has been estimated to increase from 2% for a T1a lesion without LVI to 60% for T1b lesions with LVI with an expected decrease in survival rates. Size of tumor and differentiation are other independent prognostic variables in some studies, with lesions smaller than 2 cm and well to moderate differentiation associated with a low risk of nodal involvement. It is therefore mandatory to obtain lymph node evaluation through CT or EUS in all patients with T1b disease. ER is an ideal minimally invasive treatment

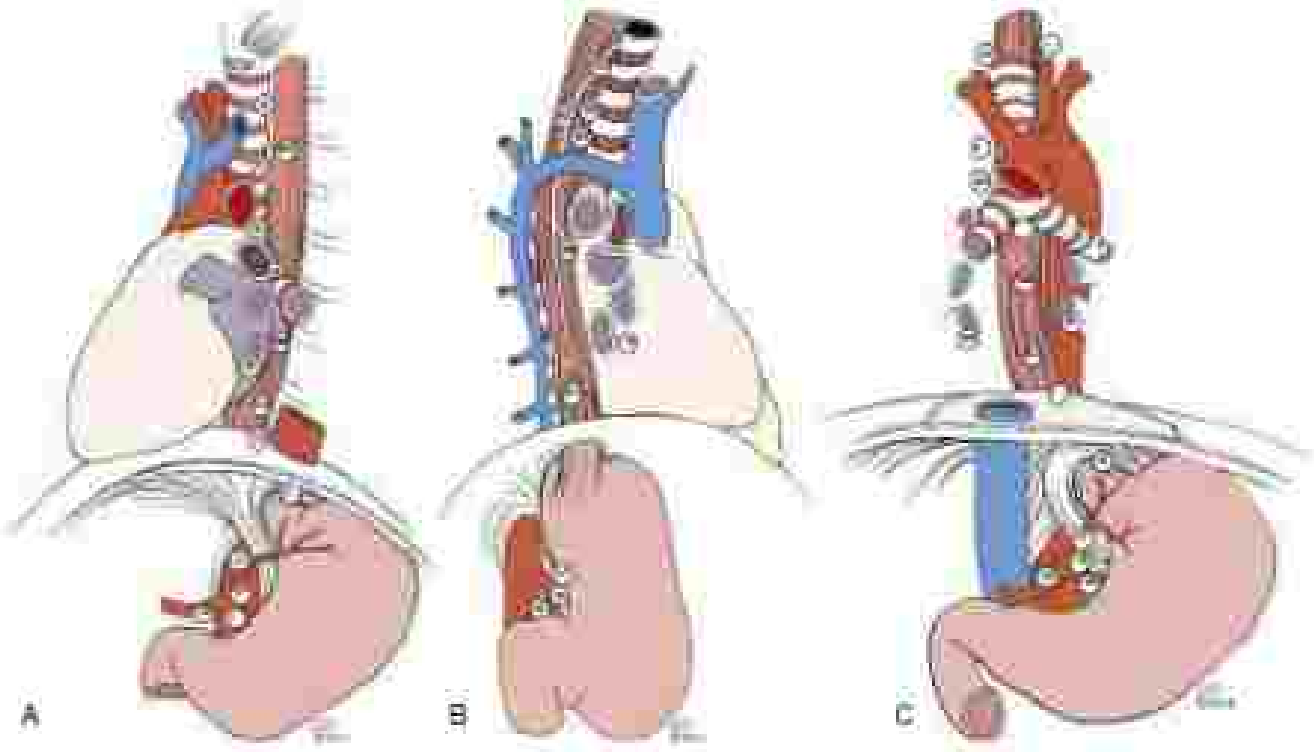

FIG. 3 Lymph node maps for esophageal cancer. Optimal lymph node stations for staging esophageal cancer from the (A) left, (B) right, and (C) anterior. 1, left lower cervical paratracheal nodes, between the supraclavicular paratracheal space and apex of the lung; 1R, right lower cervical paratracheal nodes, between the supraclavicular paratracheal space and apex of the lung; 2L, left upper paratracheal nodes, between the top of the aortic arch and apex of the lung; 2R, right upper paratracheal nodes, between the intersection of the caudal margin of the brachiocephalic artery with the trachea and apex of the lung; 4L, left lower paratracheal nodes, between the top of the aortic arch and the carina; 4R, right lower paratracheal nodes, between the intersection of the caudal margin of the brachiocephalic artery with the trachea and cephalic border of the azygos vein; 7, subcarinal nodes, caudal to the carina of the trachea; 8a, lower thoracic paraesophageal lymph nodes, from the caudal margin of the inferior pulmonary vein to the esophagogastric junction; 8M, middle thoracic paraesophageal lymph nodes, from the tracheal bifurcation to the caudal margin of the inferior pulmonary vein; 8U, upper thoracic paraesophageal lymph nodes, from the apex of the lung to the tracheal bifurcation; 9L, pulmonary ligament nodes, within the left inferior pulmonary ligament; 9R, pulmonary ligament nodes, within the right inferior pulmonary ligament; D, diaphragmatic nodes, lying on the dome of the diaphragm and adjacent to or behind its crura; 14, paracardial nodes, immediately adjacent to the gastroesophageal junction; 17, left gastric nodes, along the course of the left gastric artery; 18, common hepatic nodes, immediately on the proximal common hepatic artery; 19, splenic nodes, immediately on the proximal splenic artery; T , celiac nodes, at the base of the celiac artery. Cervical paraesophageal level VI and level VII lymph nodes are named as per the head and neck map. *(From Ilson DH, Shevanna H, Ferguson MK, Rizkallah TH. Outcome of the esophagus and esophagogastric junction: an eighth edition staging primer. Pract Gastroenterol Nutr. 2017;1[1]:26-47.)*

for tumors that are well differentiated, smaller than 3 cm, within mid and mid-third LVI. Many groups are exploring extended indications for endoscopic treatment (e.g., T1b lesions, larger tumors moderately differentiated, depending on advanced imaging to exclude nodal involvement, but this remains controversial at least for patients who could tolerate esophagectomy. More advanced tumors (T2, poorly differentiated, and with LVI) should undergo esophagectomy if the patient is a good operative candidate based on functional status.

T2, N0-1, M0

Currently, optimal therapy for T2 cancers or tumors with limited locoregional involvement (N0-1) remains controversial. Current dogma that all patients with N1 disease should be offered induction therapy is based on older staging systems in which the number of involved nodes was not taken into account. There is growing evidence that neoadjuvant therapy is not beneficial to node-negative patients and perhaps not even in those with limited (N1) nodal disease. This fits with evidence that less than 50% of patients with N1 lymph node involvement in the current staging system will develop systemic disease and raises questions about the value of toxic systemic therapy for all these patients.

In addition, it is important to bear in mind that understaging represents a major source of suboptimal treatment in up to 20% of patients with T2 disease. The overall survival for these patients is significantly lower than those correctly staged. Understaged patients with advanced nodal disease are at high risk for systemic metastases, and resection alone is inadequate. In a recent study performed at the University of Southern California, three factors were found to be associated with understaging in patients with advanced locoregional disease: dysphagia at presentation, tumor size greater than 3 cm, and poor differentiation. When none of these factors were present, 92% of patients were correctly staged. Conversely, when all three factors were present, 82% of patients were understaged. Patients with dysphagia at presentation, tumor size larger than 3 cm, and poor differentiation should be considered at high risk for advanced nodal disease, despite the objective findings on clinical staging studies, and be recommended to undergo neoadjuvant therapy before resection.

T3-4, N1-3, M0

There is a clear survival advantage to patients with T3+ or N2+ locally advanced disease who undergo neoadjuvant treatment. Recent studies also suggest a benefit of adjuvant therapy in understaged patients

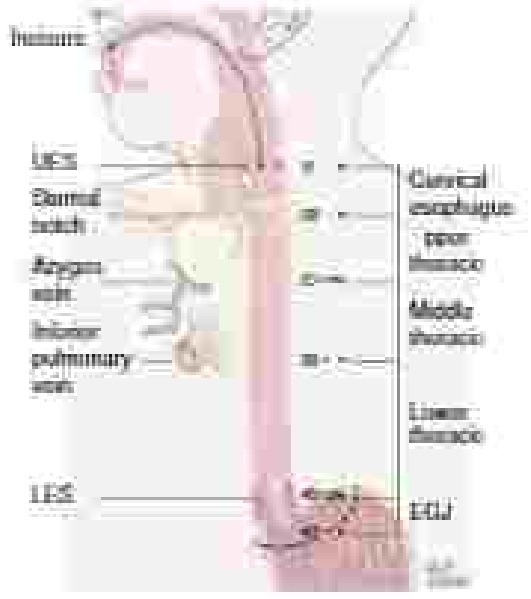

FIG. 6 Location of esophageal cancer primary site, including typical endoscopic measurements at each region measured from the incisors. Exact measurements depend on body size and height. Location of cancer primary site is defined by cancer epicenter. Cancers involving the esophagogastric junction (EGJ) that have their epicenter within the proximal 2 cm of the cardia (Siewert types II/III) are to be staged as esophageal cancers. Cancers whose epicenter is more than 2 cm distal from the EGJ, even if the EGJ is involved, will be staged using the stomach cancer TNM and stage groups. *LES*, lower esophageal sphincter; *UES*, upper esophageal sphincter. (From Rice TW, Ishwaran H, Ferguson MK, Blackstone EH, Goldstraw P. Cancer of the esophagus and esophagogastric junction: an eighth edition staging primer. J Thorac Oncol. 2017;12(1):36–42.)

who undergo primary resection. Chemoradiation has been associated with both a higher rate of R0 resections and a median disease-free and overall survival improvement. The prognostic significance of histologic tumor regression and pathologic complete response in patients with esophageal adenocarcinoma and squamous cell carcinoma has been demonstrated in several studies. The major difference between these two histologic tumors is their response to chemotherapy. Squamous cell carcinoma has a greater response to treatment, and endoscopic surveillance is regarded as a reasonable option when complete clinical response is achieved. Esophageal adenocarcinoma has higher rates of local failure and most centers would still advocate for esophagectomy even in the face of initial complete clinical response. Surgery should be timed at 6 to 10 weeks after completion of neoadjuvant treatment and should aim for an R0 resection with the highest lymph node count possible; current recommendations are for at least 15 lymph nodes.

T4b, Any N or M1

Patients with cancer invading into structures that cannot be resected (aorta, left atrium, and spine) or patients with distant disease are not candidate for curative surgical resection and the focus of their care should be palliation of their disease. This goal is achieved best in the context of a multidisciplinary team that must include an oncologist, psychologists, and palliative care specialists. Chemoradiation can deliver long-term disease control, improve dysphagia, and prolong survival and is therefore indicated in patients with adequate performance status. Although chemotherapy can help to control the growth of disseminated disease, radiation is more effective in controlling dysphagia, pain, and bleeding. Today, HER2 and microsatellite instability analysis is recommended in metastatic disease to evaluate for potential implementation of targeted therapies. Endoscopic stent insertion is effective for dysphagia relief; however, it is associated with a significant number of complications, including perforations and stent migrations. Photodynamic therapy has waned and waxed in popularity for palliating patients with dysphagia and metastatic disease. Despite good results in the short term, there are several associated

side effects (photosensitivity being the most bothersome one for patients) and perforations have been reported.

TREATMENT OPTIONS

Endoscopic Resection and Ablation

ER or ablation is useful for both accurately staging and is potentially curative to patients with early esophageal cancer. Determination of which patients should be selected for endoscopic therapy versus esophagectomy in early esophageal cancer should be done on a case-by-case basis. All patients should undergo CT scan and EUS with or without fine needle aspiration of suspicious lymph nodes to rule out metastatic disease. Patients with multifocal and/or long segments of high grade dysplasia, those with poorly differentiated histology or LVI, those with poor esophageal motility, and younger patients in whom continued surveillance may be cumbersome may be better served with an esophagectomy. Multiple endoscopic treatments may be required to attain complete eradication and different treatment modalities should be tailored to the characteristics of the neoplasm. Esophagogastroduodenoscopy (EGD) is usually performed every 8 to 12 weeks until complete eradication of neoplastic and metaplastic tissue is obtained, after which surveillance is continued.

Ablation therapies do not provide a pathologic specimen and are not as effective in treating nodules or ulcerated lesions. However, they are particularly useful in the treatment of mucosa containing long segments of columnar lined esophagus. The two most common techniques described are RFA and cryoablation. These technologies reliably ablate the mucosa down to the lamina propria layer of the esophageal mucosa and normal squamous mucosa regenerates from progenitor stem cells.

Endoscopic Mucosal Resection

EMR is most commonly performed using a cap and suction, either with a band ligation or not, after which a cautery snare is used to resect the artificially created polyp. EMR can be performed under conscious sedation and is indicated for lesions that are smaller than 2 cm. Narrow band imaging should be used liberally before and during the procedure to identify the areas of dysplastic/neoplastic epithelium. Lesions bigger than 2 cm might require piecemeal resection; however, this is not as reliable when determining surgical margins and has a higher local recurrence rate. The main advantages of EMR include a short learning curve, low perforation rate, and the possibility of performing circumferential resections. A combination of resection and ablation can also be used to achieve complete eradication; however, long segments of circumferential resection have the potential to result in stricture formation that can be occasionally difficult to treat.

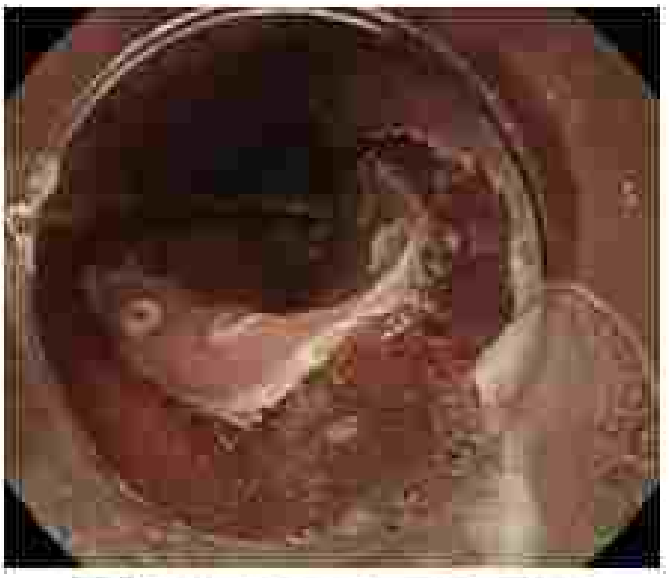

FIG. 7 Endoscopic submucosal dissection resection site.

Endoscopic Submucosal Dissection

Although it is somewhat technically challenging to perform endoscopic submucosal dissection (ESD) in a narrow lumen such as the esophagus, submucosal dissection is particularly useful for flat lesions or lesions that are larger than 2 cm. ESD is associated with a higher R0 resection rate and lower local recurrence rate than EMR. The technology required is widely available and includes high definition endoscopes, beveled dissection caps, and various endoscopic energy sources (Fig. 7). Most complications arising from ESD, including bleeding, stricture formation, and even perforation, can be managed endoscopically.

Radiofrequency Ablation

RFA has become increasingly popular thanks to its ease of use and documented efficacy. It is performed using a high-power radiofrequency generator and a variety of balloon catheters or scope directed ablation catheters. These devices, which apply bipolar energy to the epithelium, consistently ablate the superficial 0.5 mm of mucosa (Fig. 8). Although this modality has been mainly studied for metaplastic and dysplastic changes of the esophageal epithelium, it can also be applied to T1a and even T1a esophageal adenocarcinoma when nodules are not present. The most common complications reported include chest pain lasting less than 1 week, strictures requiring dilation (6% to 8%), and gastrointestinal hemorrhage (1%).

Cryotherapy

Cryotherapy is an ablative technique that causes tissue destruction by application of liquid nitrogen or carbon dioxide gas. Small areas can be treated (2 to 3 cm) while covering approximately one third or one half of the luminal circumference with each application. Multiple areas can be treated in one endoscopic session. On average, three to four endoscopies are needed to completely ablate a long segment of disease, and the procedures can be performed approximately every 6 to 8 weeks. Some small series report complete eradication rates of 75% for superficial lesions and it may be more applicable for irregular surfaces and small nodules.

Surgical Therapy

All patients who are being considered for surgery should be assessed for their fitness to undergo general anesthesia and a major surgical procedure. Definitive chemoradiotherapy should be offered to those patients who would not be able to tolerate major thoracoabdominal surgery. Pretreatment nutritional status should be assessed, especially in patients presenting with dysphagia and weight loss before diagnosis or resulting from neoadjuvant therapy. Enteral nutrition with a feeding tube (jejunostomy tube preferred) should be considered. The type of esophagectomy depends on the location of the tumor as well as the surgeon's expertise. The three most common open operations, transhiatal esophagectomy, two stage Ivor Lewis esophagectomy, or three stage McKeown esophagectomy have low mortality and low morbid minimally invasive alternatives. The choice of procedure should be based on the tumor's location and the surgeon's expertise. Probably more important than the surgical approach is the adequacy of R0 resection and the lymph node harvest. Although no defined number of lymph nodes has been definitively established, National Comprehensive Cancer Network guidelines suggest that at least 15 lymph nodes should be harvested at the time of surgery.

Minimally Invasive Ivor Lewis (2-Stage) Esophagectomy

Ivor Lewis two stage (abdominal, thoracic) esophagectomy is the most commonly performed surgical procedure worldwide for esophageal cancer. Ivor Lewis minimally invasive esophagectomy (MIE) has rapidly become the preferred surgical approach owing to decreased morbidity and faster recovery times compared with its open alternative. Given the optimal intraabdominal and intrathoracic exposure, it is an especially good choice for neoplasms in the middle and distal portions of the esophagus. The patient is positioned supine in a split leg position with moderate reverse Trendelenburg. Five

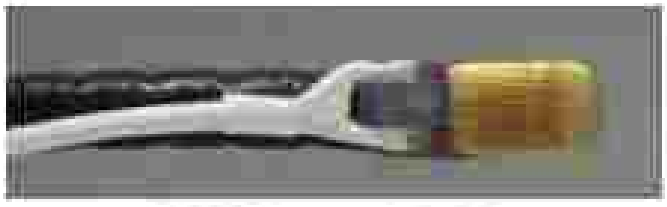

FIG. 8 Radiofrequency ablation device.

intraabdominal ports and an atraumatic liver retractor for the left hepatic lobe are positioned to expose the hiatus. After careful inspection to rule out any metastatic disease, the dissection is started at the gastrohepatic ligament, exposing the right crus. A complete D2 lymph node dissection is performed starting at the celiac trunk and following the hepatic and left gastric artery, the superior margin of the portal vein, and the pretpancreatic tissue. The left gastric vascular pedicle is divided. A thorough node dissection is particularly important for adenocarcinoma of the cardia, which has higher propensity to metastasize to these lymph nodes. Equally important is an en bloc dissection of the distal esophagus, which is easily done from the laparoscopic approach. The gastrocolic ligament is then divided just distal to the gastroepiploic arcade taking care not to injure the gastric vascular structures, which might compromise the blood flow to the newly formed conduit (Fig. 9). The use of fluorescence imaging at this stage can facilitate the identification of the right gastroepiploic artery and determine the adequacy of perfusion at the distal conduit. The dissection is carried out medially to the level of the duodenum and then extended to the fundus by dividing the short gastric vessels and the lateral phrenoesophageal ligament. The stomach is then lifted anteriorly, and the retroperitoneal attachments are divided. Pyloroplasty or botulinum (onto injection of the pylorus is performed at this stage to aid the emptying of the conduit. Transhiatal dissection of the esophagus is then performed dividing the phrenoesophageal ligament and dissecting the paraaortic and lower paraesophageal nodes and dividing the peritoneum from the crurae bilaterally. A Penrose drain is used to encircle the distal esophagus for retraction during both the abdominal and thoracic phase. A 3- to 5-cm wide gastric conduit is then created by dividing the stomach with multiple firings of a purple load linear stapler, starting at the level of the incisura on the medial side all the way proximal to the fundus leaving the last 5 cm of stomach undivided to allow retrieval during the thoracic phase (Figs 10 and 11). A running Lembert suture is then used to reinforce the staple line and a silk suture is placed 5 cm proximal to the incisura to mark the distal end of the conduit during the thoracic phase. As a final step, a 12F feeding jejunostomy tube is inserted in the small bowel.

Thoracic Phase

Traditionally performed with the patient in the left lateral decubitus position, this portion of the procedure is increasingly done with the patient in the prone position. The right lung is collapsed either by use of double lumen ventilation or by positive pressure capnothorax with laparoscopic valved thoracic ports. Four trocars are placed in the thoracic wall in a diamond pattern. After dividing the pulmonary ligament to the level of the inferior pulmonary vein, a fan retractor is placed to provide better visualization of the posterior mediastinal pleura at the level of the azygos vein. The azygos vein is divided with a vascular stapler to allow exposure of the entire esophagus (Fig. 12). Depending on tumor characteristics and patient's comorbidities, we generally perform an en bloc lymph node dissection to maximize local tumor control by resection of the tumor bearing esophagus within a wide envelope of adjoining tissues that includes both pleural surfaces, the thoracic duct, and the azygos vein. This results in a complete mediastinal node dissection from the azygos arch to the esophageal hiatus. The Penrose drain left around the esophagus is retrieved and used to retract the esophagus and facilitate dissection. The esophagus is then divided at the thoracic inlet and the proximal margin is sent for frozen section. The gastric conduit is then gently grasped and pulled up into the chest up to the level of the silk stitch previously placed, making sure no twists are present. A transoral circular stapler (Orvil, Medtronic) is then inserted through the patient's mouth into the esophageal stump. The nasogastric tube connected with the Orvil is passed through a small opening next to the staple line and removed through one of the trocars. At this point, fluoroscopic imaging is once again used to determine appropriate perfusion of the conduit. This can be traumatic to a point of maximal perfusion making sure that excessive tension is avoided. The EEA (Medtronic)

transhiatal esophagectomy, the latter was associated with higher postoperative survival. Although long-term survival differences have not been demonstrated, many experts believe this operation has a lower oncologic yield, although this has not been analyzed for the laparoscopic approach, where en bloc dissection of the distal mediastinum is possible.

McKeown (Three-Staged) Esophagectomy

For patients with a proximal thoracic tumor located near the airways or with extensive Barrett esophagus or if there is a concern of obtaining a proximal margin free of tumor, a modified McKeown esophagectomy or three-staged esophagectomy with a cervical anastomosis may represent a better option. A leak in the cervical space is generally also easier to manage compared with a thoracic leak and requires opening and packing of the neck wound. The steps of the operation are the same as for an Ivor Lewis esophagectomy. The thoracic inlet is then dissected and the specimen is extracted from an oblique incision anterior to the sternocleidomastoid muscle. A single-layer anastomosis is constructed using a running 3-0 PDS suture.

Surveillance

Most surveillance guidelines are based on retrospective studies and expert consensus rather than being validated by rigorous risk-benefit studies. For asymptomatic patients, follow-up should include a complete history and physical examination every 3 to 6 months for the first 2 years and every 6 to 12 months for the 3 years thereafter together with a comprehensive metabolic and nutritional laboratory work.

More than 90% of recurrences occur within the first 2 years; thus close surveillance for at least 24 months is recommended for these patients. Recurrences even after 5 years from primary treatment have been reported so EGDs should be performed every 1 to 2 years after the first 5 years after EMR. This should be coupled with EUS and CT of the chest/abdomen in patients with T1b disease treated by EMR alone. EGDs should also be performed every 3 to 6 months within the first 2 years after definitive chemoradiation as they provide a useful means to detect local failures. Patients who underwent esophagectomy should undergo CT of the chest/abdomen with contrast every 3 to 6 months for the first 2 years.

CONCLUSION

The science of esophageal cancer, both from the disease and treatment standpoint, has greatly evolved over the past 20 years. There continues to be a migration of squamous cell to adenocarcinoma as obesity and reflux increase in the population. Increased public awareness and improved screening technologies have led to increasingly early diagnosis of the disease, which lends itself to truly minimally invasive treatments such as ablation, EMR, and ESD, which are both patient friendly but also more than 90% curative. Good supportive care has decreased the morbidity and mortality of esophagectomy tremendously and MIE has even further decreased the morbidity to patients at no sacrifice to surgical cure rates. MIE is now more or less the gold standard for surgical treatment in most centers. Better understanding of the patient-specific risk factors for treatment failure as well as patient-specific tumor profiling and treatments, has ushered in an era of minimally invasive and precision therapeutics that holds a promise of improved outcomes for this highly lethal disease.

Multimodality Therapy in Esophageal Cancer

Jonathan Cools-Lartigue, MD, PhD, and
Daniela Molena, MD

For the vast majority of patients, esophageal cancer encompasses two main histologic subtypes: esophageal adenocarcinoma (EAC) and esophageal squamous cell carcinoma (ESCC). Esophageal adenocarcinoma represents the most common histology in the western world with a rapidly rising incidence. It originates predominantly in a background of Barrett's esophagus (BE) as a result of gastroesophageal reflux disease (GERD), necessitating close surveillance and treatment of the premalignant lesion. Squamous cell carcinoma is the most prevalent subtype worldwide, being more common in patients with significant smoking history and alcohol consumption. Both subtypes frequently present with dysphagia, which portends an advanced stage and poor outcome. Although surgery remains the mainstay of therapy, for patients with locally advanced disease, a multimodal approach has become standard and is necessary to improve survival in this population. Currently, multimodal regimens include preoperative chemoradiotherapy (CRT) or perioperative chemotherapy alone. Although this multimodal approach is associated with a 15% to 30% increase in overall survival, oncologic outcomes remain guarded, with all comers demonstrating 5-year survival on the order of 20%. The poor prognosis highlights the need for additional refinements in treatment paradigms and underscores much of the controversy in the optimal management of this malignancy. This being said, contemporary randomized controlled trials have demonstrated improvements in disease control with the application of multimodal regimens and are the topic of discussion in this chapter.

RATIONALE BEHIND SYSTEMIC THERAPY

When contemplating multimodal treatment for patients with esophageal cancer, it is important to consider the histology-specific characteristics that underlie the behavior of EAC and ESCC, specifically. These include the anatomic location of the tumor and patterns of recurrence. EAC characteristically involves the distal third of the esophagus and gastroesophageal junction (GEJ). This contrasts with ESCC, which demonstrates a predilection for the more proximal intrathoracic and cervical esophagus. These anatomic differences can affect surgical management of the disease, with cervical lesions potentially necessitating concomitant laryngectomy for local control. Lesions of the proximal or mid esophagus may also demonstrate airway invasion, which complicates surgical resection and potentially limits the ability to achieve a complete oncologic R0 resection. Given

transhiatal esophagectomy, the latter was associated with higher postoperative survival. Although long-term survival differences have not been demonstrated, many experts believe that operation has a lower oncologic yield, although this has not been analyzed for the laparoscopic approach, where en bloc dissection of the distal mediastinum is possible.

McKeown (Three-Staged) Esophagectomy

For patients with a proximal thoracic tumor located near the airways or with extensive Barrett's esophagus or if there is a concern of obtaining a proximal margin free of tumor, a modified McKeown esophagectomy or three-staged esophagectomy with a cervical anastomosis may represent a better option. A leak in the cervical space is generally also easier to manage compared with a thoracic leak and requires opening and packing of the neck wound. The steps of the operation are the same as for an Ivor Lewis esophagectomy. The thoracic inlet is then dissected and the specimen is extracted from an oblique incision anterior to the sternocleidomastoid muscle. A single layer anastomosis is constructed using a running 4-0 PDS suture.

Surveillance

Most surveillance guidelines are based on retrospective studies and expert consensus rather than being validated by rigorous risk-benefit studies. For asymptomatic patients, follow-up should include a complete history and physical examination every 3 to 6 months for the first 2 years and every 6 to 12 months for the 3 years thereafter together with a comprehensive metabolic and nutritional laboratory work.

More than 90% of recurrences occur within the first 2 years; thus close surveillance for at least 24 months is recommended for these patients. Recurrences even after 5 years from primary treatment have been reported so EGDs should be performed every 3 to 5 years after the first 2 years after EM. This should be coupled with EUS and CT of the chest/abdomen in patients with T1b disease treated by EMR alone. PET/CT should also be performed every 3 to 6 months within the first 2 years after definitive chemoradiation as they provide a useful means to detect local failures. Patients who underwent esophagectomy should undergo CT of the chest/abdomen with contrast every 3 to 6 months for the first 2 years.

CONCLUSION

RATIONALE BEHIND SYSTEMIC THERAPY

When contemplating multimodal treatment for patients with esophageal cancer, it is important to consider the histology specific characteristics that underlie the behavior of EAC and ESCC, specifically. These include the anatomic location of the tumor and patterns of recurrence. EAC characteristically involves the distal third of the esophagus and gastroesophageal junction (GEJ). This contrasts with ESCC, which demonstrates a predilection for the more proximal intrathoracic and cervical esophagus. These anatomic differences can affect surgical management of the disease, with cervical lesions potentially necessitating concomitant laryngectomy for local control. Lesions of the proximal or mid esophagus may also demonstrate airway invasion, which complicates surgical resection and potentially limits the ability to achieve a complete oncologic (R0 resection). Given

these features, adjuncts to surgical resection in the form of radiation or chemotherapy may be necessary for the purpose of organ preservation in the case of cervical esophageal lesions, or to facilitate complete tumor resection in the case of close apposition to the airway. More distal lesions, which often characterize EAC, are often more amenable to radical resection by virtue of their location and lack of unresectable structures to surround it.

As previously stated, patterns of recurrence after multimodal therapy demonstrate inherent differences between EAC and ESCC. In general, EAC demonstrates a higher predilection for hematogenous distant metastatic spread to sites such as lung, liver, bone, brain, and peritoneum. Conversely locoregional recurrence, particularly to regional nodes, tends to be marginally more prevalent in ESCC. For example, in the update to the FFCD 9703 trial, in which mixed histology EAC patients harboring stage I and II disease were randomized to receive surgery alone or CRT, Bedi et al demonstrated that patients with EAC more frequently developed distant metastatic disease compared with patients with ESCC, despite improved locoregional recurrence rates compared with patients who received surgery alone in both groups. It is important to note that rates of complete resection were identical in both groups at greater than 90%, suggesting that these observations reflect inherent, histology specific differences and not differences in treatment quality. In keeping with this observation, the time to first distant recurrence was shorter in patients with EAC (patients compared with those with ESCC: 30.9 vs 51 months), and these findings in a cohort of 349 consecutive patients with EC subjected to definitive CRT. Again, this was a mixed histology study comprising mainly patients with EAC (69.2%). Patients with ESCC demonstrated significant improvement in recurrence free survival (RFS) and distant metastasis free survival (DMFS) compared with patients with EAC. Moreover, patients with ESCC demonstrated a marginally increased rate of locoregional recurrence compared with patients with EAC. Given these observations, the ability of a given regimen to improve locoregional and distant recurrence rates needs to be assessed in a histology specific manner.

When assessing the efficacy of a regimen in the management of EC, it is important to evaluate its role with respect to local control and systemic control. These are better measured in terms of disease free survival, DFS, and overall survival (OS), respectively. Regarding local control, the main modalities used in contemporary multimodal regimens include surgery and radiation therapy, either alone or in combination. One of the most important measures of surgical quality is the ability to achieve complete oncologic R0 resection. When radiation or chemotherapy is used, local efficacy is reflected in the degree of pathologic response obtained after surgical resection. Systemic control is a factor through the administration of systemic chemotherapy. Given that the majority of patients with esophageal cancer, and locally advanced disease in particular, die as a result of systemic metastases, considerable focus has been paid to developing novel systemic regimens and optimizing standard ones. Although conceptually simple, the optimal regimen has yet to be determined, and a causal appraisal of the literature to date has the potential to seem contradictory. Similarly, the necessity of adding radiation, a predominantly local therapeutic modality, to contemporary perioperative treatment regimens in patients with EAC has come under question, given the results of recent randomized trials and meta analyses. Thus, when reviewing the available data, it is helpful to assess oncologic outcomes reported in the context of the tumor histology.

MULTIMODAL TREATMENT IN ESOPHAGEAL ADENOCARCINOMA

Chemotherapy Alone

From the standpoint of both locoregional and systemic control, the application of perioperative chemotherapy in patients with locally advanced EAC is associated with improved outcomes. To date, 5 RCTs examining perioperative chemotherapy plus surgery versus surgery alone have been published. These are outlined in Tables 1 and 2.

Locoregional Control

Studies demonstrating the efficacy of perioperative chemotherapy and surgery, compared with surgery alone in the management of patients with EAC are highlighted in Table 1. In the Cunningham (MAGIC) and Ychou trials, accrual was restricted to adenocarcinoma, but on both sides of the diaphragm, with more gastric than esophageal/esophagogastric in the MAGIC and the reverse in the Ychou study. The recently completed FNCLCC trial has yet to be published, but, as in the MAGIC trial, recruitment was restricted to adenocarcinoma, and preliminary results are impressive with respect to survival outcomes. The MRC ST02 trial recruited patients with mixed histology and to

included here because of the high proportion of patients with EAC and information regarding response rates to chemotherapy (Table 2). Effective therapeutic regimens included cisplatin and 5FU based doublets with the exception of the Cunningham (MAGIC) trial, which administered triplet therapy encompassing an anthracycline in addition to cisplatin and 5FU and TAGET 4, which used a taxane based triplet. Most studies administered chemotherapy in the preoperative and postoperative periods, with the exception is the MRC trial, where chemotherapy was administered in the preoperative setting only.

From the standpoint of local control, reflected by R0 resection rates and R0%, all highlighted studies demonstrated a benefit to the addition of chemotherapy to surgery in patients with locally advanced disease. Tebbe et al randomized patients—of whom 77% had mid or lower esophageal or GEJ tumors—to receive perioperative cisplatin and 5FU versus surgery alone. Patients randomized to preoperative therapy demonstrated improved outcomes with respect to R0 resection rate (87% vs 74%, $P = .04$). R0% was similarly improved with 5-year R0% at 38% in the chemotherapy group, versus 14% in patients randomized to surgery alone ($P = .001$). In the study by Cunningham et al, patients with gastric and lower esophageal/GEJ tumors (27%) were randomized to receive perioperative chemotherapy with 5FU, cisplatin, and epirubicin (ECF). In patients receiving perioperative therapy, an improvement in R0 resection rate (chemotherapy vs surgery alone, 79.3% vs 70.2%, $P = .03$) and a tendency for smaller tumors and less advanced nodal disease were noted. This was associated with improved R0% in patients receiving perioperative chemotherapy compared with surgery alone (hazard ratio [HR] for progression, 0.66; 95% confidence interval [CI] 0.53–0.81; $P < .001$). The trial by Kelsen et al (Table 2), which was a mixed histologic study comprised of roughly equal proportions of patients with EAC and ESCC, demonstrated improved R0 resection rate overall after chemotherapy versus surgery alone (79.3% vs 70.2%, respectively, $P = .008$). Although not broken down by histology, the results of this trial support the use of neoadjuvant chemotherapy to potentially facilitate complete resection. In the MRC study and its subsequent follow up (CT02), perioperative administration of cisplatin and 5FU was associated with a significant reduction in primary tumor size and regional lymph node positivity, compared with spontaneous findings in untreated patients. This was associated with improved R0 resection rates in patients subjected to neoadjuvant chemotherapy (69% vs 58%, $P = .001$) and was similarly associated with improved RFS (HR, 0.882; 95% CI, 0.71–0.95; $P = .003$).

The Cunningham trial formed the basis for the recommendation of ECF in patients with operable esophagogastric cancer. Various randomized studies have cast doubt on the utility of 5FU based triplets with anthracyclins; phase II data have suggested that triplets, including 5FU and a platinum agent in conjunction with a taxane, may provide improved treatment response over standard doublet therapies. The results of the phase III RCT by Al Batran et al appear to confirm these findings. The FLOT-4 trial, which has been published to an abstract to date, randomized patients with locally advanced esophagogastric adenocarcinoma to 3 preoperative cycles of ECF versus 4 preoperative cycles of FLOT (docetaxel, oxaliplatin, 5FU, leucovorin). Although R0 resection rates were not reported, R0% was significantly improved in patients receiving FLOT compared with ECF (median R0% 30 months vs 18 months, $P = .004$). These results mirrored the improved response rates observed in the former regimen from the phase II FLOT-3 trial (35% major response, 20% pathologic complete response [pCR]).

Systemic Control

All the randomized trials using chemotherapy in the perioperative setting exclusively in patients with locally advanced EAC have demonstrated improvements in OS compared with surgery alone. For example, in the trial by Tebbe et al, improved OS after 2 preoperative and 2 postoperative cycles of cisplatin and 5FU was noted in the chemotherapy arm compared with surgery alone (5-year survival CS vs surgery alone, 38% vs 24%; $P < .05$). The MRC/OEO2 trial, using the similar regimen, demonstrated analogous findings with improved OS in patients receiving chemotherapy compared with surgery alone (median survival, 16.8 vs 13.2 months; 43% survival at 2 years vs 34%; $P = .004$). Results after the MAGIC trial were similar, demonstrating a significant survival advantage in patients receiving neoadjuvant chemotherapy versus surgery alone (HR, 0.75; 95% CI, 0.6–0.93; $P = .009$; 5-year survival, 36.3% vs 23%). Finally, the FLOT-4 trial demonstrated an improvement in OS commensurate with an improvement in objective response rates to chemotherapy compared with the older MAGIC trial (median OS, 50 months vs 34 months; $P < .012$; 3-year OS, 57% vs 48%).

The mixed histology trial by Kelsen et al is the only negative study with respect to OS using perioperative chemotherapy consisting of 3 cycles of preoperative cisplatin and 5FU. Although the negative results were related to poor response rates to chemotherapy, with only 7% demonstrating a complete clinical response and 12% demonstrating a partial clinical response, on subgroup analysis, those patients who achieved a major response to chemotherapy did demonstrate a significant survival advantage (HR, 2.85; 95% CI, 1.84–4.38; $P < .001$).

Thus, when taken collectively, the results of the randomized studies to date demonstrate that neoadjuvant chemotherapy in patients with locally advanced EAC improves both locoregional and systemic control, as evidenced by improved R0 resection rates, RFS, and OS, respectively. Furthermore, OS is improved in patients who demonstrate greater a response to neoadjuvant therapy. Accordingly, as chemotherapeutic regimens become more effective, a concomitant improvement in outcomes can be expected.

Chemoradiotherapy

The outcome data outlined above demonstrate that systemic chemotherapy is associated with improved outcomes in patients with EAC

TABLE 2 Randomized Mixed Histology Trials Comparing Chemotherapy to Surgery Alone in Patients With Locally Advanced Esophageal Cancer

EAC, Esophageal adenocarcinoma; ESCC, esophageal squamous cell carcinoma; pCR, pathologic complete response; SCC, squamous cell carcinoma.

Medical Research Council Oesophageal Cancer Working. Surgical resection with or without preoperative chemotherapy in oesophageal cancer: a randomised controlled trial. Lancet. 2002;359(9319):1727–1733.

Kelsen DP, et al. Long-term results of RTOG trial 8911 (USA Intergroup 113): a random assignment trial comparison of chemotherapy followed by surgery compared with surgery alone for esophageal cancer. J Clin Oncol. 2007;25:3720–3725.

Furthermore, this improvement, particularly in the context of systemic control, is dependent on the magnitude of the primary tumor's response to preoperative chemotherapy. Response rates, particularly pCR rates on the order of 5% to 10%, have been highlighted as weaknesses of regimens that use chemotherapy alone. Along these lines, CRT regimens have been proposed in part to improve response rates, with the goal of achieving improved disease control, both locally and systemically. What has become clear is that the differential radiosensitivity of EAC and ESCC impacts disease outcome after the application of CRT regimens. Although the addition of radiation to chemotherapy improves pathologic response rates in both histologic subtypes, the benefit in patients with EAC is not as pronounced as in patients with ESCC.

Local Control

To date, only a single positive study examining the utility of CRT exclusively in patients with EAC has been published. The remaining 5 trials included patients with mixed histology and are outlined in Table 1. The Welsh study demonstrated a pCR rate of 25% and a significant down-staging effect, with 42% of patients treated with CRT found to harbor positive lymph nodes at the time of surgery compared with 82% of patients in the surgery-alone arm ($P < .001$).[1]

The CROSS trial is the largest positive trial performed to date comparing neoadjuvant CRT to surgery alone and established it as a standard therapy for both ESCC and EAC in many Western countries. The authors used a slightly different chemotherapeutic approach composed of a weekly regimen of relatively low-dose taxane and carboplatin in conjunction with concurrent radiation at a dose of 41.4 Gy. With respect to local control, a pCR rate of 29% was noted in the adenocarcinoma arm, which is remarkably consistent across studies to date. In fact, the studies by Urba et al, Burmeister et al, and Ilson et al all reported histology specific pCR rates after CRT regimens and found a remarkably consistent pCR rate of 16% to 25% in EAC, suggesting reduced efficacy of radiation in EAC compared with ESCC (see later).

In all the above mentioned trials, R0 resection was achieved in a greater proportion of patients receiving neoadjuvant CRT compared with surgery alone, with the CROSS trial and the trial by Urba et al demonstrating the highest overall rate (92% vs 69% and 96% vs 90% compared with surgery alone, respectively). In the CROSS trial, significantly more patients undergoing surgery alone were found to harbor metastatic lymph nodes compared with patients receiving neoadjuvant CRT (23% vs 11%), despite comparable preoperative clinical staging, suggesting that enhanced resectability was in part due to a primary tumor response to neoadjuvant CRT.

From the standpoint of RFS, the effects of CRT on adenocarcinoma appear less pronounced than what was observed in the chemotherapy alone trials. Histology specific RFS rates were provided in the studies by Burmeister et al and the CROSS trial. Burmeister et al failed to demonstrate any advantage of CRT over surgery alone from the standpoint of RFS. The CROSS trial was a positive study in this regard, with patients with EAC subjected to CRT demonstrating improved RFS compared with patients undergoing surgery

TABLE 1 Randomized Mixed Histology Trials Comparing Chemoradiotherapy to Surgery Alone in Patients With Locally Advanced Esophageal Cancer

alone ($P = .01$). This remained true on long-term follow up; a significant reduction in locoregional recurrence was noted in patients with adenocarcinoma after neoadjuvant CRT compared with surgery alone (27% vs 39%; HR, 0.45; CI, 0.3–0.66; $P = .0001$), thus supporting the locoregional benefit of neoadjuvant CRT.

Systemic Control

Similarly to R0 rates, OS improvement after CRT in trials, including mixed histology GEJ, appear to be driven predominantly by the results in ESCC. The trial by Walsh et al, however, which was performed exclusively in patients with EAC, was a positive study from the standpoint of OS. Patients underwent concurrent 40 Gy radiation, with 2 cycles of cisplatin and 5FU, and median overall survival was 16 months versus 11 months in favor of CRT ($P = .01$). The trial by Burmeister et al was a negative trial from the standpoint of OS, as was the CROSS trial when examining only patients with EAC. In patients with EAC, in fact, there was a trend toward improved survival, which did not achieve statistical significance on multivariate analysis (HR = 0.75 [0.57–1.01]).

The trial by Ruo et al randomized patients to receive 2 cycles of cisplatin and 5FU with concurrent 40 Gy radiation or surgical monotherapy. In patients with EAC, a survival advantage was noted, particularly in patients in whom a pCR was achieved. Overall, mean OS in EAC patients was 27 months compared with 23 months after surgical monotherapy ($P < .0001$). In the 25% of patients in whom a pCR was achieved, mean OS was 42 months, higher, albeit without attaining statistical significance, than the 18 months observed in patients with residual disease. Although not broken down along histologic lines, the study by Urba et al similarly demonstrated significant prolongation of OS in patients who attained a pCR.

When considered collectively, the data regarding CRT in patients with EAC suggest that it is effective at improving R0 resection rates, which may translate into improved RFS. However, this is dependent to some extent on the ability to achieve a pCR, which is reduced in EAC compared with ESCC when looking at the same therapeutic regimen.

MULTIMODAL TREATMENT IN ESOPHAGEAL SQUAMOUS CELL CARCINOMA

Chemotherapy Alone

The rationale for the application of chemotherapy alone to patients with locally advanced ESCC is the same as in patients with EAC, namely, to facilitate complete resection and improve both RFS and OS. To this end, chemotherapy has demonstrated a benefit in patients with ESCC. However, as with EAC, the magnitude of this benefit is related to the magnitude of the response to therapy. Given the enhanced radiosensitivity of ESCC, regimens involving the addition of radiotherapy are most frequently used today.

Locoregional Control

To date, 8 RCTs have been published evaluating perioperative chemotherapy versus surgery alone in patients with ESCC (Table 4). These include the studies by Roth et al, Schlag et al, Law et al, Burmeister et al, Ancona et al, and all three trials by Ando et al. From the standpoint of locoregional control, the data strongly support the notion that neoadjuvant chemotherapy offers some benefit compared with surgery alone. In particular, a neoadjuvant regimen comprising 5FU and cisplatin, which improves R0 resection rates, is associated with significant locoregional down-staging and improved RFS after resection compared with surgery alone.

One of the earlier studies to highlight the local benefit of neoadjuvant chemotherapy in patients with ESCC was conducted by Law et al. Thirteen, 147 patients with esophageal SCC were randomized to receive either 2 preoperative cycles of cisplatin and 5FU, followed by curative intent surgery or upfront surgery alone. The authors found that, in patients who completed preoperative chemotherapy, a curative resection was more likely (R0 resection 67% vs 35%; $P = .0031$). Furthermore, resected tumors from patients subjected to preoperative treatment were significantly smaller and harbored fewer metastatic lymph nodes than those from patients who proceeded immediately to surgery. This is in keeping with the response rates observed with this doublet regimen, which were 38% with a pCR rate of 5%. Accordingly, significantly fewer local recurrences occurred in patients randomized to preoperative chemotherapy (local recurrence 13% after chemotherapy vs 30.8% after surgery alone; $P = .01$).

Similarly, in the 2012 study by Ando et al, patients with SCC underwent 2 cycles of cisplatin and 5FU in either the adjuvant or neoadjuvant setting. Patients who received neoadjuvant chemotherapy demonstrated increased R0 resection rates, compared with patients who received upfront surgery (90% vs 81%; $P = .04$). Along these lines, there was a trend toward improved RFS, supporting the notion that enhanced resectability is associated with improved locoregional control. The overall response rate to chemotherapy in this study was 38%, with a pCR rate of 7%. Finally, the positive study by Ruotsalo et al demonstrated a consistent pCR rate of 7% and major response rate of 30% after administration of a neoadjuvant doublet regimen consisting of cisplatin and etoposide. This was associated with a significantly improved R0 resection rate (from 54% in the surgery alone group compared with 73% in patients who received chemotherapy. This translated to improved RFS at 6 months (55% vs 10%; $P = .05$) in patients who underwent preoperative chemotherapy versus surgery alone, respectively.

Collectively, the data demonstrate pCR rates on the order of 5% to 10%, with improved response rates with cisplatin doublets (about 25% to 30%). Based on the randomized evidence to date, chemotherapy improves R0 resection rates and RFS.

Systemic Control

In the study by Roth et al, survival in patients who demonstrated a major (47%) or complete (3%) response to vinblastine-, cisplatin-, and bleomycin-based chemotherapy exhibited improved survival (median survival 20 months vs 6 months; $P = .0001$), compared with patients who did not. Thus, as expected, patients who demonstrate a response to neoadjuvant chemotherapy demonstrate improved outcomes. Schlag et al similarly showed significant increase in survival for patients with ESCC who demonstrated a response (12% minor, 32% major, 6% complete) to 3 cycles of neoadjuvant cisplatin and 5FU compared with surgery alone. In patients who demonstrated a response to chemotherapy, median and 2-year survival times were improved (CT vs surgery 42.5 months vs 13.8 months; $P = .008$, and 59% vs 33%, respectively). In the study by Ancona et al, the overall survival rate was improved only in the 40% of patients who demonstrated a major response to chemotherapy. In the chemotherapy group, median and 3- and 5-year survival was improved compared with patients undergoing surgery alone (33 months, 38%, 60%, vs 20 months, 6%, 26%, respectively; $P = .01$) and nonresponders to chemotherapy (19 months, 30%, 19%, respectively; $P < .05$). In keeping with this theme, the survival benefit was most pronounced in the 12.8% of patients who demonstrated a complete response. Ruotsalo et al demonstrated a partial response rate of 40% and complete response rate of 7% after neoadjuvant chemotherapy. A significant survival advantage in patients receiving chemotherapy was noted (median and 2- and 5-year survival vs surgery alone: 16 months vs 12 months, 42% vs 30%, and 26% vs 17%; $P = .03$, respectively) and was attributed to the fact that a greater proportion of chemotherapy-treated patients was ultimately found to harbor resectable tumors.

The question about whether chemotherapy should be administered before or after surgery in patients with SCC has specifically been addressed in randomized studies. The rationale for its perioperative administration is that it can be delivered to a tumor with an intact blood supply, thus facilitating drug delivery, tumor response can be assessed in real time, and patients may be more likely to receive their chemotherapy before a prolonged decline in functional status after surgery. Advantages to adjuvant administration include avoidance of

therapy in patients who do not require it, while avoiding unnecessary delays to surgery. With respect to the latter concern, randomized data support the notion that a multimodal approach is associated with increased harm to patients with early stage resectable disease, highlighting the importance of meticulous staging. Current data support increased efficacy of chemotherapy when administered in the neoadjuvant setting. In 2003, Ando and colleagues published a Japan Clinical Oncology Group multiinstitutional phase III trial investigating postoperative cisplatin and 5FU in patients with completely resected squamous cell carcinoma versus surgery alone. This positive study led to a follow-up study, which compared the same regimen given either before or after surgery. Preoperative versus postoperative chemotherapy was directly compared with surgery alone and highlighted the superiority of the former over the latter. In addition to providing the local benefits associated with neoadjuvant therapy, OS was significantly improved in patients who received preoperative compared with postoperative therapy with 5-year survival rate of 55% versus 43% ($P = .04$).

When collectively assessed, the randomized data published thus far demonstrate that, in patients with ESCC, survival outcomes are improved in patients who demonstrate a response to neoadjuvant chemotherapy. Furthermore, the magnitude of the benefit is related to the magnitude of the response. Thus patients who demonstrate a robust response to neoadjuvant chemotherapy are more likely to derive a substantial survival benefit, with patients who achieve a pCR demonstrating the best survival outcomes overall. This finding is at the heart of why CRT regimens have been adopted, because these regimens, particularly in patients with ESCC, are more frequently associated with a pCR compared with regimens consisting of chemotherapy alone.

Chemoradiation Therapy

Local Control

To date, five RCTs have been conducted exclusively in patients with ESCC comparing neoadjuvant chemoradiation therapy to surgery alone. The studies by Nygaard et al, Le Prise et al, Bosset et al, Cao et al, and Ly et al are outlined in Table 5. As with neoadjuvant chemotherapy, improved local control has consistently been reported, although response rates after CRT are significantly higher than what is observed with chemotherapy. Overall, pCR rates ranged between 10% to 56% across the trials mentioned. The mixed histology studies conducted by Urba et al, Burmeister et al, Van Hagen et al, and Stahl et al (Table 3) all demonstrate pCR rates ranging between 27% to 49%. In fact, the trial by Burmeister et al, which demonstrated the lowest pCR rate of the mixed histology studies at 27%, used a low dose of radiation at 36 Gy in conjunction with concurrent cisplatin and 5FU. This contrasts with other studies using 40 Gy and above and formed the basis of some of the criticisms of this negative study, given the much higher pCR rates ranging between 30% to 49% observed in the other trials. These results demonstrate significantly higher local response rates compared with a pCR rate of 15% to 20% observed in patients with EAC. Not surprisingly, the addition of radiation to perioperative multimodal regimens in patients with ESCC is associated with improved R0 resection rates.

Nygaard et al, Bosset et al, Cao et al, and Ly et al were all able to demonstrate R0 resection rates ranging between 52% to 97.6% after neoadjuvant CRT. When considering the contemporary studies by Cao et al and Ly et al, multimodal therapy was associated with R0 rates of more than 90%. In the study by Cao et al, the addition of 40 Gy to triplet induction chemotherapy consisting of cisplatin, 5FU, and mitomycin was associated with an improvement in R0 resection rates to 95.2% versus 84.6% after triplet induction chemotherapy alone, thus further supporting the utility of radiation therapy in local control in ESCC.

Additional evidence of improved locoregional control in patients with ESCC patients can be further inferred from the results of the studies by Tepper et al, Bosset et al, and Le Prise et al. Both Tepper et al and Le Prise et al demonstrated a reduction in T3 and T4 tumors in patients treated with neoadjuvant CRT compared with those subjected to surgery alone. In the trial by Tepper et al, this translated to improved RFS at 5 years (28% vs 15%, $P < .05$, respectively). In addition, Bosset et al demonstrated a reduction in N+ disease in patients with ESCC after neoadjuvant RT on the order of 50%, which significantly increased RFS compared with surgery alone (HR local recurrence, 0.6; 95% CI, 0.4–0.9; $P = .04$).

As previously stated, the addition of radiation therapy to multimodal regimens appears to be particularly effective in patients with

ESCC compared with EAC. This is apparent in some of the noted histology studies, in which results are broken down according to histology. For example, the CROSS trial, in keeping with improved pCR in ESCC compared with EAC, demonstrated a significant improvement in RFS in patients with squamous histology. Median RFS was 74.7 months in the CRT group compared with 11.6 months in the surgery alone group. Similarly, even in the negative study by Burmeister et al, RFS was significantly improved in patients with ESCC after CRT versus surgery alone (HR, 0.45; 95% CI, 0.25–0.8; $P = .0018$). Thus, when viewed collectively, the data support the addition of radiation therapy to multimodal regimens in patients with squamous histology from the standpoint of locoregional control.

Systemic Control

Neoadjuvant CRT regimens in patients with ESCC have demonstrated efficacy with respect to long-term survival outcomes. All trials listed on Table 5, with the exception of those by Le Prise et al and Nossert et al, have demonstrated a survival benefit on the order of 15% at 3 to 5 years. The two negative trials used very low doses of radiation (18.5–20 Gy), which may have limited their efficacy.

The mixed histologic trials outlined in Table 5 similarly yield valuable information when trying to ascertain the efficacy of neoadjuvant CRT in patients with ESCC from the standpoint of overall survival. The trials by Urba et al and Burmeister et al were negative trials but did demonstrate superior responses to neoadjuvant CRT in patients with ESCC compared with EAC. The trial by Tepper et al was a positive study. Although results were not broken down according to histologic study, the survival difference between the two groups was striking (5-year OS 47% vs 34% in favor of neoadjuvant 5FU, cisplatin, and concurrent 50.4 Gy; $P = .003$). In keeping with the observation that radiation performs particularly well in patients with ESCC, the CROSS trial demonstrated median OS of 81.6 months compared with 21.1 months ($P = .003$) in patients who received neoadjuvant CRT compared with patients who did not, respectively. As previously stated, this was associated with a pCR rate of 49% in patients with ESCC. These results are similar to those of Ilson et al, wherein patients who achieved a pCR exhibited significant improvements in OS compared with patients who underwent upfront surgery (mean OS 61.2 months vs 42.0 months, respectively; $P = .033$). This improvement was not observed in patients who demonstrated residual disease after neoadjuvant CRT. Although this was true for patients with EAC as well, what is notable in this study is the difference in pCR rates between the two histologic entities, with 25% of patients with EAC achieving a pCR compared with 51% of patients with ESCC. Thus, when taken collectively, the magnitude of the response to neoadjuvant CT is predictive of OS outcomes. Furthermore, those patients who achieve a pCR reap the greatest benefit with regard to survival outcomes.

CONCLUSIONS

Patients with locally advanced esophageal carcinoma require a multimodal approach if favorable survival outcomes are to be achieved. However, the two major histologic subtypes represent different entities and specific consideration should be entertained when treating EC. Patients with ESCC present with more proximal tumors, and these tumors demonstrate a proclivity for early locoregional spread and early locoregional recurrence. These tumors are particularly radiosensitive and exhibit dramatic response to concurrent platinum based doublet chemotherapy and external beam radiation. This permits pCR rates on the order of 50%, which, when they occur, are predictive of improved survival outcomes. Patients with EAC tend to present with very distally located tumors and a more resistant response to radiation therapy. Despite changes to concurrent chemoradiation protocols, pCR rates remain stable, on the order of 20% to 25%. Furthermore, the patterns of spread inherent to these tumors are characterized by early distant dissemination and the establishment of distant metastasis. Accordingly, local therapies have demonstrated a more modest effect on overall survival outcomes. Emphasis on effective systemic chemotherapy early in the disease course has been marked with improvements in overall survival. These differences highlight the importance of adopting a targeted approach to the management of EC, taking into consideration a number of factors before application of a given regimen. In this manner, improved outcomes in this vulnerable patient population can be achieved.

USE OF ESOPHAGEAL STENTS

Nadeige Fadiche, MD, Arthur J. Garner, MD, MPH, Teresa A. Teo, MD, and Malcolm V. Lewis, MD, FACS

First described by French surgeon Leroy D'Etiolles in 1845, esophageal stenting was, at its inception, reserved mainly for the palliation of severe dysphagia in advanced esophageal cancer (EC). Over the years, the use of esophageal stent has steadily increased with an expansion of its indications to include benign disease. Improvement in stent design, endoscopic techniques, and complication rates have made it an attractive therapeutic option for patients with either mechanical or functional dysphagia, perforations, leaks, or fistulas.

Esophageal stenting generally has one of two main goals: (1) to maintain luminal patency and relieve severe dysphagia in the setting of benign or malignant strictures; and (2) to stem off potentially fatal luminal contamination of the mediastinum. For patients with sometimes debilitating disease, esophageal stenting offers the prospect of improved oral intake, symptomatic relief of dysphagia or aspiration, and the avoidance of morbid surgical interventions.

This chapter reviews the evolution of esophageal stenting, currently available stents, most current indications for esophageal stenting, stent placement techniques, and complications.

STENTS THROUGH THE AGES

D'Etiolles' stents, which were made of decalcified ivory, were unfortunately unsuccessful. Over the next 4 decades, several attempts by the likes of Sir Morrell Mackenzie in England yielded similarly disappointing results. The first successful esophageal stent was designed

ESCC compared with EAC. This is apparent in some of the noted histology studies, in which results are broken down according to histology. For example, the CROSS trial, in keeping with improved pCR in ESCC compared with EAC, demonstrated a significant improvement in RFS in patients with squamous histology. USE OF ESOPHAGEAL STENTS

Nadege T. Faithche, MD, Matthew Garner, MD, MPH, Tomoaki Ito, MD, and Malcolm V. Brock, MD, FACS

First described by French surgeon Ulrey Dilloffes in 1845, esophageal stenting was, at its inception, reserved mainly for the palliation of severe dysphagia in advanced esophageal cancer (EC). Over the years, the use of esophageal stent has steadily increased with an expansion of its indications to include benign disease. Improvement in stent design, endoscopic techniques, and complication rates have made it an attractive therapeutic option for patients with either mechanical or functional dysphagia, perforations, leaks, or fistulas.

Esophageal stenting generally has one of two main goals: (1) to maintain luminal patency and relieve severe dysphagia in the setting of benign or malignant strictures; and (2) to seal off potentially fatal luminal contamination of the mediastinum. For patients with sometimes debilitating disease, esophageal stenting offers the prospect of improved oral intake, symptomatic relief of dysphagia or aspiration, and the avoidance of morbid surgical interventions.

This chapter reviews the evolution of esophageal stenting, currently available stents, most current indications for esophageal stenting, stent placement techniques, and complications.

STENTS THROUGH THE AGES

Dilloffes' stents, which were made of decalcified ivory, were unfortunately unsuccessful. Over the next 4 decades, several attempts by the likes of Sir Morrell Mackenzie in England yielded similarly disappointing results. The first successful esophageal stent was designed

by Sir Charters Symonds in 1885. Symonds' stent, which was initially inserted, featured an esophageal tube affixed to a hogwood frame by a silver wire and was secured to the ear by a silk thread passing through the mouth or nose. Over the next decades, as interest in plastic polymers grew, stent design evolved. The first stents widely used in the esophagus were constructed from silicon rubber. These early stents were inserted with the assistance of a rigid esophagoscope but had a high rate of stent misplacement and migration. In the late 1950s, Celestin successfully palliated a malignant esophageal stricture using a plastic stent inserted via an open gastrostomy. The next few years would see an evolution in stent placement techniques as endoscopic tools evolved. In the 1970s, Atkinson introduced an endoscopically inserted plastic prosthesis. Unfortunately, a significant drawback of the Atkinson stent was its small internal diameter, which proved rate limiting when patients resumed a regular diet. High complication rates plagued many of these early plastic endoprostheses. Because of their rigidity and fixed internal as well as external diameters, most stents required endoscopic dilation, which invariably led to perforations. Additionally their inability to conform naturally to the structural morphology caused frequent stent migrations requiring intervention. In 1985, the modern era of esophageal stent innovation was ushered in when Ishibiger published the first description of the endoscopic placement of a self-expanding metal stent (SEMS) for a patient with a malignant esophageal stricture. In the 1990s, SEMS grew in popularity, in part fueled by the results of a series of trials conducted by Kozarek et al., which demonstrated that SEMS had higher patency rates, successful placement rates, and a better safety profile than available rigid plastic endoprostheses. Over the next few years, stent design and materials would continue to evolve. The modern esophageal stent is self-expanding and made of either plastic, Nitinol (a metal alloy), or biodegradable material. It may also come fully or partially covered. Table 1 reviews currently available stents and their characteristics.

STENT SELECTION

Selecting the appropriate stent for a given lesion, a critical step in preprocedural planning and a significant determinant of outcome, requires an understanding of the mechanical and physical properties of the various stents available (Fig. 1).

FIG. 1 Self-expanding metal stent.

The majority of SEMS are made of Nitinol, a nickel titanium alloy, that has super elasticity and shape memory. This property allows a metal's shape to be easily modulated by small temperature variations, but there is also a spontaneous return to the original shape when the temperature is outside of the transformative range. These unique characteristics are exploited in SEMS as they expand at body temperature to fit the morphology of a given lesion. Nitinol is also

resistant to corrosion and hypoallergenic. Although biologically inert, it triggers a mild inflammatory response with resulting fibrosis that is useful in reducing stent migration. Unfortunately, this same property can be a major drawback of uncovered SEMS, fostering stent stenosis by allowing fibrotic tissue regrowth through the openings in the mesh material. To counter this phenomenon, fully covered and partially covered stents were developed. These stents feature proximal and distal cuffs that remain bare and uncovered to provide additional luminal anchorage. Covered stents are believed to have less tumor ingrowth, but can potentially be more susceptible to stent migration, especially in high risk areas such as at the distal esophagus.

Self expandable plastic stents (SEPS) are double layered, featuring polyester mesh on their external surface with an embedded silicon inner lining creating a smooth inner surface. To prevent migration, flared distal and proximal ends facilitate luminal anchorage. Considering that their internal diameter tends to decrease under tension, SEPS are easily retrieved endoscopically, making them ideal for short term stenting.

Introduced in the mid 2000s, biodegradable stents (BDS) are mainly used in the setting of benign strictures, as they negate the need for retrieval. These are made of plated polydioxanone, a monofilament, which undergoes hydrolytic degradation over 8 to 12 weeks. These maintain their mechanical strength for 4 to 6 weeks.

PATIENT SELECTION

Careful clinical evaluation and characterization of the lesion of interest are necessary to optimize clinical outcome in patients receiving esophageal stenting. Baseline assessment of dysphagia, nutritional status, and quality of life (QOL) will provide a reference point from which the efficacy of the intervention can be measured. The Dysphagia Scoring Scale by Ogilvie et al. (Table 2) is a simple and effective tool to assess dysphagia in patients with strictures. Combining radiographic modalities such as esophagram, positron emission tomography computed tomography, and endoscopy can provide invaluable information about the lesion's location, size, morphology, and relationship to adjacent intrinsic structures, and thus inform stent selection.

INDICATIONS

The Food and Drug Administration (FDA) has approved esophageal stenting for the preservation of luminal patency in the setting of intrinsic or extrinsic malignant strictures, and the occlusion of concurrent esophageal fistula. In practice, however, the list of lesions amenable to esophageal stenting has increased, owing to better stent design, improved safety profile, and sophisticated endoscopic techniques. In the United States and other developed nations, stenting for malignant esophageal strictures has decreased because of improved outcomes with single dose brachytherapy. Conversely, esophageal stenting for the management of various benign conditions, such as refractory benign esophageal strictures (RBES), esophageal perforations, variceal bleeding, postsurgical anastomotic leaks, and achalasia has increased by over 50% in the past decade.

TABLE 2 Dysphagia Scoring Scale

Class	Dysphagia Scoring Scale
0	Able to consume normal diet
1	Dysphagia with certain solid foods
2	Able to swallow semisolid foods
3	Able to swallow liquids only
4	Unable to swallow saliva (complete dysphagia)

Data from Ogilvie AL, Dronfield MW, Ferguson R, Atkinson M. Palliative endoscopic management of oesophagogastric neoplasms at thoracoscopy. Gut. 1993;34:1163–1167.

Malignant Esophageal Disease

Malignant Esophageal Strictures

Malignant esophageal dysphagia results from luminal narrowing either by intraluminal growth of primary esophageal tumors, or by extrinsic compression from mediastinal and airway tract neoplasms. Primary HC remains one of the most lethal cancers of the aerodigestive tract. Because of its insidious course, clinically apparent disease is typically synonymous with advanced stage. In these patients, relief of dysphagia and resumption of oral intake provides an invaluable improvement in QOL, and in some cases, survival prospects. Since its inception, esophageal stenting has been regarded as the first line therapy for the palliation of malignant dysphagia. SEMS provides prompt relief and the opportunity to optimize patients' nutritional status. Interest in regionally targeted radiation modalities such as brachytherapy has transformed the clinical approach to malignant dysphagia. A randomized controlled trial (RCT) comparing SEMS to single dose brachytherapy demonstrated that although stenting resulted in earlier relief of dysphagia, brachytherapy provided longer lasting relief, higher QOL scores, and significantly less morbidity, as evidenced by a rate of major complication of 12% compared to 25% for SEMS. Despite these findings, the initial enthusiasm for brachytherapy is fading due to frequently noted need to insert rescue stents. Brachytherapy may be considered for carefully selected patients with mild to moderate dysphagia who have a longer life expectancy. Esophageal stenting thus remains the first line of intervention for patients with moderate to severe dysphagia who are not candidates for other modalities or patients with recurrent dysphagia after brachytherapy. Fully covered SEMS (fcSEMS) are the stents of choice for the management of malignant strictures. In recent studies, these have demonstrated a lower rate of tumor ingrowth compared with uncovered SEMS and a lower risk of stent migration when compared with covered SEPS. Although there is no difference in outcomes between fcSEMS and partially covered SEMS (pcSEMS), the latter is often subject to tumor ingrowth at its uncovered distal and proximal ends, thus making for challenging endoscopic retrieval.

Malignant Esophageal Fistulas

Malignant esophageal fistulas result primarily from esophageal tumor infiltration into surrounding structures, such as the trachea, mediastinum, pleura, and proximal abdominal cavity and less commonly from extrinsic infiltration of respiratory tract tumors, or cholecystoduodenal tumor necrosis. Regardless of the mechanism, temporary suspension of oral intake, drainage of involved spaces, and endoscopic insertion of an fcSEMS are frequently recommended. Currently, successful fistula closure rates are over 70%, and recent evidence suggests a modest survival advantage once closure is achieved. The early appeal of concurrent stenting of the tracheobronchial tract (Fig. 7), or "dual stenting," has been largely overshadowed by a higher risk of highly lethal pulmonary and vascular erosions due to aggressive pressure necrosis. Despite the scarcity of data available regarding the most appropriate stent for malignant fistulas, fcSEMS are the modality of choice by consensus.

Gastroesophageal Junction Tumors

Palliation of gastroesophageal junction (GEJ) strictures by endoscopic means is technically challenging, owing to intrinsic anatomic peculiarities. Unlike the upper and middle esophagus, the GEJ features an acute angle and varying luminal diameters, which may interfere with satisfactory stent fixation. Esophageal stenting at this location is frequently associated with an increased risk of acid reflux, distal migration, and ineffective palliation. The higher rate of complications is often compounded by the overall poorer survival ascribed to GEJ tumors and has long been a basis for an argument against stenting of these lesions. In clinical practice, pcSEMS are considered the stent of choice for GEJ strictures, as their flare ends allow for better anchorage

The introduction of modified ESEMS featuring progressive flaring of the distal end (anchoring lumen to the gastric opening) and one-way reflux valves at the distal end theoretically favors improved treatment of GJO lesions. A recent RCT by Persson et al. comparing modified ESEMS with pcSEMS in 95 patients with malignant GJO strictures showed no difference in stent migrations, although there was a trend toward better relief of dysphagia with ESEMS.

Bridge to Surgery

Preoperative esophageal stenting in patients with locally advanced EC undergoing neoadjuvant therapy may allow for nutritional optimization before surgical resection. Although several small studies have demonstrated improved oral intake, weight stabilization, and QOL when SEMS, SEPS, or BDS were used as a bridge to surgery in a neoadjuvant setting, a retrospective study by Markakis et al. reported worse oncologic outcomes with SEMS. A lower rate of complete resection (71.0% vs 85.3%; $P = .041$), shorter disease free interval (6.5 vs 9.0 months; $P = .040$), and worse 3-year overall survival (25% vs 48%; $P = .023$) were noted in the preoperative SEMS group. One possible explanation resides in the fact that SEMS-induced mural inflammation may distort the tissue planes and interfere with the complete rate of resection. There is currently no evidence regarding oncologic outcomes with preoperative stenting during neoadjuvant therapy for SEPS and BDS. Of note, although stent migration rates in this setting are upward to 50%, they may represent a favorable response to neoadjuvant therapy.

Benign Esophageal Disease

Benign Refractory Esophageal Strictures

The mainstay in the treatment of benign esophageal strictures is peri-orifice endoscopic balloon dilation. However, for a subset of patients, dysphagia will persist despite repeated dilation, thus requiring more aggressive interventions. BSEMS are most commonly encountered after caustic injuries, radiation to the chest or mediastinum, postsurgically after esophagogastric anastomosis, or after endoscopic interventions such as per oral endoscopic myotomy and endoscopic mucosal resection. Although no study has, to date, evaluated the impact of dilation time on outcomes, proponents of temporary stenting for BSEMS purport that continued radial pressure on the esophageal lumen may result in sustained luminal patency. The challenge in selecting a stenting modality for BSEMS resides in the transient nature of the intervention. The ideal stent needs to be easily retrievable, and yet resistant to migration. To this end, ESEMS are the most commonly used. Although initially showing great efficacy, Polyflex, the only FDA-approved SEPS for BSEMS was discontinued in the United States owing to a disappointing safety profile. Its insertion resulted in migration rates up to 50% and a rate of severe stent-related complication nearing 25%. There are currently no RCTs evaluating outcomes for various stent designs in the management of BSEMS. A recent meta-analysis by Thomas et al. examined the performance of ESEMS in 199 patients with BSEMS. The efficacy of ESEMS for palliation was 86.2% with a migration rate of 24.4% and a successful retrieval rate of 87%. BDS has shown similar efficacy to ESEMS and has the added advantage of not requiring retrieval. However, BDS has a higher rate of stent-related complications such as retrosternal pain and bleeding. In brief, esophageal stenting with either ESEMS or BDS is an intervention of last resort in benign esophageal strictures, reserved for carefully selected patients with BSEMS.

Benign Perforations, Anastomotic Leaks, and Fistulas

Benign esophageal perforations (BEP) can be classified as spontaneous, such as in Boerhaave's syndrome, iatrogenic or traumatic. As for fistulas, contamination of surrounding mediastinal or pleural spaces by esophageal luminal contents can have dire consequences, triggering highly lethal inflammation and infection. For the practicing surgeon, early determination of the etiology and severity of the leakage is crucial, as these considerations will guide therapeutic management and determine outcomes. A contained perforation or anastomotic leak in an otherwise clinically stable patient may be successfully treated with conservative measures. In these patients, nil per os, intravenous hydration, nasogastric drainage, and broad-spectrum antibiotics are the mainstays of therapy. In patients with noncontained leaks, esophageal stenting may allay the potential morbidity of surgical intervention and is now increasingly used (Figs. 3 and 4). As with traditional surgical approaches, the goal of therapy in using stents in these patients remains complete drainage of the contaminated spaces, successful sealing of the leak, possible diversion of oral secretions, and prevention of widespread infection. In a recent meta-analysis comparing SEMS to surgical intervention in patients with esophageal leakage, Persson et al. reported a higher success rate (88% vs 8%)

FIG. 3 Left to right: Self-expandable plastic stent, partially covered self-expanding metal stent (SEMS), and "all-age" fully covered SEMS. Early removal SEMS.

FIG. 4 Acquired tracheoesophageal fistula. (Courtesy Dr. Richard K. Freeman, MD.)

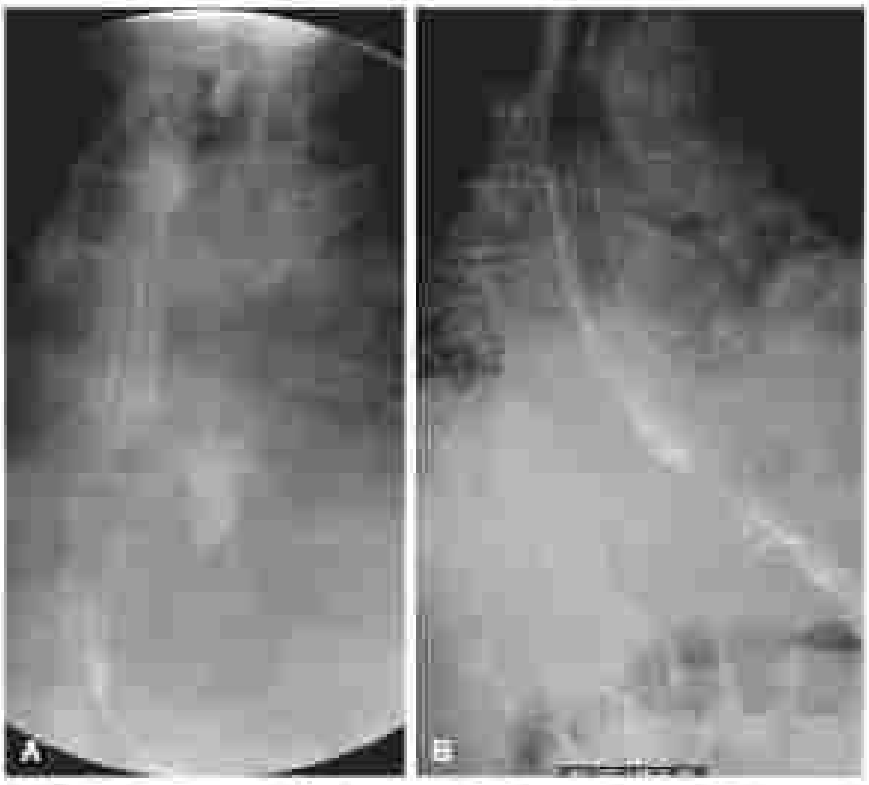

FIG. 4 (A) Upper gastrointestinal (GI) series with water-soluble oral contrast medium demonstrating contralateral conveyance of contrast medium from the left side of the esophagus approximately 2 cm below the level of the cervical constriction, with esophageal perforation. (B) Repeat upper GI series with water-soluble oral contrast medium in the same patient as in Fig. 4A demonstrates a distal esophageal stent in good position, there is no evidence of contrast medium extravasation to suggest a persistent leak.

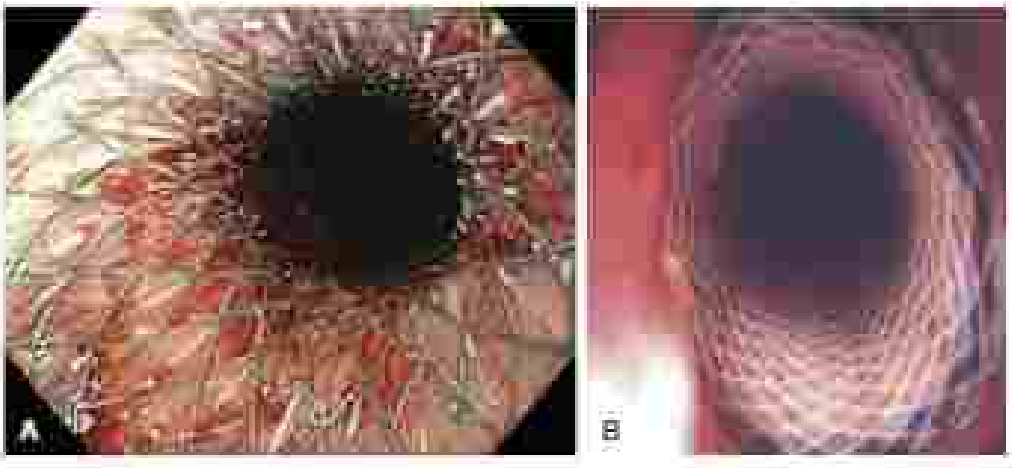

FIG. 5 Endoscopic view of duplicate self-expanding metal stent (A) and self-expands in plastic stent (B).

and a lower mortality rate (7.5% vs 17%) when SEMS were used. We recommend the use of covered stents—either ASEMS or pcSEMS—for the management of hemodynamically stable patients with SEP. Concurrent drainage of the involved space, broad-systemic antibiotic therapy, intravenous fluid administration, and temporary diversion of oral secretions are often employed to optimize clinical outcomes.

Achalasia

The role of esophageal stenting in the treatment of achalasia is evolving. Over the last 3 decades, the introduction of temporary stenting using retrievable SEMS has renewed interest in this modality. In 2018, a long-term follow-up of a prospective comparison of pneumatic dilation and SEMS of various diameter in 120 patients with achalasia showed a higher clinical remission rate at 15 years (83.3% vs 9) when 30-mm SEMS were used compared to pneumatic dilation. Although surgical and endoscopic interventions such as Heller myotomy and per oral endoscopic myotomy are the mainstays of definitive therapy for achalasia, temporary retrievable stenting with SEMS may be an option for the surgically unfit patient (Fig. 5).

PROCEDURE

Meticulous planning is necessary when considering esophageal stenting. Although both conscious sedation and general anesthesia are

comparable, the latter would best serve a patient at high risk for aspiration. Preprocedural endoscopic evaluation of the lesion should be comprehensive. The luminal diameter, location, and size of the lesion of interest must be carefully assessed and documented. Evaluating the friability of the luminal tissue is equally as important, as it could portend a greater risk than usual of bleeding, pressure necrosis, or mural erosion after the procedure. Endoscopic debridement of the lesion is no longer routinely performed but could be considered for the small subset of patients in whom the severity of the stenosis might prevent stent insertion. Particular attention should be paid to stent size. The internal diameter of the stent should be slightly larger than the lesion of interest, thus allowing for adequate radial force to be applied. An inadequately small stent diameter may increase the risk of migration, whereas an oversized stent may lead to perforation and excessive pressure necrosis. The length of a stent should be at least 4 cm longer than that of the lesion, overlapping it both proximally and distally by at least 2 cm. Esophageal stenting can be achieved using either fluoroscopic or endoscopic guidance. We use a Seldinger technique to advance a guidewire endoscopically into the esophagus 2 to 3 cm past the distal end of the lesion. Next, the endoscope is removed, and the stent delivery system is advanced over the guidewire. The endoscope is then reinserted, and the stent positioned and deployed under direct visualization. Caution should be used to ensure that the stent is not fully deployed until satisfactory positioning has been achieved. Using fluoroscopy, the guidewire is inserted using a catheter. Once a satisfactory position has been secured, a small amount of water soluble contrast medium is injected through the catheter to delineate the structure. Radiopaque markers are then used to delineate the location and length of the structure on the patient's skin. Next, after the catheter is removed, the delivery system is advanced over the guidewire and the stent is deployed under continuous fluoroscopic monitoring. Repeat endoscopy or an upper gastrointestinal series 24 to 36 hours postdeployment is often performed before the resumption of oral intake is permitted.

COMPLICATIONS

Close to 30% of patients undergoing an esophageal stent placement experience complications (Table 3). These events are often classified as early or late (Table 4). Events of mild to moderate severity such as retrosternal pain or reflux symptoms typically resolve within 1 or 2 weeks postprocedure. Persistence of retrosternal pain beyond 2 weeks may indicate the need for endoscopic removal of the stent. Recent studies have shown improvement of reflux symptoms with the use of stents equipped with a distal reflux valve, especially in patients with GOJ lesions. Tumor ingrowth is most commonly seen with uncovered or partially covered stents, but now can be successfully managed with a stent-in-stent technique (Fig. 6). This chapter focuses on the major complications of stent migration and vascular and aerodigestive erosions.

Tissue Erosion

Stent erosion into neighboring mediastinal structures such as the big vessels and the airway is rare but highly lethal when it occurs. Tissue necrosis resulting from high radial pressure exerted on the esophageal wall is often compounded by poor tissue perfusion and impaired wound healing secondary to malnutrition or radiation exposure. Indeed, a history of radiation to the chest or mediastinum increases the risk of tissue erosion up to tenfold. Similarly, distal stenting of the esophageal and tracheal is also associated with an increased risk of tissue erosion.

Vascular Erosion

Vascular erosion is rare but highly lethal. Although aortoesophageal fistula is perhaps the most common, vascular erosion involving the retroesophageal subclavian and common carotid arteries have been reported. One must always have a high degree of suspicion as to its possibility. For example, an abrupt sentinel hematemesis associated with retrosternal chest pain in a patient with a history of esophageal stent placement should prompt immediate evaluation and intervention before a potential catastrophic exsanguination. Emergent management of an aortoesophageal fistula involves prompt control of the potentially fatal hemorrhage, followed by timely vascular repair (Fig. 7). Concurrent activation of the massive transfusion protocol and airway protection may be necessary. In such an emergent setting, endoscopic balloons can often be used to control the bleed, and stent surgeons have even successfully used Sengstaken-Blakemore tubes for this purpose. Temporary intravascular occlusion and emergent surgery are also options. Once control is obtained, it can be followed with endovascular repair of the aortic defect. After the patient is stabilized, attention can then be turned to the esophageal defect. Following removal of the offending stent, a small defect may be primarily repaired with muscle interposition. An esophagectomy may be necessary for larger defects. Alternatively, in moribund patients, a conservative approach involving diversion of esophageal contents and palliative care may be more appropriate.

TABLE 3 Overview of Adverse Events Related to Esophageal Stent Placement for Different Indications

Complications	Malignant Dysphagia (n = 1017)	Benign Dysphagia (n = 73)	Esophageal Leakage (n = 339)
SERIOUS ADVERSE EVENT (%)			
Major bleeding	8.0	3.0	1.3
Aspiration pneumonia	5.0	1.5	10.7
Perforation	2.0	1.5	1.8
ADVERSE EVENTS (%)			
Retrosternal pain	30.0	6.5	8.5
Reflux symptoms	7.0	2.6	8.5
Recurrent dysphagia: case	31.0	26.0	20.0
Stent migration	11.0	21.5	16.5
Tissue ingrowth/ overgrowth	14.0	2.3	2.7
Food obstruction	7.0	2.3	1.1

Aerodigestive Erosion

Tracheoesophageal erosions have been reported in 6% to 9% of patients after esophageal stenting (Fig. 8). Unlike the dramatic presentation seen with vascular erosion, patients often present with nonspecific symptoms such as dyspnea and frequent pulmonary infections. Although a chest computed tomography scan may help identify the lesion of interest, bronchoscopic and endoscopic evaluations are often necessary to characterize the extent and size of the defect. The management of tracheoesophageal fistulas depends on the patient's hemodynamic status and on the underlying pathology that led to esophageal stricture. In a patient that presents in extremis, securing the airway must be the priority. One should maintain spontaneous ventilation if possible, but the patient should be promptly intubated if there is an inability to ventilate. A variety of intubation methods can be used if ventilation is difficult including controlled exposure intubation, use of a double lumen tube, employing a bronchial blocker, or isolating the patient to ventilate. In some cases, tracheal stenting and esophageal diversion may be needed, and definitive management may be delayed. Stable patients with good functional status and with good esophageal tissue integrity can undergo either a primary repair with muscle interposition or an esophagectomy. Otherwise, tracheal stenting, esophageal diversion, and palliative care should be considered.

Stent Migration

Stent migration is perhaps the most common complication of esophageal stricture, occurring in 11% to 25% of cases. Over the last 2 decades, various interventions aimed at reducing the frequency of migrations, such as anchoring the stent to the esophageal wall, have been introduced. Endoclips are used to secure the proximal stent end to the esophageal wall, but a high migration rate persists (Fig. 8). Endoscopic suturing using the only FDA-approved suturing device Apollo Overstitch (Fig. 9) has also shown some potential benefit in small studies; however, high-quality evidence is not available. The best treatment of migration is probably prevention. A study by Freeman et al. evaluating the impact of stent indwelling time in 162 patients treated with esophageal stenting showed a significant reduction in stent-related complications in patients who had a shorter indwelling time (Table 5). In patients with anastomotic leaks, a 30% ($P = .04$) reduction in stent migration rates was noted with a stent duration of fewer than 14 days. Patients with acute perforation experienced a 34% reduction in stent migration when the indwelling time was fewer than 28 days.

CONCLUSIONS

Esophageal stenting remains a mainstay in the palliation of advanced malignant strictures. Although its indications have greatly expanded to include various benign esophageal disease, complications associated with this procedure mandate thorough preprocedural evaluation of the patients as well as an individualized therapeutic approach.

TABLE 5 Rates of Complication Based on Stent Indwelling Time in the Management of Esophageal Leaks and Perforations

	Anastomotic Leak			Perforation		
	<2 Weeks	>2 Weeks	P Value	<4 Weeks	>4 Weeks	P Value
Number	28	36		36	22	
Migration	4 (14%)	7 (44%)	.04	9 (9%)	9 (41%)	.0007
Dysphagia	5 (17%)	8 (28%)	.38	4 (4%)	6 (29%)	.0022

Management of Esophageal Perforation

Eric Lambright, MD

Esophageal perforation is an ominous disease process and is universally fatal without appropriate and optimal management. Even with prompt diagnosis and optimal management, mortality rates are significant and have consistently ranged from 15% to 20%. There are multiple options related to the management of esophageal perforation, and a definitive uniform recommendation for treatment has not been established. Esophageal perforation and physiologic sequelae are related to the extravasation of oral and gastric secretions into the mediastinum with resultant intense and rapidly progressing inflammatory process. This process quickly overwhelms the body's defensive capacity, resulting in life-threatening impacts. The first clinical description of esophageal perforation was presented by Herman Boerhaave in 1720. He described the events of a Dutch Naval Grand Admiral who developed acute chest pain after an episode of vomiting after a gluttonous meal who had rapid clinical decline with profound chest pain, fever, and ultimately death. Postmortem analysis documented a distal esophageal perforation. The cause of esophageal perforation has evolved over time, and iatrogenic causes have become the most common cause (▶ Box 1). The principles of care for the patient with esophageal perforation reflect basic and classical surgical management. Prompt diagnosis, source control, eradication of sepsis, and optimal intensive care management are required to achieve and maximize survival. These principles will be reviewed.

ETIOLOGY

Anatomically, the most common site for esophageal perforation remains within the thoracic esophagus. Greater than 80% of perforations occur in that location. A small percentage occurs within the cervical esophagus and only rarely are perforations confined to the intraabdominal segment of the esophagus. The most common cause of esophageal perforation is iatrogenic related to esophageal instrumentation. Perforations will occur in areas of normal anatomic narrowing such as proximal to the cricopharyngeus or within the distal esophagus. Interruption of manipulations of pathologically abnormal esophagus by endoscopy may also cause perforation. Iatrogenic perforation accounts for approximately 20% of esophageal perforations. Less common causes of perforations include traumatic injury, ingestion of either foreign body or caustic material, suppurative necrotizing infection, or surgical intervention within the neck or chest in juxtaposition to the esophagus.

Patient symptoms at the time of presentation will be dependent on multiple factors, but fundamental issues are anatomic location of perforation, time from inciting event, and patient comorbidities. Provided a presenting patient has no changes to his or her baseline sensorium or mental status, pain remains a near-uniform complaint. Esophageal perforation must be suspected in any patient who has recently undergone esophageal instrumentation who has atypical neck or chest discomfort. Appropriate evaluations are required. Individuals who have suffered from iatrogenic esophageal perforation will infer complaints of excruciating and burning chest or upper abdominal discomfort. At times, clinicians may pursue an alternative diagnosis such as myocardial infarction or aortic dissection before entertaining the possibility of esophageal perforation. Patients will also describe some degree of dysphagia, odynophagia, or dysphonia. Signs on physical examination are typically very nonspecific in the setting of esophageal perforation. Subcutaneous crepitus is rarely identified. Findings such as decreased breath sounds or pleural rubs can be identified but do not provide for diagnostic clarification.

BOX 1 Causes of Esophageal Perforation

Iatrogenic
- Esophagoscopy with dilation, biopsy, or stent placement
- Transesophageal echocardiography
- Esophageal ultrasonography

Iatrogenic: Boerhaave syndrome

Traumatic
- Blunt
- Penetrating
- Surgical intervention: cervical intervention or mediastinal surgery

Ingestion: caustic or foreign body

Neoplastic
- Primary esophageal malignancy
- Mediastinal malignancy with esophageal involvement and erosion

Infectious—mediastinal necrotizing process

Management of Esophageal Perforation

Eric Lambright, MD

Esophageal perforation is an ominous disease process and is universally fatal without appropriate and optimal management. Even with prompt diagnosis and optimal management, mortality rates are significant and have consistently ranged from 15% to 20%. There are multiple options related to the management of esophageal perforation, and a definitive uniform recommendation for treatment has not been established. Esophageal perforation and physiologic sequelae are related to the extravasation of oral and gastric secretions into the mediastinum with resultant intense and rapidly progressing inflammatory process. This process quickly overwhelms the body's defensive capacity, resulting in life threatening impacts. The first clinical description of esophageal perforation was presented by Herman Boerhaave in 1724. He described the events of a Dutch Naval Grand Admiral who developed acute chest pain after an episode soon after a gluttonous meal who had rapid clinical decline with profound chest pain, fever, and ultimately death. Postmortem analysis documented a distal esophageal perforation. The cause of esophageal perforation has evolved over time, and iatrogenic causes have become the most common cause (Box 1). The principles of care for the patient with esophageal perforation reflect basic and classical surgical management. Prompt diagnosis, source control, eradication of sepsis, and optimal intensive care management are required to achieve and maximize survival. These principles will be reviewed.

ETIOLOGY

Anatomically, the most common site for esophageal perforation remains within the thoracic esophagus. Greater than 80% of perforations occur in that location. A small percentage occurs within the cervical esophagus and only rarely are perforations confined to the intraabdominal segment of the esophagus. The most common cause of esophageal perforation is iatrogenic related to esophageal instrumentation. Perforations will occur in areas of normal anatomic narrowing such as proximal to the cricopharyngeus or within the distal esophagus. Interruption of manipulations of pathologically abnormal esophagus by endoscopy may also cause perforation. Iatrogenic perforation accounts for approximately 20% of esophageal perforations. Less common causes of perforations include traumatic injury, ingestion of either foreign body or caustic material, suppurative necrotizing infection, or surgical intervention within the neck or chest in juxtaposition to the esophagus.

Patient symptoms at the time of presentation will be dependent on multiple factors, but fundamental issues are anatomic location of perforation, time from inciting event, and patient comorbidities. Provided a presenting patient has no changes to his or her baseline sensorium or mental status, pain remains a near-uniform complaint. Esophageal perforation must be suspected in any patient who has recently undergone esophageal instrumentation who has acute cervical neck or chest discomfort. Appropriate evaluations are required. Individuals who have suffered from iatrogenic esophageal perforation will infer complaints of excruciating and burning chest or upper abdominal discomfort. At times, clinicians may pursue an alternative diagnosis such as myocardial infarction or aortic dissection before entertaining the possibility of esophageal perforation. Patients will also describe some degree of dysphagia, odynophagia, or dysphonia. Signs on physical examination are typically very nonspecific in the setting of esophageal perforation. Subcutaneous crepitus is rarely identified. Findings such as decreased breath sounds or pleural rubs can be identified but do not provide for diagnostic clarification.

BOX 1 Causes of Esophageal Perforation

Iatrogenic
- Esophagoscopy with dilation, biopsy, or stent placement
- Transesophageal echocardiography
- Esophageal ultrasonography

Iatrogenic: Boerhaave syndrome

Traumatic
- Blunt
- Penetrating
- Surgical intervention: cervical intervention or mediastinal surgery

Ingestion: caustic or foreign body

Neoplastic
- Primary esophageal malignancy
- Mediastinal malignancy with esophageal involvement and erosion

Infectious—mediastinal necrotizing process

Tachycardia related to presence of the profound inflammatory process is typically present. Hypotension usually suggests a significant interval from inciting event to presentation. As with other acutely life threatening disease processes, clinical suspicions require appropriate and prompt diagnostic evaluations. Thus a low threshold for additional interrogation is warranted.

Radiographic diagnostic assessments are typically required for not only diagnostic confirmation but also for anatomic clarification with reference to location of perforation, disease associated with the esophagus, and any abnormality that would be identified distal to the area of perforation. Plain films of the chest offer nonspecific findings such as pleural effusion, subcutaneous emphysema, pneumomediastinum, or hydropneumothorax. However, chest radiographs in individuals with esophageal perforation are not consistently normal. A contrast swallow test remains the gold standard for evaluation of esophageal perforation. It is our practice to perform barium esophagography because these evaluations consistently have lower rates of false negative testing results when compared with water soluble contrast material. Additionally aspiration of barium is rarely associated with pneumonitis in contrast to water soluble materials. In patients who have been intubated, evaluations can be done through nasoenteric tubes. Cross sectional imaging with chest computed tomography (CT) can also complement contrast swallow evaluations and can provide useful diagnostic information, such as pathologic changes within the esophagus, clarification of the status of the pleural spaces, and other unsuspected anatomic findings. Endoscopy can also be useful for diagnostic clarification and does not appear to add any significant risk even in the setting of a possible esophageal perforation. Again, false negative assessments are not infrequent. Liberal use of endoscopy should be considered because additional information that could potentially impact therapeutic planning, such as anatomic location of the injury, associated pathologic changes of the esophagus, such as stricture or neoplasm, and assessment of the esophagus distal to the area of perforation can also be obtained. After diagnoses of esophageal perforation, standard and optimal medical care should be implemented. Broad spectrum antibiotics, including antifungal therapy, should be initiated. Appropriate physiologic support and interventions for relief of pain will be needed. Essential information, including cause of perforation, exact anatomic location, duration from inciting event, and knowledge of any underlying esophageal disease, is required to formulate an optimal therapeutic plan. Patients' underlying comorbid states must also be considered.

TREATMENT

Regardless of anatomic location, basic principles of management are control of leak, drainage of infection, eradication of sepsis, and, optimally, maintenance of gastrointestinal continuity. The combined expertise of surgeon, anesthesiologist, and intensivist is required for successful management. Typically, operative therapy is required for treatment of esophageal perforation. In unique situations, Cameron described criteria for nonoperative treatment of esophageal perforation, including contained perforation, free drainage of contrast back into the esophageal lumen, and minimal symptoms. Rigorous attention to all these details is required, should nonoperative management be considered. Clinical deterioration or changes would necessitate appropriate interventions. Additional observations have been made that further clarified and reinforced the principles of conservative management. Classically, nonoperative therapy consists of nasogastric decompression, broad spectrum antibiotics, and nutrition support. Intensive care unit monitoring would typically be necessary.

With the increasing use of CT imaging in the evaluation of patients in the emergency department with chest discomfort, surgeons are often asked to evaluate individuals with pneumomediastinum of unclear clinical importance. Not uncommonly, patients will present after a vomiting episode with these CT findings without any evidence of clinical deterioration. Our practice is to manage these individuals with appropriate esophagography and, provided this is normal, support with a brief period of cessation of oral intake, antibiotics, and clinical observation. Within a day or so, symptoms resolve, and patients will require no further evaluations or follow up. Active management and thoughtfulness are required when considering nonoperative therapy for esophageal perforation because most clinicians favor definitive interventions for a defined life threatening surgical disease process.

OPERATIVE TREATMENT

There are several different approaches from a technical perspective to achieve the goal of esophageal leak control and drainage of infection and debridement of devitalized soft tissue. Most commonly, primary buttressed repair of the perforation is performed. At times, based on underlying esophageal disease, esophageal resection with either primary reconstruction or diversion may be necessary. Perforations within the cervical esophagus are typically approached through the left neck. A right thoracotomy is chosen for injuries to the midesophagus. Distal esophageal perforation would typically be managed through a left thoracotomy approach through the seventh intercostal space. The use of stenting with appropriate mediastinal debridement has been involving. Operative intervention for management of esophageal perforation typically includes use of the following: primary repair, diversion and exclusion, closure over a T tube, and esophageal resection with immediate or staged reconstruction.

When approaching cervical esophageal perforation, a left neck incision just anterior to the sternocleidomastoid would be favored. After division of the omohyoid and thyroid vein, excellent exposure to the cervical esophagus can be achieved with retraction of the carotid sheath and contents laterally. The esophagus can be mobilized from the prevertebral fascia. Appropriate debridement of any infected material can be achieved. If the mucosal abnormality can be identified, primary repair is performed. However, exhaustive evaluation of the esophagus is not recommended because, typically, drainage of the area provides for appropriate management with ultimate esophageal healing. Nutrition support and antibiotics would be used as adjunctive management. The surgeon must ensure that all areas of contamination are drained. A low threshold to enter the mediastinum by an alternative access such as right thoracotomy must be maintained. Appropriate use of closed suction drain is necessary. Perforations within the thorax, esophagus cannot be managed with drainage alone because survival rates with this management strategy are unsatisfactory.

Regardless of anatomic location and exposure via either a right thoracotomy or left thoracotomy, principles of primary operative repair of esophageal perforation are standard, meticulous closure of the esophageal defect, debridement of devitalized tissue with evacuation of all infected material, and wide drainage. A buttressed repair is typically used. An intercostal flap can be promptly mobilized on entering the chest. Pleural debris and contamination are promptly evacuated. The mediastinal pleura is opened, and exposure of the esophagus is achieved. Esophageal perforation is identified. Provided there is no underlying esophageal structural disease such as neoplasm or achalasia, it is rare that primary repair of the esophageal defect cannot be considered, even when there is significant time delay from inciting event to therapeutic intervention. Complete exposure to the full extent of the esophageal perforation is required. Typically, the mucosal defect will extend more superficially than the esophageal muscularis disruption. Esophageal musculature is opened to identify the full extent of the injury. A meticulous mucosal approximation is achieved. We will typically use an absorbable monofilament suture in an interrupted fashion. A running repair is also appropriate. Esophageal musculature can be mobilized to achieve a second layer of closure to reinforce the primary mucosal repair. A running absorbable braided suture can achieve this goal. Additional buttressing of the repair should be performed. Options for reinforcement include intercostal muscle flap or pleural parietal flap. We have found that the integrity of pleural flap reinforcement is often inadequate

Although less rarely used, intercostal flaps of the diaphragm or gastric fundus reinforcement may be helpful. While mediastinal drainage, nasogastric decompression, and nutrition are adjuncts to care. Other techniques that are used in the management of esophageal perforation include esophageal dilatation and exclusion or closure over T tubes. This technique is less commonly implemented but is technically very straightforward, and interventions can be completed in an efficient manner in physiologically unstable patients. Exclusion and diversion involves the creation of a cervical esophageal fistula with gastrostomy tube placement with stapling of the distal esophagus and appropriate mediastinal drainage. Biliary T tubes can be used to create a controlled esophageal fistula. The tube is positioned within the perforation and brought out through the chest wall. The T tube can then be slowly removed over multiple months.

Management of esophageal perforation in the setting of underlying esophageal disease such as malignancy, benign stricture, or achalasia is very challenging. Attempts at primary repair in the setting of a diseased esophagus or any evidence of distal obstruction (either anatomic or functional) will fail. If esophageal perforation is sustained during an esophageal dilation for achalasia, primary repair of the perforation, as well as myotomy to relieve the distal obstruction, will be needed. Typically, the perforation is repaired, and, on the contralateral side of the esophagus, a myotomy extending onto the stomach is performed. Perforation sustained in the setting of a dilation for benign or malignant strictures is very challenging. Primary repair cannot be achieved, and resection may be required. On the basis of a patient's physiologic stability, primary esophageal reconstruction can be considered; however, esophageal diversion with end cervical esophagostomy may be required. In a patient who has a newly diagnosed esophageal cancer who sustained an iatrogenic perforation, we would typically consider esophageal stenting and mediastinal drainage as optimal initial intervention to achieve initial control of the sepsis and leak and subsequently allow for appropriate oncologic staging assessments. Esophageal stents achieve the goal of sealing the leak, as well as relieving any potential distal obstruction.

With advances in stent technology, stenting of esophageal perforations has become another tool to assist in the management of this life-threatening disease process. Even with optimal surgical intervention, persistent leak after Boerhaave's injury is not uncommon. Options for management of the fistula, depending on patient's clinical status, would include surgical intervention or esophageal stenting. Thus stenting can be considered as relevant in the initial management of iatrogenic esophageal perforation, as well as in the setting of iatrogenic perforation. If esophageal perforation is recognized at the time of endoscopy, esophageal stenting can be performed in a straightforward way and may limit any mediastinal contamination. Again, basic principles of esophageal management must be followed with leak control and drainage. Options for drainage would include percutaneous or thoracoscopic intervention.

When dealing with diagnosis of esophageal perforation and the options for therapeutic management, prompt intervention is necessary with minimal time for preparation. Basic understanding of the multiple technical options for management, experience in using the different technical interventions, with adherence to the fundamental principles for esophageal perforation, is required for successful patient-centered outcomes.

POSTOPERATIVE CARE

The perioperative management after surgical treatment for patients with esophageal cancer requires ongoing active management. Hemodynamic instability with septic physiology is expected and will likely take a period of days to improve. Mechanical ventilatory support is often necessary. Ongoing optimal antibiotic and antifungal care is required. Nutritional support is used as an adjunct. Rigorous surveillance for residual septic foci will be needed. As the patient's physiology improves, discussions regarding enteral tube placement will be necessary. Nutrition can be supported with either feeding gastrostomy tube or jejunostomy tube. Typically, we would perform a contrast evaluation of the repair approximately 1 week after surgery. Provided this is satisfactory, slow reinitiation to normal regular diet over a week would be implemented. The exact frequency of esophageal stricture after primary repair of esophageal perforation is unknown; however, should patients develop symptomatic stricturing, standard dilation would typically provide for resolution.

RESULTS

Esophageal perforation remains a highly morbid disease. Overall mortality rate remains approximately 20%, with spontaneous perforations having a mortality rate approaching 30% and instrumental perforation approximately 10%. Cervical esophageal perforations have the lowest rate mortality with thoracic perforations having the highest rate. Delay in diagnosis with implementation of treatment beyond 24 hours significantly increases the mortality rate. Primary emergency repair has a mortality rate of approximately 12%. Esophageal resection and exclusion have higher event rates. Although the exact frequency of postoperative complications is unclear, morbidity is very common, including pneumonia, prolonged ventilatory support, multisystem organ dysfunction/failure, and persistence of esophageal leak.

Esophageal perforation remains a significant and potentially daunting clinical challenge. Fundamental surgical principles of prompt diagnosis, effective control of leak, eradication of mediastinal sepsis, optimal adjunctive supports, and rigorous surveillance for postprocedural issues must be followed. Multiple technical options are considerations for management. However, primary reinforced repair and wide drainage remains the standard consideration. Esophageal stenting appears to have an expanding role in the management of esophageal perforation; however, standard guidelines continue to evolve.

STOMACH

BENIGN GASTRIC ULCER

Daniel T. Dempsey, MD, MBA

Benign gastric ulcer is a disc[illegible] and surface [illegible]

[illegible]

TYPES OF BENIGN GASTRIC ULCER

Johnson initially defined [illegible] gastric ulcer [illegible] ulcers are the most common [illegible] gastric ulcer. They typically occur at or near the angularis incisura on the lesser curvature [illegible]

gastric ulcers are not associated with gastric acid hypersecretion, and thus vagotomy has not traditionally form part of the surgical treatment. Type 2 ulcers usually occur in the distal stomach and are associated with duodenal ulcer disease, either active or chronic. Type 3 ulcers occur in the prepyloric region. Pathophysiologically, type 2 and 3 gastric ulcers are believed to resemble duodenal ulcers, and thus truncal vagotomy to ameliorate acid hypersecretion has been part of the surgical treatment. Recently two additional types of gastric ulcer have been described, resulting in a "modified Johnson classification" (Table 1). Type 4 gastric ulcer occurs high on the lesser curvature near the gastroesophageal (GE) junction. Excision of type 4 ulcers may get close to the esophagus, requiring [illegible] reconstruction (Csendes operation). Type 5 gastric ulcers are believed to be drug induced and typically occur toward the greater curvature, making them amenable to simple wedge resection. Neither type 4 nor 5 gastric ulcers are believed to be associated with acid hypersecretion, so vagotomy is probably unnecessary.

SURGICAL OPTIONS FOR GASTRIC ULCER

When operating on a patient with gastric ulcer, the choice of operation depends on a variety of technical and clinical factors, which will be discussed further below. Fundamentally, operations for gastric ulcer fall into two categories: those that excise the ulcer and those that do not (Table 2). If the ulcer is not excised, it must be biopsied to rule out cancer. Formal gastric resection with anastomosis is avoided in unstable patients. Before embarking on resection, it is prudent to assess during surgery whether the ulcer involves the pancreas, portal triad, or celiac artery or branches. For low risk patients with distal gastric ulcers, distal gastrectomy with (type 2 and 3 ulcers) or without (type 1 ulcers) truncal vagotomy is the treatment of choice. Reconstruction consists of Billroth 1 gastroduodenostomy or Billroth 2 gastrojejunostomy (Fig. 1). The latter may be preferred when there is concomitant duodenal ulcer disease (type 2 gastric ulcer). With both types of reconstruction, we prefer to do the anastomosis to the greater curvature side of the gastric remnant. Roux reconstruction is much preferred with small gastric remnants when the gastrojejunostomy is close to the GE junction, but it should be avoided with large gastric remnants. For low risk patients with high gastric ulcers (type 4), distal subtotal gastrectomy and in continuity excision of the high lesser curvature ulcer can be considered, with reconstruction via Roux-en-Y esophagogastrojejunostomy (Csendes procedure) if resection encroaches on the gastric cardia (Fig. 2). For type 4 ulcers that are more distally located (or type 1 ulcers that are unusually proximal), a more limited distal gastric resection and lesser curvature extension can be performed, with reconstruction by gastrojejunostomy (Billroth 2 or Roux) (Pauchet procedure). Simple wedge resection is a good option for type 5 gastric ulcers, but it is difficult to perform for prepyloric ulcers (type 2 and 3), juxtacardial ulcers (type 4), and

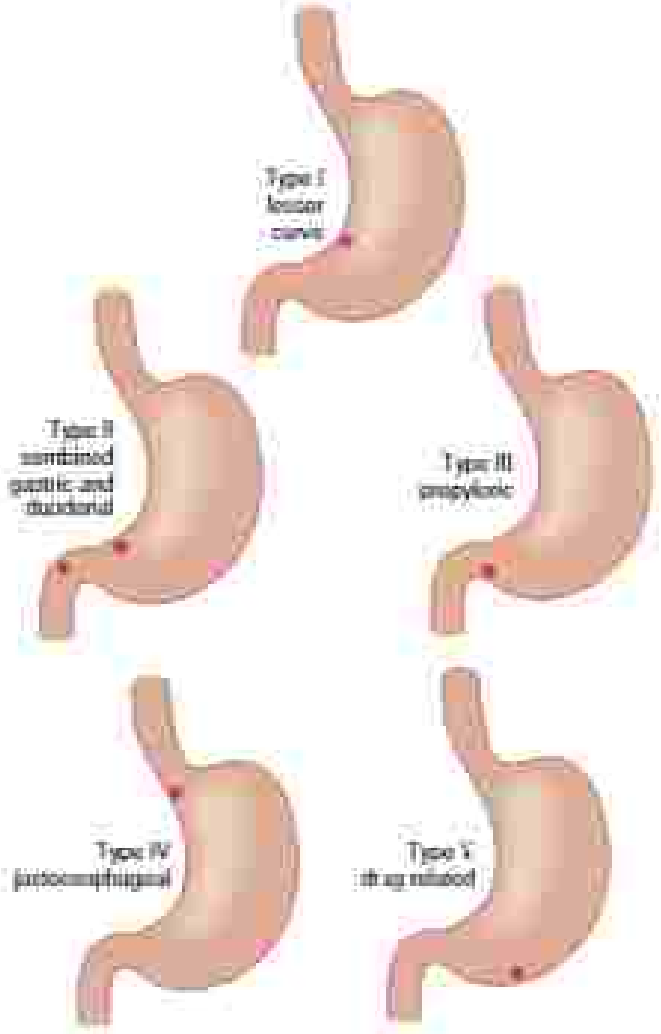

FIG. 1 Types of gastric ulcer [illegible]

TABLE 1 Modified Johnson Classification

Type	Location	Acid Hypersecretion
I	Lesser curvature; incisura	No
II	Body of stomach, incisura, and duodenal ulcer (active or healed)	Yes
III	Prepyloric	No
IV	High on lesser curve, near gastroesophageal junction	No
V	Anywhere (medication induced)	No

ulcers on the lesser curvature. For type 2 and 3 gastric ulcers that are left in situ, truncal vagotomy and gastrojejunostomy (with ulcer biopsy) may be a reasonable alternative to distal gastric resection. Similarly, for type 4 gastric ulcers, distal gastrectomy without ulcer excision (but with ulcer biopsy) can be considered (Billroth-Mikulicz operation).

TABLE 2 Choice of Operation for Gastric Ulcer by Type*

Ulcer Type	Option 1 (Remote Ulcer)	Option 2 (Biopsy Ulcer)
Type 1	Distal gastrectomy	[illegible] gastrotomy and drainage (with or without wedge excision)
Type 2	Distal gastrectomy and vagotomy	[illegible] gastrotomy and drainage
Type 3	Distal gastrectomy and vagotomy	Vagotomy and drainage
Type 4	Camalot or Pyeloplasty procedures	Kelling-Madlener procedure, or vagotomy and drainage
Type 5	Wedge resection	Patch/oversew

INDICATIONS FOR OPERATION

Most patients with benign gastric ulcer never see a surgeon. They present to primary care or gastrointestinal (GI) practices or emergency departments, with complaints of upper abdominal pain, nausea, vomiting, or iron deficiency anemia. These complaints are evaluated with upper endoscopy with or without upper GI radiology. If a gastric ulcer is diagnosed, it is appropriately biopsied to rule out gastric cancer. If biopsy and cytology specimens are benign, the patient is treated with acid suppression, and the causative factors discussed above (*H. pylori*, NSAIDs, smoking) are eliminated if possible. Then the upper endoscopy is repeated in 2 to 3 months to document ulcer healing and to perform repeat biopsy. With this approach, the likelihood of misdiagnosing a gastric adenocarcinoma or lymphoma as a benign gastric ulcer is low.

If helicobacter is eradicated, NSAID and aspirin use is stopped, and smoking is eliminated, almost all gastric ulcers will heal with a 2- to 3-month course of proton pump inhibitor therapy, and recurrence or nonhealing is unusual. But, if helicobacter infection, NSAID or aspirin use, or smoking persists, recurrent gastric ulcer is the rule, as the condition of acid suppression. It is doubtful that definitive operation can completely nullify this fact, although recurrence of peptic ulceration (gastric or marginal ulcer or both) may be delayed after operation. For optimal results after operation for gastric ulcer, it is very important to screen for and document after surgery the absence of helicobacter infection, NSAID use, and smoking. Vagotomy or long-term acid suppressive medication may prevent recurrent peptic ulcer in some patients, and clearly patients having operation for gastric ulcer who cannot stop long-term NSAIDs or aspirin should receive long-term acid suppressive medication. Selective COX-2 inhibitors should be considered in patients with ulcers requiring NSAIDs because these may have a lower risk of peptic ulceration.

PERFORATED GASTRIC ULCER

The most common indication for operation in benign gastric ulcer is perforation. Patients with gastric ulcer perforation present with acute abdominal pain and tenderness, usually with signs of peritoneal irritation (ie, rebound tenderness and referred rebound tenderness). Because of the severity and acuteness of the symptoms, these patients must commonly present to the emergency department where computed tomography (CT) scanning reveals free intraperitoneal air, usually with free fluid as well. If water-soluble oral contrast has been administered, the scan often reveals oral extravasation

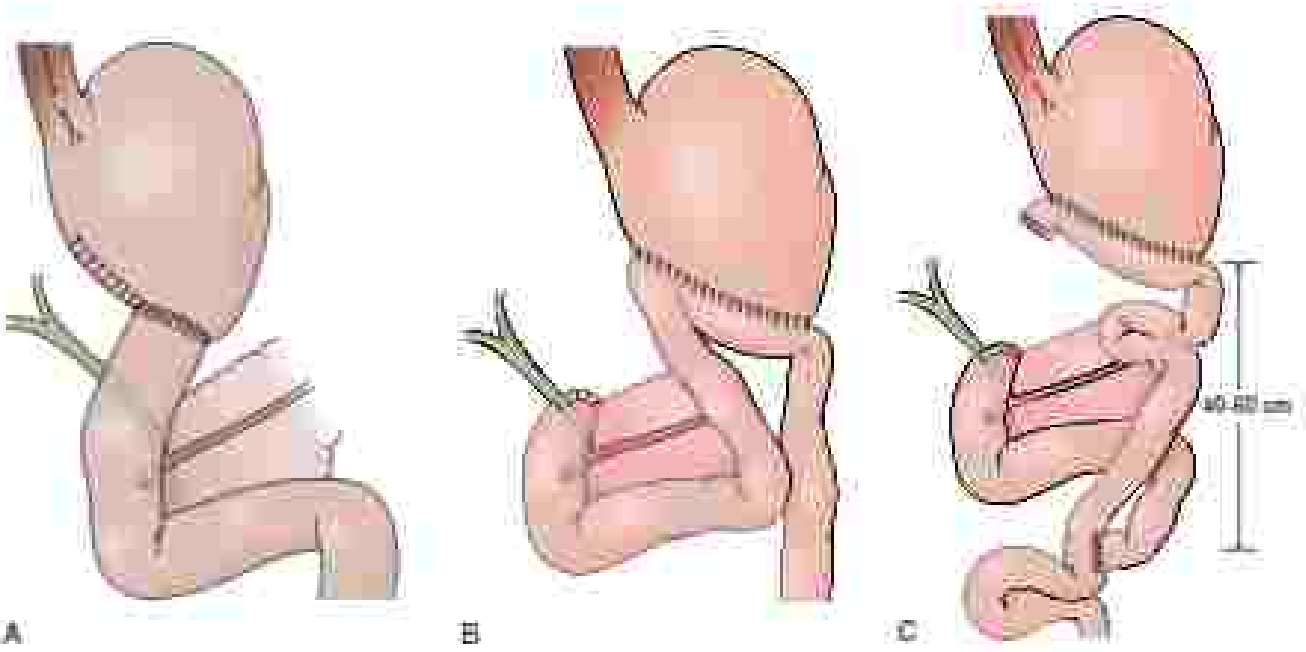

FIG. 2 These types of reconstruction after distal gastrectomy. (A) Billroth I (A gastroduodenostomy) is performed to avoid the greater curvature. (B) Billroth II (A gastrojejunostomy is created to reattach to the alimentary circuit. Several variations may be observed in this type of reconstruction.) (C) Roux-en-Y prevents duodenogastric reflux. Here the stomach is connected to the stomach of the Roux limb. Typically 40 to 50 cm of the Roux limb is used.

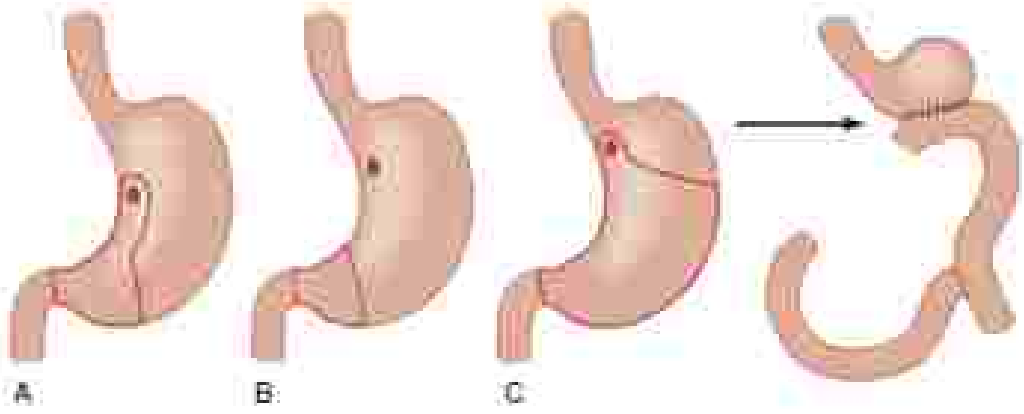

FIG. 3 Operations for a type IV gastric ulcer. (A) Partial procedure. (B) Billroth I without procedure. (C) Combined procedure (sleeping gastrojejunostomy).

from the stomach. Gastric wall thickening is difficult to evaluate on CT if the stomach is collapsed. Simple upright chest radiography usually shows free air under the diaphragm, but this classic radiologic finding may be absent in 20% of patients with perforated gastric ulcer.

Intravascular volume depletion is the rule, so fluid resuscitation begins with 1 to 2 L of isotonic fluid. Induction of general anesthesia in the patient with severe hypovolemia may result in cardiovascular collapse and cardiac arrest. Intravenous antibiotics (cefazolin and flagyl, if unstable) are administered. Careful insertion of a nasogastric (NG) tube before surgery for gastric decompression is prudent, especially if water-soluble oral contrast has recently been administered or if imaging shows gastric distention. Operation is planned to occur usually within 2 hours of presentation. Rarely, nonoperative treatment is indicated if the patient is clinically stable, without signs and symptoms of sepsis, and with good radiologic evidence that the perforation has sealed.

Operation may be done open or laparoscopically. Copious irrigation of the soiled peritoneal cavity is performed with 5 to 10 L of warm saline. The entire anterior surface of the stomach is inspected. If no perforation is seen, the lesser sac is entered through the gastrocolic omentum and retained and the posterior stomach inspected. If still no perforation is found, it may be along the greater or lesser curvatures. If the patient is hemodynamically unstable or a poor operative risk, the perforated gastric ulcer should be biopsied and closed, either with a Graham (omental) patch or with a wedge resection of the ulcer

TABLE 3 Choice of Operation for Gastric Ulcer by Indication

Indication	Option 1	Option 2	Option 3
Perforation	Patch or wedge excision	Patch or wedge excision with vagotomy and drainage	Distal gastrectomy[a]
Bleeding	Oversew or wedge excision	Oversew with vagotomy and drainage	Distal gastrectomy[a]
Obstruction	Vagotomy and distal gastrectomy	Vagotomy and gastrojejunostomy	
Nonhealing/Intractability	Distal gastrectomy (with vagotomy for type 2 and 3)	Wedge excision with vagotomy and drainage	

[a] Consider addition of vagotomy for type 2 and 3 gastric ulcer.

TABLE 4 Rockall Score to Assess Rebleeding and Mortality Risk in Upper Gastrointestinal Bleeding

Variable	0 Points	1 Point	2 Points	3 Points
Age (yr)	<60	60–79	≥80	
Shock	None	HR >100, SBP >100 systemic	SBP <100 systemic	
Comorbidity	None	[illegible]	[illegible]	Renal or liver failure, metastatic cancer
Diagnosis	Mallory-Weiss	All other	GI cancer	
Bleeding stigmata	None		Visible vessel/active bleeding

(Table 3). The latter is appropriate for perforations that occur along the lesser curvature, on the anterior or posterior surface of the proximal stomach in the low-risk patient who is hemodynamically stable. The operative choice for a chronic, stable gastric ulcer is controversial. Some surgeons still perform a wedge excision of the ulcer with the goal of removing the ulcer crater and the surrounding inflammatory tissue. Others advocate the addition of vagotomy and drainage with the goal of decreasing the acid secretion that seems to be the most significant factor in the pathogenesis of peptic ulcer disease. Whether the ulcer is excised or left in place, the surgeon must be certain by appropriate preoperative evaluation that the ulcer is benign. Ulcers that are refractory to medical therapy, that recur after simple excision, or that are associated with a large mass should be resected with a wide margin, and frozen section examination should be performed to exclude malignancy. Ulcers that are confirmed to be benign by frozen section should be managed as described above. Ulcers that are associated with a mass, but are found to be benign on frozen section, may be managed by a wide excision of the ulcer and the surrounding mass. Ulcers that are associated with a mass and are found to be malignant on frozen section require a gastrectomy with a wide margin of resection and a lymphadenectomy. Ulcers that are associated with a mass and are found to be malignant on frozen section require a gastrectomy with a wide margin of resection and a lymphadenectomy. Ulcers that are associated with a mass and are found to be malignant on frozen section require a gastrectomy with a wide margin of resection and a lymphadenectomy.

[illegible] GASTRIC ULCER

Although still a common cause for hospitalization, bleeding gastric ulcer is no longer an indication for operation in most cases, due to the increasing effectiveness of medical therapy for bleeding gastric ulcer. The most common cause of bleeding is hospital- or patient-related peptic ulcer disease. Small, [illegible] ulcers in the duodenum or stomach are the most common peptic ulcer bleeding. Most [illegible] patients with bleeding peptic ulcer disease will stop bleeding spontaneously. Only a small percentage of patients will need to undergo operation for bleeding peptic ulcer disease. Risk assessment tools have been developed to help predict which patients are at high risk for rebleeding and death. One of the most widely used is the Rockall score (Table 4). Most of these tools can predict with reasonable accuracy who does and does not have a life-threatening ulcer bleed, but they are useful as guides. Patients with a low score of 0 to 2 are very unlikely to have a life-threatening bleeding ulcer, whereas patients with a score of 5 or more may be at high risk of rebleeding or death. In general, patients at high risk present with hematemesis, hypotension, or tachycardia, or have multiple units of blood transfusion. These patients require early surgical consultation. Urgent upper endoscopy, even those with high-risk endoscopic features, such as active bleeding or visible vessel in the ulcer crater, should be performed. Endoscopic hemostasis, in the form of cautery, injection, or epinephrine and application of clips, is common and is successful in most cases. Surgical intervention is required in patients who continue to bleed despite endoscopic therapy and a transfusion. Those patients with persistent hypotension should also be considered for surgical intervention. Patients who have had multiple bleeding episodes, are elderly, or have other medical problems may also be considered for operation for bleeding gastric ulcer even if they have had more than one transfusion. Those who have recurrent or rebleeding ulcers, or those who have ulcers extending to a large area, such as the lesser curvature or upper antrum, have a higher mortality rate if treated nonoperatively. The operative mortality rate is around 5%.

Biopsy is a crucial part of the bleeding ulcer operation. Although the appropriate operation for a clinically or hemodynamically unstable patient with a bleeding ulcer is a wedge resection, a suitable alternative for bleeding ulcers in the greater curvature or fundus of the stomach is a vagotomy and antrectomy. Antrectomy is used because it is not only curative for the ulcer but also removes the area of the stomach that is most likely to contain gastrin-producing cells. Gastrin is a hormone that stimulates acid secretion. Removal of the antrum, which contains the majority of gastrin-producing cells, decreases the amount of acid secretion. Vagotomy is also curative for the ulcer because it decreases the amount of acid secretion. Vagotomy and antrectomy is the most common operation performed for bleeding gastric ulcer. Vagotomy and pyloroplasty is also a common operation performed for bleeding gastric ulcer. Vagotomy and gastrojejunostomy is also a common operation performed for bleeding gastric ulcer. Vagotomy and gastrojejunostomy is also a common operation performed for bleeding gastric ulcer.

OBSTRUCTING GASTRIC ULCER

The most common cause of gastric outlet obstruction in the adult patient is cancer (pancreatic, duodenal or gastric). So, when considering operation for obstructing distal gastric ulcer, the surgeon must ask whether the patient might have malignant obstruction. Whereas upper endoscopy, biopsy, contrast radiography, endoscopic ultrasound, CT, or magnetic resonance imaging may all be suggesting that the obstruction is benign, malignancy, although rare, remains a real possibility. The classic operation for obstructing gastric ulcer is vagotomy and distal gastrectomy, but vagotomy and gastrojejunostomy may be an acceptable alternative. The latter procedure has a lower operative mortality risk, and, in the event of severe dumping, the gastrojejunostomy is potentially reversible if gastric outlet patency can be maintained. However, distal gastrectomy confirms the absence of cancer. Vagotomy should be performed because obstructing gastric ulcers are likely to be Johnson type 2 or 3 lesions.

NONHEALING GASTRIC ULCER (INTRACTABILITY)

Operation for nonhealing gastric ulcer should be unusual today because our understanding of ulcer pathophysiology is more complete than ever. Acid suppression, eradication of helicobacter, cessation of NSAIDs, and smoking cessation should heal the ulcer. So why would the gastric ulcer persist. Could it be cancer? Is the patient noncompliant? Is there unrecognized gastric stasis or emesis/gastric reflux? Are there important factors in ulcer pathogenesis that we haven't discovered yet? These are all important questions for the surgeon to consider before operating on a patient for nonhealing gastric ulcer. Furthermore, it must be recognized that patient noncompliance and unknown pathophysiologic factors may predispose to ulcer recurrence or poor functional results after gastrectomy for nonhealing ulcer. This may be particularly problematic in thin patients who are easy to operate on but who have minimal nutritional reserves in the event of a poor functional outcome.

In the event that operation for nonhealing ulcer is necessary, the ulcer should be excised either with distal gastrectomy or wedge resection. This both excludes cancer and resects the vulnerable part of the stomach. If distal gastrectomy, the classic operation, is performed, then vagotomy should be added for type 2 and 3 gastric ulcers. If the ulcer is wedged out, then vagotomy and drainage should be added.

MARGINAL AND RECURRENT ULCER

Ulcers that occur at or near the gastroenterostomy are termed marginal ulcers. They may occur on either side of the anastomosis, where on the distal side, they are generally believed to be due to acid peptic injury to small bowel mucosa, which is ill equipped to defend itself against unbuffered gastric juice. This occurs most commonly in Roux gastrojejunostomy because the anastomosis is devoid of the buffering effects of duodenal contents, which fully protect a Billroth 2 anastomosis. When on the proximal side of the anastomosis, the ulcer is generally thought to be due to ischemia, stasis, foreign body (suture), bile reflux, or the circumstances that led to the gastric ulcer in the first place (recurrent ulcer). Marginal ulcer complicates Roux or Y gastric bypass in about 8% of patients, and presently this is the most common cause of marginal ulcer, which may also complicate gastrojejunostomy for cancer or ulcer.

The medical treatment of marginal ulcer is identical to gastric ulcer: acid suppression, eradication of helicobacter, cessation of NSAIDs, and smoking cessation. Indications for operation are also identical to those for gastric ulcer: perforation, bleeding, obstruction, and intractability. The realization that reoperation for recurrent or marginal ulcer puts the patient at increased risk (and closer to total gastrectomy) underscores the importance of patient education and good management after the first ulcer operation, which includes minimizing the risk factors for ulcer recurrence. In addition to elimination of helicobacter, NSAIDs, and smoking, we consider every patient who has had an operation for gastric ulcer a candidate for lifelong acid suppression, unless the patient has had a vagotomy.

Perforated marginal ulcer may be treated with simple patch closure, which is certainly appropriate in high-risk and unstable patients. It may also be the preferred treatment in patients with Roux-en-Y gastric bypass because resection may necessitate esophagojejunostomy, be risky in high-risk patients with perforated gastrojejunostomy after distal gastric resection, resection of the anastomotic region (segmental jejunal resection with additional gastrectomy) is preferred. The addition of truncal vagotomy may be considered. If the remaining gastric remnant is 50% or less, reconstruction should be Roux gastrojejunostomy to avoid bile reflux esophagitis. If the remaining remnant is larger than 50%, reconstruction should be via Billroth 1 or 2 technique to minimize recurrence of marginal ulceration. If the original operation was a simple loop gastrojejunostomy, consideration may be given to reversal (if the gastric outlet is patent) or distal gastrectomy with Billroth 1 or 2 reconstruction.

Bleeding marginal ulcer can usually be managed without surgery with the help of endoscopic hemostatic techniques or angiographic embolization, unless the ulcer has eroded into a named visceral vessel such as the splenic, left gastric, or middle colic artery. Those patients requiring emergency operation may have torrential bleeding and often present with a less impressive "herald bleed." Whereas gastrotomy and transluminal oversewing of the bleeding vessel may prove adequate, resection of the anastomotic region may be expeditious and safer. Perioperative angiographic embolization might complement the operation. Marginal ulcers associated with obstruction or intractability should be treated with discise resection of the anastomosis, followed by Roux or Billroth reconstruction, depending on how close the anastomosis is to the GE junction.

MANAGEMENT OF DUODENAL ULCERS

F. Charles Brunicardi, MD, [illegible] F. Kamran Qasim, MD, MPH

In the past 30 years, we have seen a remarkable decline in the incidence of duodenal ulcers (DUs) and peptic ulcers overall. This is due to wide acceptance and availability of proton pump inhibitors (PPIs) and selective histamine blockers, and from eradication efforts against *Helicobacter pylori*. Despite the reductions in incidence of DU, the morbidity and mortality for patients hospitalized with DU remains unchanged. For those patients requiring surgery, the 30-day postoperative mortality rate has been a steady 10% since the early 2000s. Although medical management of DUs is now well established, challenges remain; for example, poor patient compliance may result in ulcer recurrence and rebleeding, whereas the long-term use of PPIs has recently been associated with dementia, *Clostridium difficile* colitis, and osteoporosis. In addition, disparities in social determinants of health and economic health are associated with poor access to acid-reducing medications, increased rates of *H. pylori*, and increased rates of complicated DU. Finally, increased societal burdens related to obesity, diabetes, cardiovascular disease, and an aging population mean that patients presenting with DU today are sicker than those presenting in previous decades. For surgeons, the most common presentation of DU is in the setting of bleeding, perforation, and obstruction; therefore, proficiency in the surgical management of DU remains a critical skill for general surgeons.

There have been few high-quality, published studies on the incidence of DUs in the past 10 years. Systematic reviews in the late 2000s concluded that, in the developed world, 1 to 2 people out of every 1000 will be diagnosed with peptic ulcer disease each year. A total of 95% of DU are attributable to *H. pylori*, use of nonsteroidal antiinflammatory drugs (NSAIDs), or both. Less common causes of DU include gastrinoma (Zollinger–Ellison syndrome, 1% to 3% of ulcers), smoking, steroid or cocaine use, and dysmotility. Of patients hospitalized for duodenal ulceration, 10% will require surgery, most commonly resulting from persistent hemorrhage, with a 30-day postoperative mortality rate of 10%. DUs develop as a result of suprapeptic acid secretion despite normal serum gastrin levels. In response to increased acid burden, columnar cells from Brunner glands migrate and replace the duodenal epithelium. Normal duodenal epithelium is susceptible to *H. pylori* colonization; however, this metaplastic tissue facilitates colonization and impairs mucosal defense. *H. pylori* infection is associated with a vigorous local immune response, mediated by macrophages, neutrophils, and lymphocytes, and local release of interleukin (IL)-1β, IL-2, IL-6, IL-8, IL-12, and tumor necrosis factors. A positive feedback loop between *H. pylori* infection and further acid secretion via histamine *N*-methyltransferase hastens and sustains the inflammatory process. Together, these effects result in the development of the DU.

Patients with DU classically present in one of four ways. Uncomplicated DU is diagnosed based on a presentation of dyspepsia, presence of ulcer risk factors such as NSAID and tobacco use, and epigastric pain beginning 2 to 3 hours after meals. Pain that radiates to the back should be concerning for ulcer erosion to adjacent structures and pending perforation. Patients with perforated ulcer present with peritonitis and an acute abdomen, typically can state the exact timing of symptom onset, and are often visibly uncomfortable and will lay still in bed. Tachycardia is the most common initial finding with fever, hypotension, and tachypnea representing late findings. Bleeding ulcers may present as melena or upper gastrointestinal (GI) hemorrhage. Hematemesis is associated with higher mortality rates because it typically represents a higher rate of ulcer bleeding. Ulcer should also be considered in patients undergoing workup for signs of gastric outlet obstruction, including vomiting, loss of appetite, and weight loss. Upper GI endoscopy is indicated in the workup of non-perforated ulcers. More than 90% of ulcers are visualized in the first portion of the duodenum, may be hidden in the duodenal bulb, and ulceration in the more distal portions should raise concern for gastrinoma. In contrast to gastric ulcers, routine biopsy of DUs is not supported by evidence because the complication rate for biopsy is much higher than the rate of malignancy. Biopsy should be done for DU in the setting of obstruction, giant ulcer (>2 cm), or known high malignancy risk.

MEDICAL MANAGEMENT OF DUODENAL ULCERS

Medical management of DU is centered around the eradication of *H. pylori* infection and protection of the intestinal wall from acid damage. While physicians treat the ulcer, ultimately, the patient's body is responsible for healing; therefore, optimal nutrition and a healthy lifestyle (i.e., tobacco cessation) are critical. The initial diagnosis of DU by endoscopy should be supplemented by testing for *H. pylori* via serology, stool antigen test, breath test with carbon-labeled urea, or endoscopic biopsy of the ulcer (not routinely recommended). Although any of these are appropriate for diagnosis of *H. pylori* and some have more than 95% sensitivity or specificity, only carbon-labeled urea breath testing or fecal antigen testing are appropriate for proving eradication after treatment. We recommend therapy against *H. pylori* be initiated in the presence of DU regardless of testing results, because the recurrence and rebleeding rates associated with a false-negative test are unacceptably high compared with the relative safety of combination therapy. Eradication of *H. pylori* significantly reduces rates of ulcer recurrence and bleeding.

Traditional "triple therapy" has been associated with 80% eradication rate, whereas "quadruple therapy" has been associated with a slightly higher rate, but this difference in large meta-analyses is not statistically significant. Recommended regimens are listed in Table 1. NSAIDs and aspirin should be avoided; however, patients with a cardiovascular indication for low-dose aspirin use should continue to use it. Smoking cessation is essential, and patients should be considered for a formal cessation program. Patients who have uncomplicated DU disease should be managed with short-term antisecretory drugs, such as PPIs, for 2 to 4 weeks, whereas patients with complicated DU disease should receive long-term PPI therapy.

SURGICAL MANAGEMENT OF DUODENAL ULCERS

Operative management of DUs is indicated in the setting of perforation, recurrent or refractory hemorrhage, and persistent obstruction; therefore, the ulcer operation should be designed toward the indication. Typically, the modern surgeon is presented with an ulcer operation only in the urgent/emergent setting. Deciding whether to operate in the first instance is the main, if an operation is indicated, the next step is categorizing the patient as either stable or unstable to determine which operation should be performed. Elective ulcer surgery on stable patients is an uncommon occurrence. Unstable patients should be managed using damage control techniques and with a goal of restricting anesthesia time to less than 1 hour if possible. For example, it would be unsafe to perform a concurrent acid-reducing procedure, such as a vagotomy and drainage, in an unstable patient.

TABLE 1 Treatment for *H. pylori* as Recommended by 2017 American College of Gastroenterology

Regimen	Duration	Considerations*
First-line triple therapy: PPI, clarithromycin, amoxicillin, metronidazole	14 days	Known local clarithromycin resistance rates <15%; no history of macrolide exposure
First-line quadruple therapy: PPI, bismuth, tetracycline, metronidazole	10–14 days	Ideal for patients with penicillin allergy or previous macrolide use. May be used as initial therapy or if patient fails triple therapy
Levofloxacin salvage regimen: PPI, levofloxacin, amoxicillin	10–14 days	May use if patient does not respond to either triple or quadruple therapy

*Always consider the patient's unique history of previous antibiotic use, renal and hepatic function, and local resistance patterns in selecting regimen.
PPI, proton pump inhibitor

Perforated Duodenal Ulcer

Perforated duodenal ulcer is a surgical emergency. Patients present with an acute abdomen, peritonitis, epigastric pain, tachycardia, and leukocytosis. The 30-day mortality risk of perforated duodenal ulcer in the literature ranges from 3% to 40%; however, a plurality of studies agree that true risk is in the 2% to 10% range. Advanced age, higher American Society of Anesthesiologists classification, elevated body mass index, and perforation diameter are all nonmodifiable risk factors associated with increased mortality. The only modifiable risk factor associated with mortality is time to operation, wherein a delay of 3 hours is associated with a doubling of mortality risk. Shock is associated with a nearly threefold increase in mortality. Although fluid resuscitation is essential, the surgeon must be aware that time to operation is an important consideration. Patients may rarely present with a contained perforation and no signs of peritonitis. This subset of patients can be cautiously managed nonoperatively.

Before surgery, the patient should receive broad-spectrum antibiotics, including antifungal coverage. Surgical approach may be either laparoscopic or via upper midline incision, according to surgeon preference and proficiency with the goal of short operative time. Fluid in the peritoneum should be sent for culture and sensitivity. Liberal irrigation after benign perforation (5 to 10 L warm saline) was previously the standard of care. Recent research has questioned whether a liberal irrigation strategy spreads contamination to distant areas, worsening infection risk. At this time, we recommend suction and irrigation to control visible contamination. Routine biopsy is not necessary for perforated DU but should be performed in patients with giant ulcer (> 2 cm) or suspicion of malignancy.

Closure of Ulcer Perforation

Most perforated DU ulcers are small in diameter, typically 0.5 cm or smaller. Benson Graham is credited with the first description of omental patch closure with his publication of 51 successful cases in 1008, and the Graham patch remains the most durable repair for a small perforated ulcer. A well-vascularized, sessile, free pedicle of omentum is mobilized to cover the perforation. Interrupted sutures are placed on either side of the perforation through healthy portions of the duodenum but left untied. There should be no attempt to repair the primary defect, as suture material is likely to either tear the friable tissue surrounding the ulcer or to cause stricture of the intestinal lumen. Next, the omental flap is laid on the defect and the sutures are gently tied down (Fig. 1). The seal is tested for air leak by submerging the repair under saline and insufflating the stomach through a nasogastric tube. In the setting of air leak, additional interrupted sutures may be placed circumferentially around the patch. Drains are optional, however there is no evidence to support their routine use.

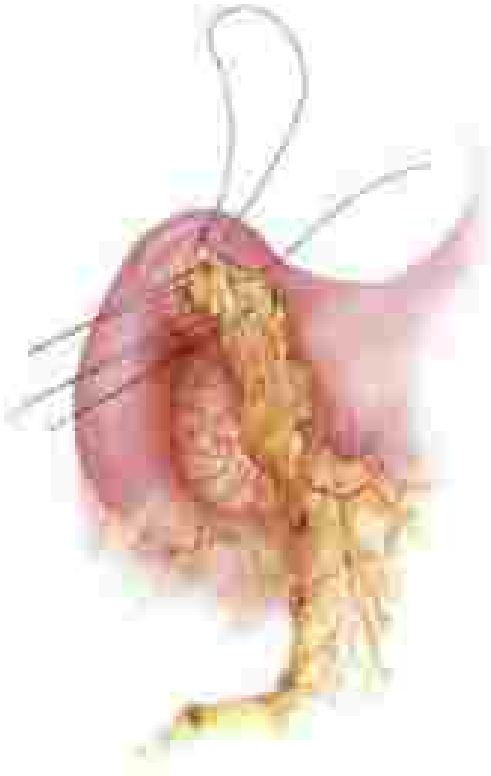

FIG. 1 The omental patch repair. (From Llorente JL, Sánchez C. Atlas of Gastroenterological Surgery, 2nd ed. Online CD-ROM. Houston, Methodist DeBakey Heart; 2007.)

Giant ulcers (>2 cm) should not be managed with a patch repair because of a risk of leak, undertaking, and stricture. The goals of an operation for giant perforation are to (1) control GI outflow, (2) provide the patient with nutrition, and (3) avoid creating a difficult duodenal plump in a hemodynamically unstable patient. "Damage control" surgical technique with tube duodenostomy is recommended. In this procedure, the duodenum is knuckled and the ulcer well freshly debrided. A Malecot catheter is placed directly into the ulcer defect and a purse-string absorbable stitch closes the ulcer defect around the malecot. A pedicle of omentum is mobilized and placed around the purse-string at the base, and a closed suction drain is placed nearby (Fig. 2). Combined, the omental pedicle and closed suction drain serve to control an expected small volume of leakage. Consideration should be given for placement of both a decompressive

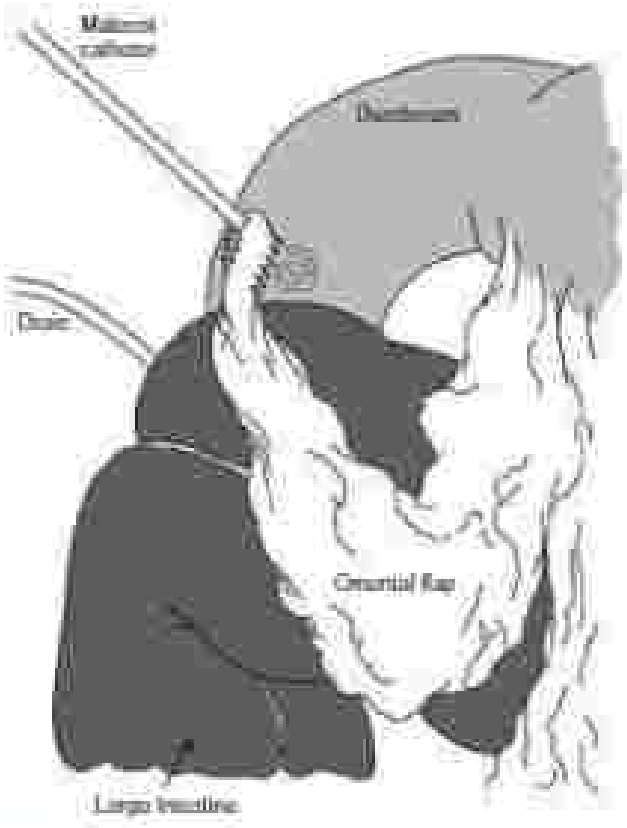

FIG. 2 Omental tube duodenostomy for giant perforated duodenal ulcer. *Modified from Kudo SE, Ogawa S, Hosokawa S. The rationale use of a wide tube duodenostomy in large duodenal perforations that cause shock. Br J Surg Case Rep 6: pp 205–214 2017.*

tube gastrostomy and feeding jejunostomy. Although both decompress the stomach and control gastric outflow, tube gastrostomy is superior to nasogastric decompression for postoperative respiratory outcomes, such as pneumonia. The peritoneum should be liberally irrigated and the abdomen closed.

Postoperatively, the patient is managed in the intensive care unit with the Malecot tube placed to gravity drainage and left in place for a minimum of 6 weeks to allow for tract formation. Enteral feeding is begun through the tube jejunostomy as soon as postoperative ileus resolves. Oral feedings are initiated at postoperative day 5 or 6 at the earliest and should begin conservatively with a liquid diet. Before removal of the Malecot drain, a 2- to 3-day champ trial should be initiated. Routine imaging of the drain before removal is optional. After removal, a dry gauze dressing should be placed until the tract closes.

Variability in ulcer location, patient condition, adhesions, and inflammation necessitate adaptability in managing perforated, giant ulcers. In a hemodynamically stable patient with giant, perforated DU, the preferred option is mobilization of the duodenum via kocherization, debridement of the ulcer edge to fresh, viable tissue, and then Roux-en-Y reconstruction between the ulcer edge and a limb of jejunum. Additional options include a loop of jejunum sutured to the ulcer or an antrectomy and Billroth II reconstruction with truncal vagotomy. If performing truncal vagotomy, nerve specimens should be sent to pathology for confirmation and documentation. Each of these procedures is associated with increased operative time and risk of leak in the postoperative period.

Minimally Invasive Treatment

As mentioned previously, the choice of laparoscopic versus open approach for a stable patient with perforation should be made based on surgeon experience. Multiple studies have demonstrated equivalence in the two approaches among experienced surgeons. We recommend an open approach for surgeons who do not routinely perform laparoscopic foregut surgery. The principles of laparoscopic repair of perforated duodenal ulcer are the same as those for open surgery.

There are several reports, predominantly from 2009 through 2014, on the use of natural orifice transluminal endoscopic surgery with or without laparoscopic guidance to repair small perforated DUs. This technique has been hypothesized to represent a lower physiologic insult. The proposed technique begins with diagnostic laparoscopy to confirm perforation. Once the perforation is identified, an endoscope is advanced transorally to the site of perforation. Either a small tongue of omentum or the falciform ligament is pulled into the defect. The endoscope is then used to place clips attaching the omental or falciform plug to the duodenal wall. This technique is best suited for small perforations, with the most ambitious studies estimating 50% of small perforations can be ultimately managed in this manner. Because there have been no recent reports or randomized trials of the natural orifice transluminal endoscopic surgery technique published to date, we cannot recommend this technique.

Postoperative and Long-Term Management

Postoperative care for patients with perforated DU is standardized. Sepsis protocols should be followed. In accordance with the 2015 *STOP-IT Multicenter Study of Duration of Antibiotics for Intra-abdominal Infection* trial, antimicrobials should be continued for 4 to 7 days postoperatively and then stopped. Nasogastric tube removal and oral feeding decisions are made on clinical grounds, typically after upper GI radiographic studies. The placement of a decompressive gastrostomy tube during surgery allows the patient to be managed without a nasogastric tube and decreases postoperative respiratory complications. Typically, we recommend against routine placement of closed suction drains because of a lack of supporting evidence; if placed, the drains should be removed 24 hours after the patient tolerates oral feeding.

BLEEDING DUODENAL ULCER

Although the most common indication for operation in DU is perforation, the most common indication for hospitalization of DU is bleeding. A total 75% of cases of upper GI bleeding due to DU will respond to medical management alone. The Glasgow Blatchford score has been validated to predict which patients may be safely managed as an outpatient and which will need endoscopic management. The full Rockall score (which takes into account endoscopic findings) is best at predicting mortality after hospitalization and first endoscopy. A multitude of techniques exist for endoscopists, including epinephrine injection, bipolar cautery, endoclipping, and thrombin/thrombin application. Epinephrine injection should always be accompanied by another modality. If the first endoscopy is unsuccessful or the patient exhibits persistent shock, a second attempt at endoscopic management is indicated. With modern endoscopy, only 5% to 10% of patients with bleeding DUs will require an operation.

For patients who continue to bleed after two endoscopies or who are hemodynamically unstable, catheter directed angioembolization or surgical exploration is mandated. Whether surgery or angiography is the first modality of choice is highly dependent on physician experience and protocols at the hospital level. Rather than recommend surgery versus angioembolization, we believe that each hospital should establish protocols for patients who fail endoscopic management. If possible, teams should drill, simulate, and train in a multidisciplinary fashion for these patients because these cases represent a challenge to time and logistics.

Operative morbidity and mortality for bleeding DUs is high; however, the majority of these patients succumb to multiorgan failure rather than exsanguination. Early identification of patients who are likely to fail endoscopic management is a critical decision

point that will affect survival. Transfusion of six or more units of packed red cells is a commonly accepted indication for operation. Once this threshold is hit, operative intervention should not be delayed because these patients likely have large bleeding vessels destined to fail other management modalities. Prompt surgery to avoid blood loss and shock and minimize the total transfusion required will affect postoperative mortality. The gastroduodenal artery, located in the posterior and proximal duodenum, is commonly involved and is amenable to both angioembolization and surgical oversewing.

Operation for Bleeding Duodenal Ulcer

Preoperative endoscopic evaluation identifies the site of bleeding in 80% of cases. An upper midline incision is performed and the duodenum is kocherized. The surgeon's nondominant hand can compress the gastroduodenal artery at this time, limiting hemorrhage. For cases in which the site of bleeding is known, a limited incision of the anterior duodenal wall at the site of the bleeding is appropriate. In cases in which the bleeding site has not yet been identified, the duodenum is opened with a longitudinal incision, and extended into the pylorus to examine the duodenal bulb and gastric antrum. Bleeding at the ulcer bed is controlled locally using a combination of "U" stitches and figure-of-8 stitches proximal and distal to the actual bleeding site. Suture ligation of the gastroduodenal artery has been shown to decrease rebleeding, but surgeons should be aware of variant anatomy, including a 8.5% incidence of accessory right hepatic artery arising from the gastroduodenal artery.

Once bleeding has been controlled, consideration is made between closing the duodenotomy and ending the operation or performing a definitive acid reducing operation. Previously, a definitive acid reducing surgery was mandated because of high rebleeding rates; however, in the modern era of PPIs, *H. pylori* testing and eradication, and avoidance of NSAID therapies, these operations are no longer required. In the rare instance of a stable patient who is unlikely to be compliant with postoperative medical management or who has a giant (>2 cm) bleeding ulcer, there are options for definitive ulcer management: antrectomy with vagotomy, truncal vagotomy with pyloroplasty, or a vagotomy can be combined with a gastrojejunostomy for drainage.

GASTRIC OUTLET OBSTRUCTION

Of all indications for ulcer operation faced by the modern surgeon, operation for relief of gastric outlet obstruction is the least frequent and most likely to be planned. DU may present as gastric outlet obstruction resulting from edema and dysmotility associated with obstruction. These patients typically complain of nausea, emesis, weight loss, early satiety, epigastric pain, and distention. The patient's history in combination with upper endoscopy remains the diagnostic modality of choice, and an obstructing mass must be excluded via computed tomography scan and biopsy of the ulcer. This acute obstruction is typically reversible with bowel rest, PPIs, and *H. pylori* diagnosis and eradication.

If an ulcer is allowed prolonged time without treatment, chronic DU may form, and can lead to obstruction via scar formation. Compared with acutely obstructed patients with DU, chronically obstructed patients may additionally complain of weight loss and should be examined for signs of underlying GI malignancy, such as jaundice and adenopathy. The malignancy rate in this patient population is significantly higher compared with all other presentations of DU, ranging from 10% to 40%. Endoscopic dilations and medical ulcer treatment can delay operation for months or years in at least one half the patients with benign gastric outlet obstruction from duodenal ulcer or serve as a palliative operation in the malignant setting. Malignancy presenting as DU should be managed according to oncologic guidelines such as those of the National Comprehensive Cancer Network. The decision to operate for benign gastric outlet obstruction resulting from chronic duodenal ulcer should not be undertaken lightly because each operation is prone to complications. If required, antrectomy with vagotomy, loop gastrojejunostomy, and Billroth II are all potential options. The procedure of choice should take into account surgeon experience and the patient's unique anatomy.

DIFFICULT DUODENAL STUMP

During resection, careful consideration must be made for the duodenal stump. Leak from the duodenal stump is associated with significant morbidity and mortality. This complication is most associated with the Billroth II procedure. Tissue edema, technical error, infection, local blood clot formation, overuse of sutures leading to ischemia, and concurrent pancreatitis are known contributory factors.

To prevent creation of a difficult duodenal stump, the ulcer bed, if not resected, should have secure hemostasis because it will be unreachable postoperatively by endoscopy should bleeding occur. Whenever possible, the duodenal stump should be closed with a stapler and reinforced with Lembert sutures. If stapled closure cannot be accomplished because of inflammation, adhesions, or scarring, then interrupted suture closure in two layers can be used. The closure should be tested by immersing it in saline and observing for air bubbles. Next, healthy omentum is sewn over the closure and closed suction drain placed in close proximity. Should leak from the duodenal stump occur, it is managed conservatively except in the setting of peritonitis or sepsis. Primary repair of the leak is typically not successful, thus Roux-en-Y reconstruction, end-to-side duodenojejunostomy, or catheter drainage and controlled fistula creation are recommended.

CONCLUSION

Modern general surgeons still face challenges in the management of DUs. Few indications exist for a planned operation addressing DUs; therefore, younger surgeons are no longer able to build of a repertoire of experience in elective ulcer operations. Surgeons today operate in the face of life threatening hemorrhage, perforations resulting from perforation, and obstruction is typically older, more acutely ill patients with chronic diseases. The modern surgeon needs to treat DUs in a team-based setting, working closely with endoscopists, intensivists, interventional radiologists, anesthetists, and emergency physicians. Success depends on the recognition of complications of DU (bleeding, perforation, and obstruction) and mobilization of the team to find the optimal treatment. To maximize survival, complicated cases must proceed through presentation, resuscitation, receipt of medications, endoscopy, and angiography, and if all else fails, to the operating room for emergency surgery. The surgical time should be kept as short as possible by performing the most straightforward operation that the patient can tolerate.

MANAGEMENT OF ZOLLINGER-ELLISON SYNDROME

E. Christopher Ellison, MD, FACS, and Mary E. Dilsaver, MD, ME, [illegible]

Zollinger Ellison syndrome (ZES) is a medical condition characterized by severe and refractory peptic ulcer disease that may or may not be associated with diarrhea. It was first described in 1925 by Zollinger and Ellison, who reported two cases of ulcer diathesis associated with jejunal ulcerations and required total gastrectomy after multiple failed ulcer operations. In both of the initial patients, non-beta islet cell tumors were identified in the pancreas. Zollinger and Ellison postulated that these tumors were possibly secreting a hormone that caused acid secretion and the peptic ulcer disease. In the discussion of the paper presented at the American Surgical Association in 1935, Lester Dragstedt, the father of vagotomy, commented that the cells in these tumors identified in the pancreas could be similar to the cells in the gastric antrum that produce gastrin. The syndrome name was suggested by Ben Eiseman at the Society of University Surgeons meeting in 1956. Subsequent investigation by a group at the University of Liverpool in 1960, led by Rodney A. Gregory and Hilda J. Tracy, found that tumors from patients with ZES contained high amounts of a gastrin like substance by using a bioassay on extracts of the tumors. Before the early 1970s, diagnosis of the condition required astute clinical assessment and a high index of suspicion because there were no blood and or imaging tests to help establish the diagnosis.

In 1966, the gastric radioimmunoassay (RIA) was described by James H. McGuigan and became readily available in the early 1970s. This now serves as the mainstay of diagnosis. In early reports, before gastrin RIA, patients usually had multiple gastric operations before establishing the diagnosis. Multiple reports showed that total gastrectomy was the foundation of successful treatment and reduced the mortality of the syndrome because the cause of death was usually related to complications of the ulcer diathesis, such as perforation or bleeding. Fortunately, advances in pharmacology, control of acid secretion with histamine 2 (H_2) antagonists and proton pump inhibitors (PPIs) have obviated the need for total gastrectomy. Total gastrectomy is no longer part of the management of ZES except in highly unusual cases. Today, it is established that ZES is caused by the secretion of gastrin from neuroendocrine tumors that arise in the pancreas, duodenum, or ectopic sites. The tumors are called gastrinomas. The syndrome is associated with multiple endocrine neoplasia type I (MEN-1) in 20% to 25% of cases. Surgical treatment today is focused on resection of gastrinoma and reliance on long-term pharmacologic suppression of acid secretion for control of the peptic ulcer disease and management of the hyperparathyroidism and other endocrine conditions that may be associated with MEN-1.

CLINICAL PRESENTATION

Gastrinoma is the second most common functional neuroendocrine tumor with an annual incidence reported as 1 to 3 cases per million people. Gastrinoma is the underlying cause of peptic ulcer disease in approximately 0.1% to 1% of patients and, as such, it is the cause of all causes of ulcer disease.

ZES is usually diagnosed in the fifth decade of life. Although it may occur in children, adolescents, or the elderly, it is diagnosed between ages 30 and 60 years in 90% of patients. ZES most commonly occurs as a sporadic disease; however, in 20% to 25%, it is associated with MEN-1. Indeed gastrinoma is the most common functional neuroendocrine tumor in MEN-1 occurring in 50% of patients. Hence, in the workup of patients with suspected gastrinoma, MEN-1 must be excluded. In addition, patients with MEN-1 should be screened for gastrinoma. Patients with MEN-1 have onset of the disease at a younger age. The 50th percentile of the age of onset of ZES was 33.2 years for patients with MEN-1 compared with 43.5 years for sporadic gastrinoma. In addition, gastrinoma may occur in association with Von Hippel Lindau syndrome and Von Recklinghausen's disease.

Importantly, ZES is not the initial diagnosis in 97% of patients. The symptoms at presentation for this disease have changed little despite more effective pharmacologic treatment of gastric hypersecretion and widespread use of these agents for symptoms of dyspepsia and other digestive complaints. The clinical presentation is not specific for gastrinoma and there is overlap of symptoms associated with this illness and other more common gastrointestinal conditions accounting for the high frequency of misdiagnosis and delay in diagnosis. In reported series, abdominal pain and diarrhea were the most common symptom occurring in more than 70%, followed by heartburn (40%), nausea (30%), vomiting (25%), and weight loss (17%). Only 11% of patients had a single symptom.

Although there is an increased awareness of ZES, multiple authors have noted that the diagnosis is more difficult today given the common use of PPIs. The diagnosis can usually be established by measurement of fasting serum gastrin levels when off PPIs, yet the average time from onset of symptoms to diagnosis remains between 6 and 8 years. Contributing to the delay in diagnosis is that many patients with ulcer disease are effectively treated with H_2 antagonists or PPIs without excluding the possible diagnosis of ZES. Such treatment controls the acid secretion and related symptoms and hence may further delay the diagnosis if gastrinoma is not considered in the initial differential diagnosis.

CLINICAL PATHOLOGIC CORRELATION

Gastrinomas are usually found in the pancreas or duodenum within the region known as the gastrinoma triangle which includes the head of the pancreas and duodenum (Fig. 1). This imaginary triangle is bounded by the cystic duct, the second and third portion of the duodenum and the neck and body of the pancreas. Two-thirds of primary gastrinomas occur in this region. In addition, gastrinomas may occur in ectopic locations such as the stomach, bile duct, periportal lymph nodes, ovaries, lungs, and heart. In contrast to the original studies of ZES, most gastrinomas are now found in the duodenum and not the pancreas. It has been estimated that 50% to 70% of gastrinomas occur in the duodenum. These are usually most common in the first portion of the duodenum with a descending incidence as one goes more distally. Duodenal gastrinomas tend to be very small and can be difficult to identify preoperatively and during operation. In patients with MEN-1, both pancreatic and duodenal gastrinomas occur. Patients with MEN-1 are more likely to have multiple tumors in the pancreas or duodenum.

Most gastrinomas are malignant. Yet, gastrinomas are characteristically slow growing and well differentiated and have a low proliferative rate with a Ki-67 of 1% to 2%. Hence, the disease is usually more indolent and slow growing than other gastrointestinal malignancies. Gastrinomas are associated with lymph node metastasis in 50% to 80% of patients, but unlike most cancers, lymph node metastases have minimal impact on survival. Liver metastases occur in about 25% of patients and are more common with pancreatic primary tumors, particularly those occurring to the left of the superior mesenteric vessels. Unlike lymph node metastases, liver metastases portend a poor prognosis. The extent of liver involvement is an important predictor of survival. In patients with diffuse

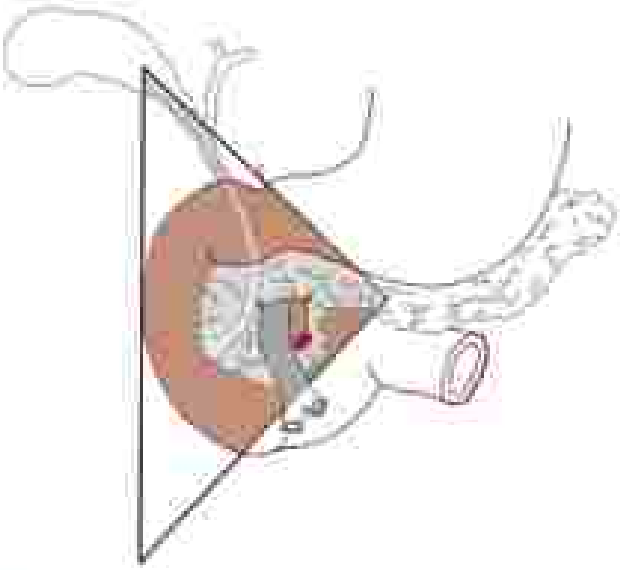

FIG. 1 The gastrinoma triangle is an imaginary space marked by the cystic duct, the duodenum, and the junction of the neck and body of the pancreas. (From University of Cincinnati Surgical Associates, Inc., and Ariel Surgical Handbook. ... on Philadelphia: Elsevier 2003.)

liver metastases, the 10-year survival is 10% to 12% compared with 97% in the absence of liver metastases. In addition, the prognosis is better in patients with single liver lobe metastases with a 10-year survival of nearly 60%. Regardless of location, the primary tumor size is predictive of distant metastasis (Table 1).

A staging system for neuroendocrine tumors of the pancreas, stomach, and duodenum has been proposed by a multidisciplinary international group at the Frascati Consensus Conference in 2006 (Rindi et al.) and the reader is referred to that article for the suggested readings.

DIAGNOSIS

Although ZES is rare, a patient should be referred for prompt workup for the presence of refractory peptic ulcer disease, longstanding diarrhea, ulcer disease in the absence of *Helicobacter pylori* infection, or failure to improve after treatment for established *H. pylori* and acid suppression therapy. In addition, the presence of hypercalcemia and hypercalciuria should raise suspicion of possible MEN-1; these patients should be screened for gastrinoma and MEN-1. The algorithm for the diagnosis of gastrinoma is shown in Fig. 2. The diagnostic steps include measurement of gastric acid, baseline fasting gastrin levels, and secretin-stimulated serum gastrin levels as well as imaging.

Fasting serum gastrin is the appropriate initial diagnostic test for patients with suspected ZES; however, it is not sufficient alone to establish the diagnosis as several medical conditions may cause hypergastrinemia. Most commonly, pernicious anemia, atrophic gastritis, and pharmacologic acid suppression may cause achlorhydria, which can cause hypergastrinemia resulting from the absence of acid suppression of gastrin secretion from the G cell in the gastric antrum. Other conditions that may cause fasting hypergastrinemia associated with increased acid hypersecretion include *H. pylori* infection, gastric outlet obstruction associated with peptic ulcer, antral G-cell hyperplasia, retained antrum, short bowel syndrome, and renal failure. Pernicious anemia and atrophic gastritis and the associated achlorhydria are the most common causes of hypergastrinemia. In these patients, it is not unusual for the fasting gastrin level to exceed 1000 pg/mL. Hence, a fasting serum gastrin level greater than 1000 pg/mL is not diagnostic for ZES unless it occurs in association increased gastric acid secretion (gastric pH <2).

TABLE 1 Primary Tumor Size and Frequency of Distant Metastases

Tumor Case	Diameter Range (cm)	No. of Patients	% (Mean) Metastases
T0 (no tumor)	0	18	0
T1	0.8–1.9	23	48
T2	1.2–2.6	22	14
T3	2.2–7.6	16	12
T4	3.3–8.5	29	59

Modified from Ellison EC, Johnson LK. *Zollinger-Ellison syndrome: a comprehensive review of historical, scientific, and clinical considerations.* Curr Probl Surg 2006;44:13–106.

It is important to emphasize that determination of gastric pH and verification of acid production is essential to confirm the diagnosis of ZES. If there is no acid in the stomach of a patient not being treated with H_2 antagonists or a PPI, then the patient is unlikely to have the diagnosis of ZES; no acid, no ZES!

Serum gastrin is measured by RIA, a readily available technique. It is preferable to send properly collected specimens to a reference laboratory for determination of serum gastrin levels. The director of your hospital laboratories will have access to an appropriate reference laboratory. The patient should be off pharmacologic acid suppression with PPI for a minimum of 72 hours (ideally, 7 days) before testing. H_2 receptor antagonists should be prescribed during this time to control acid secretion. In ZES, a normal fasting gastrin is very rare, occurring in only 4% to 5% of patients. This renders serum gastrin measurement a very good screening test for ZES, with a sensitivity that approaches 99%. If the fasting gastrin is normal and the clinician continues to suspect ZES, then a referral to medical center with expertise in gastrinoma is warranted.

Patients with suspected ZES whose have fasting hypergastrinemia and measurement of a gastric pH showing the presence of gastric acid should undergo confirmation with provocative stimulation of gastrin with secretin. Following an overnight fast, patients are given an intravenous bolus injection of secretin of 0.4 μg/kg of body weight. Blood drawn for determination of gastrin levels are collected and analyzed at 0, 2, 5, 10, 20, and 30 minutes following secretin administration. In our experience, it has not been necessary to discontinue PPIs or H_2 blockers for this test. Minimal side effects of intravenous secretin administration may include flushing and nausea.

Multiple definitions for a positive secretin test exist based on the absolute change in gastrin concentration. The most common threshold used is an increase in gastrin of 110 pg/mL over baseline, as proposed by Deveney. We have found this threshold to be accurate in nearly 100% of patients. Rarely, false negative or false positive tests may occur. The false positive rate is 0% in patients without achlorhydria when an increase over baseline of more than 110 pg/mL is used.

Once the biochemical diagnosis of gastrinoma is confirmed, the patient should be screened for MEN-1 with measurement of serum calcium, parathyroid hormone, and prolactin.

TUMOR LOCALIZATION

In patients considering surgical exploration, imaging is required to localize the gastrinoma. The initial localization test should be cross-sectional imaging with computed tomography (CT) scan of the abdomen and pelvis, with fine cuts through the pancreas, or magnetic resonance imaging (MRI). Neuroendocrine tumors are hypervascular and therefore demonstrate a greater degree of enhancement than the normal pancreas during the arterial and capillary phases of the

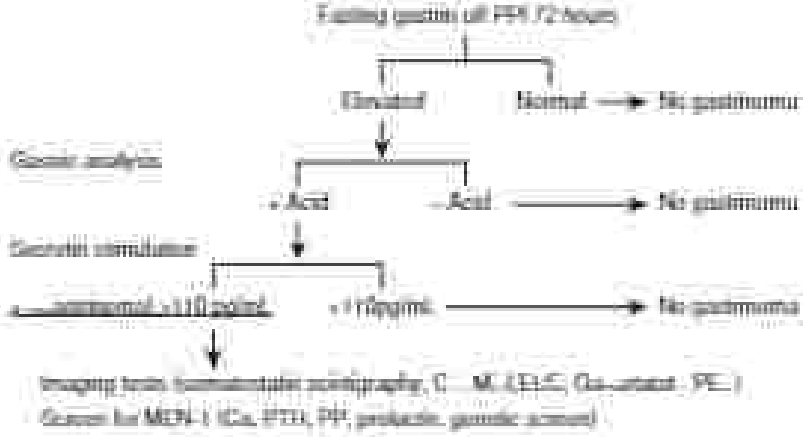

FIG. 2 Diagnostic algorithm for Zollinger-Ellison syndrome. *Ca*, calcium; *CT*, computed tomography; *EUS*, endoscopic ultrasound; *MEN-1*, multiple endocrine neoplasia type 1; *MRI*, magnetic resonance imaging; *PET*, positron emission tomography; *PPI*, proton pump inhibitor; *PTH*, parathyroid hormone.

FIG. 3 ^{68}Ga-dotatate positron emission tomography showing duodenal gastrinoma and liver metastases.

contrast bolus. This is helpful in identification and differentiation of pancreatic neuroendocrine tumors (PNETs) from pancreatic cancer. Dual-phase MRI of the abdomen with delayed images may be helpful in delineating the primary tumor or metastases to the liver. Somatostatin receptor scintigraphy (SRS) can also be helpful in the preoperative localization of gastrinoma. SRS has been reported to be significantly better than all of the conventional imaging methods in the identification of gastrinomas later found at surgery, but SRS will still miss 20% of gastrinomas.

In most countries, ^{68}Ga dotatate positron emission tomography (PET)/CT has replaced SRS for localization of neuroendocrine tumors, including those causing ZES (Fig. 3). Gastrinomas are slow growing tumors. ^{99}In-diethylenetriamine PET/CT is not commonly used for initial evaluation. Because of the slow metabolic activity of gastrinomas in initial stages, they are not typically avid on ^{18}F-fluorodeoxyglucose PET/CT. In contrast to FDG PET/CT, ^{68}Ga Dotatate PET demonstrates a high uptake because neuroendocrine tumors express significant somatostatin 2 receptors. ^{68}Ga Dotatate PET identified significantly more lesions than ^{111}In DTPA octreotide scintigraphy. The National Comprehensive Cancer Network guidelines has added ^{68}Ga Dotatate PET/CT as an appropriate test in the management of neuroendocrine tumors.

Endoscopic ultrasound (EUS) is an invasive alternative to be considered when cross-sectional imaging and ^{68}Ga Dotatate PET have not identified the location of the gastrinoma. In addition, a biopsy can be accomplished at the time of EUS. The sensitivity of EUS to localize small PNETs is excellent (as high as 97%) compared with CT (86%) or MRI (79%).

Alternatively, a selective secretin stimulation test may be performed with direct secretin injection into the hepatic, splenic, gastroduodenal, and superior mesenteric artery with sampling from the right hepatic vein for measurement serum for gastrin. Very small doses of secretin are selectively administered intraarterially with sampling at 0, 20, 40, and 60 seconds. A step-up in hepatic vein gastrin will indicate the dominant blood supply of the tumor and its likely location.

To minimize costs, one may consider the following sequence to imaging: Cross-sectional imaging with CT or MRI followed by ^{68}Ga dotatate PET. If these studies are negative, then EUS should be considered.

INDICATIONS FOR SURGERY IN GASTRINOMA

After the diagnosis of gastrinoma is established, then the surgeon should consider whether an operation is indicated. In sporadic patients, exploration is warranted in the presence of a positive imaging study. In addition, sporadic gastrinoma patients with negative imaging warrant exploration as tumors in the duodenum, pancreas, or lymph node primaries may be very small and not detectable by imaging. Exploration by an experienced gastrinoma surgeon will identify a tumor in 80% to 90% of patients with negative imaging. Survival in patients that have negative imaging studies or who have no tumors identified at operation is exceedingly high, approaching 99% 20 year disease free survival without later stage progression.

In the MEN-1 patient, surgical treatment of the associated parathyroid hyperplasia is essential. This typically involves a 3½ gland parathyroidectomy or a total parathyroidectomy, followed by transplant of parathyroid tissue in to the forearm. Control of hyperparathyroidism with normalization of serum calcium will reduce baseline gastrin levels and may reduce the medication requirements to control gastric acid secretion. This has been reported to be done at the same time as abdominal exploration; however, our preference is to perform parathyroidectomy as the first procedure and the exploration for gastrinoma at a later date.

The role of resection of gastrinoma in MEN-1 patients is less clear. Some groups recommend pancreaticoduodenectomy or total pancreatectomy for gastrinoma with MEN-1. From one studies, those of the National Institutes of Health, and in the current European Neuroendocrine Tumor Society and North American Neuroendocrine Tumor Society guidelines for treatment of ZES MEN-1 patients, however, these aggressive resections are not routinely recommended. First, without aggressive resection, these patients may survive up to 30 years; hence, the benefit of such surgery has been difficult to establish. Second, the metabolic sequelae, including diabetes and pancreatic insufficiency, may worsen the quality of life for these patients.

In our institution, the decision to remove the gastrinoma in a patient with MEN-1 is determined by imaging. (1) Image negative patients are observed and do not undergo exploration given the low cure rates with surgery; (2) image positive patients with no distant metastases undergo exploration for local surgical resection because resection has been shown to improve survival independent of a medical cure.

GOALS OF SURGERY

Tumor control is the primary goal of surgery in ZES. First, removal of the primary tumor or tumors is accomplished to reduce the possibility of metastatic disease at a later date. Second, removal of all tumors can potentially correct the hypergastrinemia that causes ZES and reduce the need for long term PPI use. It is agreed that gastrinomas have a greater potential to metastasize to the liver even when they are small (<2 cm). Size is clearly related to distant metastases; therefore, surgical tumor control is beneficial. Norton and colleagues showed ZES patients having surgery have improved long term survival and were less likely to develop metastases. Ellison showed a long term survival advantage in both sporadic and MEN-1 patients having a BI or BII resection compared with those having an R2 resection in which BII is defined as complete surgical excision with normal postoperative serum gastrin levels, R1 is defined as residual microscopic disease or complete tumor excision and persistent hypergastrinemia, and R2 is defined as gross residual disease with persistent hypergastrinemia.

TECHNIQUE OF SURGICAL EXPLORATION AND RESECTION OF GASTRINOMA

Preoperative Management

Before the operation, the serum gastrin levels, secretin provocative test, and imaging should be reviewed. If there is any question to the accuracy, they should be repeated. The surgeon should consider whether special equipment may be necessary including intraoperative ultrasound, an endoscope, and cart if endoscopy is planned as part of the procedure to identify duodenal tumors, and indocyanine green for intravenous injection, and a near infrared light source that may aid in tumor localization.

The morning of surgery, the patient should receive the routine administration of a proton pump inhibitor, the anesthesiologist should have this available because redosing may be necessary.

Operative Management

General endotracheal anesthesia is preferred. A nasogastric tube should be inserted. A gastric pH should be determined at the beginning of the case to determine the effectiveness of acid pharmacologic acid suppression. The pH should be greater than 5; if it is not, an additional dose of PPI may be necessary. The anesthesiologist should monitor the nasogastric tube output because, in ZES, large volumes of gastric secretion may occur.

Laparotomy is performed through a midline incision. Although there are reports of laparoscopic exploration and there will likely be reports of robotic exploration, an open approach provides the surgeon with the best exposure and tactile feedback to help identify very small tumors. No gastric procedure should be planned unless there are specific complications of ZES that may require surgical treatment such as gastric outlet obstruction, a bleeding ulcer, perforation, and, in patients with previous gastric surgery, marginal ulceration or gastrojejunocolic fistula.

The essential steps in surgical exploration for gastrinoma include:

1. Midline laparotomy.
2. Palpation of the intraabdominal organs, including running the small intestine, is necessary to exclude secondary tumors or tumors in an ectopic location. Masses in the liver may be further examined by ultrasound and should be biopsied by excision or needle biopsy depending on the size. Given the extensive preoperative imaging in gastrinoma, the surgeon will rarely be surprised by unsuspected metastatic disease, but this may occur, particularly with small miliary (<1 mm) lesions over the surface of the liver that we have observed in 2% of patients.
3. Exposure.
   a. A wide Kocher maneuver is performed to the extent that the surgeon can visualize the left renal vein. This will facilitate bimanual palpation of the head of the pancreas and possible use of intraoperative ultrasound.
   b. Division of the gastrocolic omentum to widely open the lesser sac for exposure of the body and tail of the pancreas.
4. Intraoperative localization may be facilitated by the intravenous administration of indocyanine green 0.1 mg/kg and within 1 minute of injection examination of the pancreas and duodenum with near infrared fluorescence visualization (Fig. 6).
5. Assessment of the pancreas.
   a. Bimanual palpation of the head of the pancreas, taking note of any masses for later excision.
   b. Bimanual palpation of the body and tail of the pancreas is facilitated by incising the peritoneum overlying the inferior edge of the body and tail of the pancreas.
   c. Use of intraoperative ultrasound to map the head, uncinate process, body, and tail of the pancreas, noting any hypoechoic masses for later excision.
6. Palpation of the hepatoduodenal ligament and removal of any enlarged lymph nodes, which are sent for standard histology unless no primary gastrinoma is identified in the typical locations, in which case, they are sent for frozen section because these represent an ectopic lymph node primary.
7. Excision of suspicious pancreatic nodules and frozen section.
   a. In the head of the pancreas and uncinate process, local excision of tumors less than 2 cm in diameter and not involving the pancreatic duct as determined by intraoperative ultrasound. These tumors are hypervascular and use of bipolar coagulation aids in the dissection. Larger tumors may require a pancreaticoduodenectomy.
   b. In the body and tail of the pancreas, the tumors usually are near the pancreatic duct and, as such, distal pancreatectomy and splenectomy are preferred to avoid injury to the pancreatic duct. Because the majority of gastrinomas are malignant, splenectomy is warranted, as is distal pancreatectomy to remove lymph nodes in the splenic hilum.
8. Examination of the duodenum and removal of duodenal nodules in the same stage. This requires a longitudinal duodenotomy and internal palpation of the duodenum. Most of the tumors are in the first portion of the duodenum with descending incidence the further distal in the duodenum. Use of external palpation or ultrasound will only identify 20% to 30% of these tumors. Although intraoperative endoscopy and transillumination of the duodenum may also be helpful in some cases to identify, a duodenal gastrinoma false negative results are not infrequent. Suspected duodenal gastrinomas may be locally excised and do not require duodenal resection. The tumors are submucosal, and closure of the mucosal defect created by the excision is warranted. For lesions on the anterior or lateral wall of the duodenum, full thickness excision is possible. The duodenum is closed longitudinally with a single layer of 3-0 interrupted silk sutures. We have not found an advantage to transverse closure.
9. A closed suction drain is placed near any sites in the pancreas in which a tumor was locally excised or the transected pancreas if a pancreatectomy was performed.

Postoperative Management

The nasogastric tube is removed at the discretion of the attending surgeon. PPI treatment is continued by intravenous administration

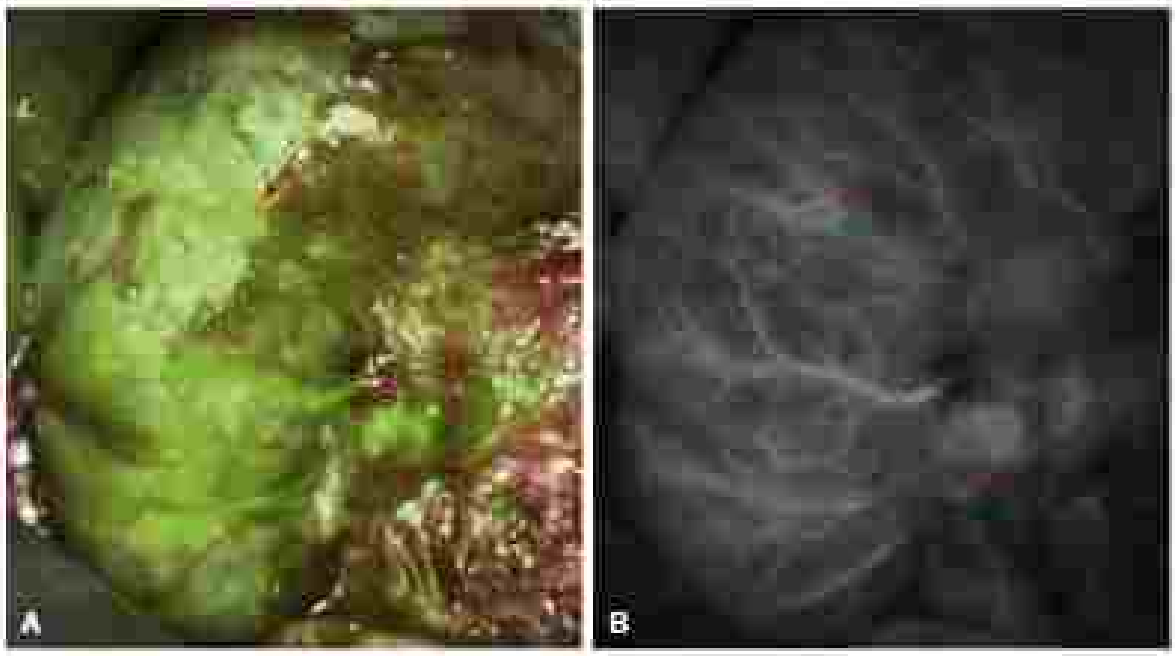

FIG. 4. Near-infrared fluorescence of pancreatic head and duodenum 30 seconds after intravenous (A) indocyanine-green injection (overlay and (B) grayscale overlay. A portaduodenal metastatic lymph node (arrowhead) and a duodenal wall gastrinoma 2 cm medial to the major papilla (arrow) are visible. (From Hartwig W., Jimeno A, Wilson J, et al. Indocyanine-green near-infrared fluorescence visualization of the duodenal gastrinoma in a patient with Zollinger–Ellison syndrome. Surgery. 2010;148(1):8-14.)

until the patient is taking liquids orally, he or she then may be switched to an oral form. Partial cell hyperplasia induced by the hypergastrinemia may take 3 months or more; as such, PPI treatment should be continued for 3 months in a patient with normal postoperative fasting gastrin. A fasting gastrin level is drawn on day 3 and repeated at the first clinic visit. In a patient with established ZES, we have not seen postoperative false-positive elevations of gastrin caused by continued PPI therapy. If postoperative fasting gastrin levels are elevated, then PPI therapy should be continued and repeat imaging completed at 6 months after surgery with consideration of reoperation if there is positive imaging.

Results of Treatment

Biochemical cure of sporadic gastrinoma is reported in 30% to 50% of patients (Table 2); however, recurrence has been documented in nearly one-third of patients. The average time to recurrence is 5 to 10 years. Regardless of achieving biochemical cure, complete resection of all gross tumors is associated with improved survival. The 10-year disease-specific survival in patients having R0/R1 resection of sporadic gastrinoma is 85%, compared with 40% for patients having R2 resection and 25% for those having no resection. Pancreatic gastrinoma survival fares well when compared with other PNETs (Table 3).

TABLE 3 Median Survival of Pancreatic Gastrinoma Compared with Other Pancreatic Neuroendocrine Tumors

Tumor Type	Median Survival (yr)
Insulinoma	12.7
Gastrinoma	10.2
VIPoma	2.7
Mixed tumors	5.9

Modified from Krueger KM, Hilsabeck N, Kelebow E. Malignant functioning neuroendocrine tumors of the pancreas: a survival analysis. Surgery. 2010;148(3):580-589.

In our experience of MEN 1 patients operated on with a curative intent, cure was achieved in only 6% of patients; others report similar results (Table 4). The 10-year survival with gastrinoma in MEN 1 with R0/R1 resection was 90%, compared with only 42% for patients having an R2 resection or no resection. Because R2 resections do not increase survival, MEN 1 patients with extensive metastatic disease or locoregional spread that precludes complete resection rarely benefit from surgical resection, and these patients are typically not offered surgery.

- [illegible]
- Somatostatin analog, [illegible]
- Somatostatin receptor [illegible]
Short-acting octreotide
Long-acting octreotide
- [illegible]
- Lanreotide (Somatuline Depot)

Recurrent Gastrinoma

Norton and colleagues reported 223 patients in a prospective database that had an initial operation for ZES and then were subsequently managed with serial cross-sectional imaging (CT, MRI, ultrasound, and somatostatin scintigraphy). They reported that 52 patients (23%) underwent reoperation a mean of 6 years after the initial surgery for recurrent ZES with gastrinoma on imaging. Of the 52 reoperated patients, 12 had ZES with MEN 1. They found that, after reoperation, 18 of 52 patients were initially free of disease (35%), after a mean follow-up of 8 years, 13 of 52 remained disease free (25%). During follow-up, 30/52 (57%) of the reoperated patients died, of whom 7 died of disease (13%). The overall survival from first surgery was 84% at 20 years and 68% at 30 years.

These findings are important and suggest that ZES patients should have systematic imaging after curational surgery, and if gastrinoma recurs or is persistent, be given the option for reoperation. Patients with persistent or recurrent gastrinoma with negative imaging are unlikely to benefit from reoperation. Data concerning reoperation for recurrent image positive gastrinoma in MEN 1 are less clear; we are less likely to recommend reoperation in this situation.

Management of Metastatic Disease

Patients with malignant gastrinoma of the pancreas and duodenum not infrequently present with liver metastases. In these situations, it is essential for the surgeon to work collaboratively with a multidisciplinary team. The extent of disease burden in the liver often dictates the quality and length of survival. Surgical excision of both the primary tumor and liver metastases has been reported in the literature; however, its use should be considered carefully. Some authors suggest that select patients may see a survival benefit if a complete or near complete (90% or more) resection of hepatic metastases can be achieved. In addition, there are reports of long-term survival with liver transplantation for metastases from PNETs including gastrinoma.

A variety of options for the treatment of metastatic disease is shown in Box 1. The decision to proceed with treatment depends on the rate of disease progression and the patient's symptoms. Because gastrinoma is a rare condition, it is recommended that clinical trials be considered to help elucidate the best treatments in the future.

SUMMARY

In conclusion, ZES is a syndrome caused by gastrinoma. Two-thirds of cases are located within the gastrinoma triangle and associated with symptoms of peptic ulcer disease and diarrhea. The diagnosis of ZES is established by measuring fasting levels of serum gastrin, gastric pH, and secretin provocative gastrin stimulation. ZES is frequently associated with MEN 1; hence, this must be excluded in all patients. Treatment of ZES consists of medical control of symptoms with PPIs and evaluation for potentially curative surgery. Preferred preoperative imaging studies include cross-section MRI or CT and Octreotate PET/CT scans. EUS may be performed to further evaluate primary tumors if other testing is negative. All patients with resectable sporadic gastrinoma should undergo surgical exploration. The goal of surgery is tumor control. Two-thirds of the primary tumors are located within the gastrinoma triangle. Intraoperative tumor localization requires methodical exposure of the pancreas and duodenum for possible duodenal gastrinoma. In patients with MEN 1, surgical resection should be pursued only if there is a tumor located on imaging in the absence of metastatic disease. Patients with sporadic ZES and negative imaging should undergo surgery. In those patients who have synchronous or metachronous liver metastases, surgery should be performed if all visible tumor can be removed safely. Patients with recurrent ZES should be restaged and operation considered if localized tumor is identified. Patients with liver metastases benefit from coordinated care with a multidisciplinary team and not infrequently will have survival prolonged by surgical resection.

MANAGEMENT OF MALLORY-WEISS SYNDROME

Yu Liang, MD, and David W. McFadden, MD

Mallory Weiss syndrome was first described by G. Kenneth Mallory and Soma Weiss in 1929. They described 15 patients with a history of alcohol use who developed violent vomiting or retching followed by massive hemoptysis. Four of the 15 patients were found to have vertical gastric mucosal lacerations at the gastroesophageal junction (GEJ); Mallory Weiss tears (MWTs). In 1932, Mallory and Weiss reported six more cases of massive hemoptysis following forceful vomiting. It became clear to Mallory and Weiss that vomiting was the primary predisposing factor. For the next 40 years, there were sporadic case reports of Mallory Weiss syndrome in the literature.

The proliferation of flexible endoscopy in 1970s and 1980s transformed the diagnosis and treatment of upper gastrointestinal (UGI) hemorrhage. MWTs were found in about 10% of UGI bleeding (3%–15%) compared with ulcers being found in 50% of UGIB. Although forceful vomiting remains the most common cause of MWT, other associating factors have been reported in case studies or small case series. These precipitating factors include esophagogastroduodenoscopy, straining during defecation, lifting, blunt abdominal injury, epileptic convulsions, coughing, and hiccups under anesthesia. Before the advent of flexible endoscopy, UGIB from MWT treatment consisted of supportive observation or laparotomy for surgical hemostasis.

PATHOPHYSIOLOGY, INCIDENTS, AND RISK FACTORS

There are two possible scenarios for pathophysiology of MWT during emesis. During forceful vomiting, there is a sudden increase in pressure gradient between the abdominal and thoracic cavity. The pylorus closes while the lower esophageal sphincter, the gastric cardia, and the diaphragmatic hiatus relax. At the same time, the abdominal wall, the diaphragm, and the distal gastric wall contract to forcefully propel gastric content retrograde. This leads to retrograde prolapse of the proximal stomach into the esophageal lumen with tearing of the gastric and, occasionally esophageal, mucosa. Alternatively, the sudden increase in intragastric pressure and relaxation of gastric cardia leads to sudden dilation of gastric cardia and distal esophagus. This abrupt dilation may also lead to tissue laceration of the GEJ mucosa. For patients without hiatal hernia, MWTs tend to be located at the GEJ. For patients with hiatal hernia, MWTs tend to be located at gastric cardia. Isolated esophageal mucosal tears are unusual. The most common location for MWT is at the lesser curve (Fig. 1).

Wuerth and Richey recently published a nationwide analysis of UGI hemorrhage admissions from 2002 to 2012 in the United States. Their report showed a 21% decrease in all UGI hemorrhage. Because treatment of *Helicobacter pylori* and the use of proton pump inhibitors (PPIs), bleeding from gastritis and peptic ulcer decreased by 35% and 30%, respectively. MWTs accounted for about 7% of all UGIB. The hospitalization rate for MWT was essentially unchanged between 2002 and 2012. The mortality from UGIB decreased by 28%, whereas mortality from MWT decreased by 36% (Tables 1 and 2).

The majority of patients with gastrointestinal bleeding are males in their 50s and 60s. There are some distinct differences in the characteristics of patients bleeding from MWT compared with patients bleeding from ulcers (Table 3). About one half of the patients with MWT bleeding have a history of alcohol use, compared with 20% of patients with bleeding ulcers. Patients with liver disease have more severe MWT bleeding compared with those without. The prevalence of MWT in the cirrhotic population is comparable to the prevalence of MWT in the general population. Patients with bleeding from MWT are less likely to be in shock compared with patients with bleeding ulcer, 14% versus 6.7%, respectively. Patients with MWT bleeding have higher American Society of Anesthesiologists risk score compared with patients with bleeding ulcers. Endoscopic treatment was successful in 90% of patients with MWT bleeding and 95% successful in bleeding from ulcers.

Multiple small case series in the past demonstrated that 20% to 90% of patients with MWT have a hiatal hernia. Some consider hiatal hernia as a necessary predisposing factor; however, case series by Sugawa et al. found only 20% of the patients with Mallory Weiss syndrome have a hiatal hernia. A recent matched case control study reviewed more than 2000 cases of MWT and found hiatal hernia in only 26% of patients compared with 22% in the non-MWT controls (not significant). An association between hiatal hernia and MWT remains unanswered.

Diagnosis

Patients with UGIB from MWT usually present with a history of forceful nonbloody emesis follow by hematemesis. Only about 10% report a history of melena. Abdominal pain is uncommon. Association with alcohol is variable. Definitive diagnosis of MWT is impossible without direct visualization by flexible endoscopy or surgery.

Flexible endoscopy is the standard diagnostic and therapeutic modality for treatment of UGIB. Resolution is essential for visualization of the Mallory Weiss lesions at the cardia mucosa. About 75% of the lesions will have no active bleeding at the time of endoscopy. Most lesions are 0.5 to 2.5 cm but lesions up to 5 cm have been reported. Complete evaluation of the UGI track is also essential because coexistence of bleeding from varices, gastritis, duodenitis, or ulcer are seen in up to 10% of the patients with MWT. During flexible endoscopy, lesions are also classified based on their risk of rebleeding using the Forrest classification (Table 4). Other diagnostic modalities for GIB include tagged red blood cell scan, angiography, and multidetector computed tomography (MDCT) angiogram. For patients bleeding from MWT, angiography of the left gastric or inferior phrenic artery may show a tissue contrast collection at the GE junction. MDCT angiogram is now considered equivalent to angiography. Triphasic MDCT (precontrast, arterial and portal phases) provides better results than computed tomography angiograms especially in patients with portal hypertension or patients with concern for bleeding from within the liver.

Treatments: Endoscopy, Angiography, Surgery

Patients with UGIB need to be treated for hemodynamic instability prior to diagnostic or treatment intervention. The treatment outline is summarized in Fig. 2. If the patient is obtunded from shock, intubation for airway protection is essential. Initial laboratory studies should include hematocrit, type and cross match, coagulation parameters, and liver function tests. Any derangement in coagulation should be corrected quickly. Platelet transfusion should be considered for patients with thrombocytopenia or for patients on dual antiplatelet therapy for cardiovascular disease. However, platelet transfusion may not be effective in patients on dual antiplatelet therapy. If unable to place InG or IJG venous access, large central venous access should be placed for resuscitation with crystalloids or whole blood. Organ perfusion status should be monitored by blood pressure, heart rate, and urine output.

UGIH, upper gastrointestinal hemorrhage.
Modified from Wuerth BA, Rockey DC. Changing epidemiology of upper gastrointestinal hemorrhage in the last decade: A nationwide analysis. Dig Dis Sci. 2016;61(5):1288–1295.

Antiemesis medication should be started for all patients with persistent nausea and vomiting. High-dose PPIs by continuous infusion or intermittent dosing has shown to decrease need for endoscopic intervention and transfusion. It is recommended to continue PPI for at least 2 weeks after bleeding stops to promote healing and hemostasis. For massive UGIH, erythromycin can be administered 20 to 90 minutes before endoscopy to facilitate clearing of blood from the stomach and improve endoscopy visualization.

Initial UGIH bleeding workup should include nasogastric tube placement and gastric lavage with 500 mL of saline to assess for the presence of blood. Gastric lavage may also be needed during endoscopy to remove blood in the stomach that may obscure visualization. Retrograde view of the GEJ is essential for diagnosis and treatment. At the time of initial endoscopy, between 30% and 70% of MWTs will have no bleeding. These can be treated with PPI alone and do not need repeat endoscopy for proof of healing. Endoscopic treatment modalities available during endoscopy include hemoclip, banding, thermal coagulation, injection of sclerosing, or vasoconstricting agents. Each modality has its own advantages and disadvantages. There is no good study to advocate one modality over another, and the choice of modality is often dependent on the preference of the endoscopist.

Endoscopic Treatment

Injection of 15 to 20 mL of epinephrine leads to tamponade and local vasoconstriction to stop the bleeding. Sclerosing agents injected into the bleeding site causes tissue necrosis and subsequent thrombosis; however, the use of sclerosing agents is limited due to concern for extensive necrosis leading to perforation. In general, monotherapy with injection of epinephrine or a sclerosing agent has a high risk of rebleeding and should be combined with another modality such as hemoclip or banding.

Thermal coagulation can be applied by monopolar, bipolar, multipolar, or argon plasma coagulation (APC). Bipolar is considered safer than monopolar. Thermal coagulation should not be used repeatedly at the same location out of concern for perforation. This is especially true in the esophagus because it lacks serosa. In APC, an electric current travels through ionized argon gas released from the tip of a probe and heats up the nearby target. APC should be avoided in patients with portal hypertension because it may increase bleeding from varices.

An endoscopically placed clip and fund powder mechanical closure of the bleeding vessel. Blood vessels larger than 2 mm are more difficult to control using a traditional "through the scope" clip. Clip and fund placement are angle and location dependent and some lesions may require a newer technology called over the scope (OTS) clip. The lesion is first suctioned into an opening of the scope; the OTS clip is then placed over the lesion. This allow for precise placement of the clip onto its target. OTS clips are much less location or angle dependent because the suction stabilized the lesion before clip placement. The suction step also allows for clip placement on a lesion that cannot be visualized in a head on fashion. This device can place clips on a lesion that is visualized tangentially. Multiple studies showed OTS clips are more effective for hemostasis compared with through the scope clips. Some studies suggest OTS clips are successful at MWT bleeding and are becoming the first line treatment for UGIH.

TABLE 3 Clinical Characteristics of Patients With Bleeding MWS and PU Bleeding

	MWS	PU	P Value
No. patients	281	1570	
Age, n (%), years			
<65	135 (48.0)	673 (42.9)

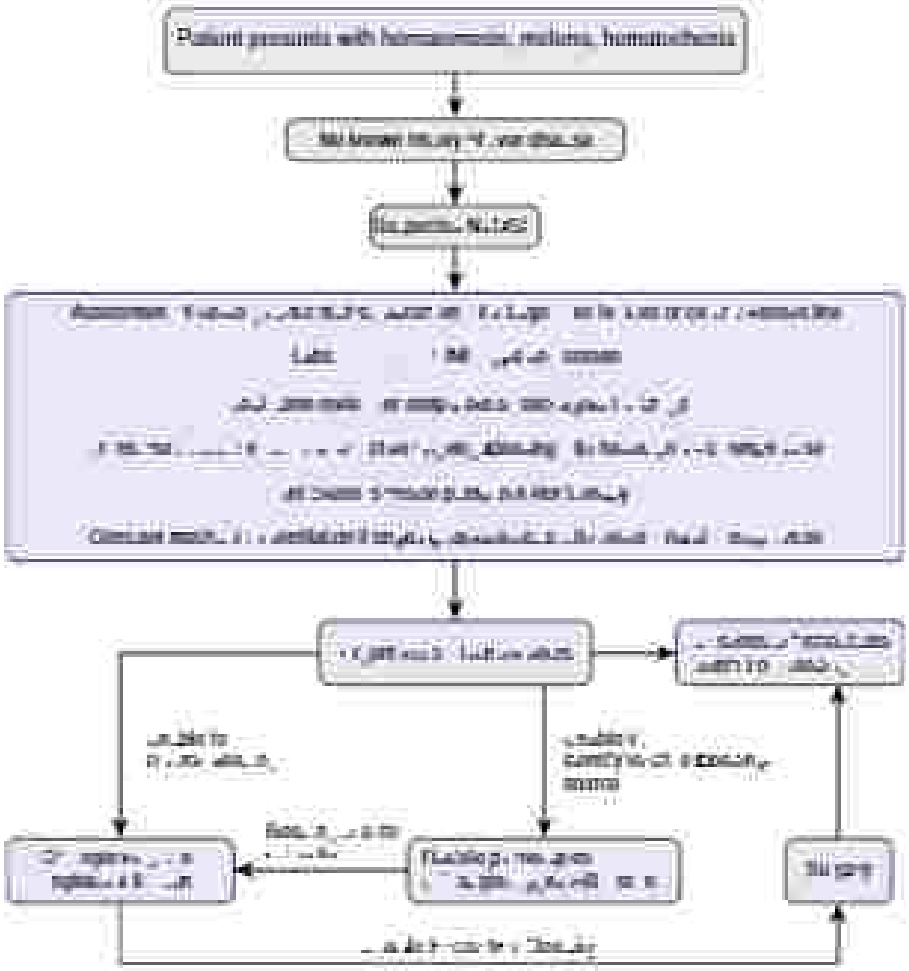

Fig. 1 Initial evaluation and management of nonvariceal gastrointestinal bleeding. CBC, complete blood count; CMP, comprehensive metabolic panel; CT, computed tomography; EGD, esophagogastroduodenoscopy; Hb, hemoglobin; IMR, international normalized ratio; IR, interventional radiology; IV, intravenous; NVUGIB, nonvariceal upper gastrointestinal bleeding; PRBC, packed red blood cells. (Modified from Yamout S, Lee M. Approach to Category 1/1 bleeding and management of nonvariceal upper gastrointestinal bleeding. Clin Hem 2018;64(2):113–9.)

Topical hemostatic agents (e.g., Hemospray, EndoClot) can also be used to treat UGIB. These agents concentrate coagulation factors and create a plug to stop bleeding at injured blood vessels. Intermittently, Hemospray is being used as a first-line agent or as a bridge to surgery. In one study that looked at the use of Hemospray on lesions at high risk of rebleeding (Forrest class IIa or IIb), primary hemostasis was 95% with a 15% rebleeding rate in 7 days. A French study with 202 subjects showed Hemospray was easy to use and created primary hemostasis in 97%, with a rebleeding rate of 25% at 8 days. Multiple studies showed Hemospray and EndoClot can be used as a bridge to surgery for high-risk lesions.

New, innovative strategies to treat UGIB are emerging. Potential future endoscopic modality includes ultrasound-guided angiography, new hemostatic agents, new mechanisms of delivery for hemostatic agents to wider area, and endoscopic suturing devices.

Angiography

Transcatheter arterial embolization or infusion of vasopressin is a treatment option for patients who are poor surgical candidates and who have failed endoscopic treatment. Vasopressin infusion has been replaced by embolization because of a 40% risk of recurrence and risk of major complications using vasopressin. Choice of embolization agent includes autologous clot, microspheres, and glue. UGIB is often sporadic because of vasoconstriction from hypovolemia or temporary clot formation. At the time of angiography, only about 50% will have active extravasation. Provocative angiography injects vasodilator, anticoagulant, or a thrombolytic agent to induce bleeding and can double the detection rate. The left gastric artery accounts for 80% of UGTB involving the stomach. Bleeding from an MWT usually involves either the left gastric artery or inferior phrenic artery. Empiric embolization of these arteries based on endoscopic localization may be necessary if angiography is unable to identify any extravasation. When compared with surgical treatment, embolization has a higher rebleeding rate, more than 50% in some reports. Embolization is usually a last resort for patients who are poor surgical candidates.

Surgical Treatment

Endoscopic therapy is successful in 90% of UGIB caused by MWT. Unlike endoscopy, there has been minimal change to the surgical treatment of MWT. Since the widespread use of endoscopy and enteric innovation in endoscopic tools, less than 5% of patients with MWT will require surgical intervention. Patients who fail initial endoscopic treatment usually get a second endoscopy before proceeding to surgery.

Surgical treatment for MWT usually requires laparotomy. Before surgery, the bleeding source and location is identified by endoscopy. A high anterior longitudinal gastrotomy will allow visualization of the lesion at the GE junction. The MWT is oversewn using absorbable sutures. If the lesion cannot be visualized because of massive hemorrhage, packing of the gastric lumen will compensate any active bleeding and allow time for resuscitation. The packing is then sequentially removed to find the active bleeding and repair. The surgeon should

look for other bowel injury as part of MWT because up to 80% of MWT will coexist with other lesions. The anterior gastrotomy is closed using staples or two layer sutures. Care must be taken to not narrow the gastric lumen or the GE junction. If a hiatal hernia exists and it is difficult to see the bleeding MWT, one trick the senior author has used is to insert a Foley catheter through the gastrostomy and up to the distal esophagus. Gently inflation of the balloon combined with gentle downward traction will usually reduce the GE into the operative field.

There are a lack of data for laparoscopic assessing of MWT using endoscopic guidance. Laparoscopic ports are placed similar to standard hernia surgeries. Endoscopy is used to guide the laparoscopic placement of full thickness sutures to close the MWT through an anterior gastrotomy. There are not enough data in the literature to comment on this strategy and it poses multiple potential problems. First, there is no good way to control bleeding if gastric blood interferes with visualization. Second, patients with MWT who end up in the operating room usually have failed another modality and are unstable. These patients require quick access of the gastric lumen and control of the bleeding vessel, for which laparoscopy and endoscopy are not suited.

Sengstaken-Blakemore Tubes

The use of Sengstaken-Blakemore tubes for control of Mallory-Weiss bleeding has been reported with varying degrees of success. Its use is controversial and considered an act of desperation. Concern about their usage in patients with Mallory-Weiss syndrome centers on the risk of extending the mucosal tears into full thickness tears of the esophagus or stomach. The presence of a hiatal hernia is also a contraindication to the use of such tubes because the asymmetric pressure gradient generated by the gastric balloon may lead to necrosis and perforation of the herniated portion of the stomach.

SUMMARY

MWT is a linear laceration of the mucosa at the GEJ. The mucosal tear is most commonly associated with violent emesis. The UGIB caused by MWT is self limiting in 80% to 90% of cases. Initial treatment of unstable patient must start with resuscitation and stabilization. Endoscopy is the main stay for diagnosis and treatment. Fewer than 10% of patients will require surgical treatment of UGIB for MWT.

MANAGEMENT OF GASTRIC ADENOCARCINOMA

Aslam Ejaz, MD, MPH, Bradley T. Baxman, MD, MS, and Farhan Zaheer, MD, MHS, FACS

In the United States, gastric adenocarcinoma will be responsible for an estimated 26,240 new cases, resulting in 10,800 deaths in 2018. Although the incidence and mortality of gastric cancer has been decreasing for several decades, it remains the 6th leading cause of digestive tract cancer in the United States. The worldwide incidence of gastric cancer, however, varies greatly, with more than 70% of gastric cancers occurring in the developing world and approximately 50% occurring in East Asia. Because of the high incidence seen in these populations, screening programs are common and have likely contributed to a decrease in mortality from this disease. However, because of the lower incidence observed in the United States, screening for gastric adenocarcinoma is not routinely performed and no reliable biomarkers currently exist for this disease.

As with many cancers, chronic inflammation appears to play a vital pathogenic role in the development of gastric adenocarcinoma. Among known infectious causes, the most identifiable and common are chronic *Helicobacter pylori* infection and Epstein-Barr virus infection. Other risk factors include gastric polyps, exposure to nitrosamines and pickled foods, low consumption of fruits and vegetables, high salt intake, tobacco use, previous gastric surgery, pernicious anemia, and obesity.

Approximately 10% to 15% of gastric cancer cases occur in patients with a family history of gastric cancer. Inherited gastric cancer syndromes include hereditary diffuse gastric cancer (E-cadherin/CDH1 mutation), familial adenomatous polyposis, and Lynch syndrome (hereditary nonpolyposis colorectal cancer). Genetic counseling and screening should be offered and discussed with all patients with an inherited gastric cancer syndrome. For patients with a CDH1 mutation, prophylactic total gastrectomy is recommended in family members older than 20 years of age. Furthermore, females with hereditary diffuse gastric cancer are at increased risk for the development of breast cancer and should receive appropriate surveillance.

PATHOLOGY/HISTOLOGY

More than 90% of malignant gastric tumors are classified as adenocarcinoma (glandular in origin); however, gastric adenocarcinoma can be highly heterogeneous. The most commonly used classification scheme is the Lauren classification, in which gastric adenocarcinoma is divided into two main histologic subtypes: diffuse (poorly differentiated) and intestinal (well differentiated). The diffuse subtype is more common in patients with an inherited syndrome and often carries a much poorer overall prognosis. The intestinal subtype is often seen in high-risk populations and the elderly, with a strong association with *H. pylori* infection.

In 2014, the Cancer Genome Atlas Network published the results of a comprehensive molecular evaluation of 295 primary gastric adenocarcinomas. As part of this genomic profiling, gastric cancer was divided into four subtypes: tumors positive for Epstein-Barr virus (EBV); microsatellite unstable tumors (22%); genomically stable tumors (20%); and tumors with chromosomal instability (50%). These classifications may serve as the basis for future targeted therapies and treatments.

DIAGNOSIS AND STAGING

Symptomatology related to gastric cancer is often vague and nonspecific. These symptoms, if present, often mimic other gastrointestinal disorders and may include epigastric pain, nausea, vomiting,

look for other lesions after repair of MWT because up to 80% of MWT will coexist with other lesions. The anterior gastrotomy is closed using staples or two layer sutures. Care must be taken to not narrow the gastric lumen or the GE junction. If a hiatal hernia exists and it is difficult to see the bleeding MWT, one trick the senior author has used is to insert a Foley catheter through the gastrotomy and up to the distal esophagus. Gently inflation of the balloon combined with gentle downward traction will usually reduce the GEJ into the operative field.

There are a lack of data for laparoscopic assessing of MWT using endoscopic guidance. Laparoscopic ports are placed similar to standard hiatal hernia surgeries. Endoscopy is used to guide the laparoscopic placement of full thickness sutures to close the MWT through an anterior gastrotomy. There are not enough data in the literature to comment on this strategy and it poses multiple potential problems. First, there is no good way to control bleeding if gastric blood interferes with visualization. Second, patients with MWT who end up in the operating room usually have failed another modality and are unstable. These patients require quick access of the gastric lumen and control of the bleeding vessel, for which laparoscopy and endoscopy are not suited.

Sengstaken-Blakemore Tubes

The use of Sengstaken-Blakemore tubes for control of Mallory-Weiss bleeding has been reported with varying degrees of success. Its use is controversial and considered an act of desperation. Concern about their usage in patients with Mallory-Weiss syndrome centers on the risk of extending the mucosal tears into full thickness tears of the esophagus or stomach. The presence of a hiatal hernia is also a contraindication to the use of such tubes because the asymmetric pressure gradient generated by the gastric balloon may lead to necrosis and perforation of the herniated portion of the stomach.

SUMMARY

MWT is a linear laceration of the mucosa at the GEJ. The mucosal tear is most commonly associated with violent emesis. The UGIB caused by MWT is self limiting in 80% to 90% of cases. Initial treatment of unstable patient must start with resuscitation and stabilization. Endoscopy is the main stay for diagnosis and treatment. Fewer than 10% of patients will require surgical treatment of UGIB for MWT.

MANAGEMENT OF GASTRIC ADENOCARCINOMA

Aslam Ejaz, MD, MPH, Bradley N. Reames, MD, MS, and Fabian Johnston, MD, MHS, FACS

In the United States, gastric adenocarcinoma will be responsible for an estimated 26,240 new cases, resulting in 10,800 deaths in 2018. Although the incidence and mortality of gastric cancer has been decreasing for several decades, it remains the 6th leading cause of digestive tract cancer in the United States. The worldwide incidence of gastric cancer, however, varies greatly, with more than 70% of gastric cancers occurring in the developing world and approximately 50% occurring in East Asia. Because of the high incidence seen in these populations, screening programs are common and have likely contributed to a decrease in mortality from this disease. However, because of the lower incidence observed in the United States, screening for gastric adenocarcinoma is not routinely performed and no reliable biomarkers currently exist for this disease.

As with many cancers, chronic inflammation appears to play a vital pathogenic role in the development of gastric adenocarcinoma. Among known infectious causes, the most identifiable and common are chronic *Helicobacter pylori* infection and Epstein-Barr virus infection. Other risk factors include gastric polyps, exposure to nitrosamines and pickled foods, low consumption of fruits and vegetables, high salt intake, tobacco use, previous gastric surgery, pernicious anemia, and obesity.

Approximately 10% to 15% of gastric cancer cases occur in patients with a family history of gastric cancer. Inherited gastric cancer syndromes include hereditary diffuse gastric cancer (E-cadherin/CDH1 mutation), familial adenomatous polyposis, and lynch syndrome (hereditary nonpolyposis colorectal cancer). Genetic counseling and screening should be offered and discussed with all patients with an inherited gastric cancer syndrome. For patients with a CDH1 mutation, prophylactic total gastrectomy is recommended in family members older than 20 years of age. Furthermore, females with hereditary diffuse gastric cancer are at increased risk for the development of breast cancer and should receive appropriate surveillance.

PATHOLOGY/HISTOLOGY

More than 90% of malignant gastric tumors are classified as adenocarcinoma (glandular in origin); however, gastric adenocarcinoma can be highly heterogeneous. The most commonly used classification scheme is the Lauren classification, in which gastric adenocarcinoma is divided into two main histologic subtypes: diffuse (poorly differentiated) and intestinal (well differentiated). The diffuse subtype is more common in patients with an inherited syndrome and often carries a much poorer overall prognosis. The intestinal subtype is often seen in high-risk populations and the elderly, with a strong association with *H. pylori* infection.

In 2014, the Cancer Genome Atlas Network published the results of a comprehensive molecular evaluation of 295 primary gastric adenocarcinomas. As part of this genomic profiling, gastric cancer was divided into four subtypes: tumors positive for Epstein-Barr virus (EBV); microsatellite unstable tumors (22%); genomically stable tumors (20%); and tumors with chromosomal instability (50%). These classifications may serve as the basis for future targeted therapies and treatments.

DIAGNOSIS AND STAGING

Symptomatology related to gastric cancer is often vague and nonspecific. These symptoms, if present, often mimic other gastrointestinal disorders and may include epigastric pain, nausea, vomiting,

dyspepsia, postprandial fullness, anorexia, and weight loss, among other symptoms. As previously discussed, screening for gastric adenocarcinoma is not routinely performed in the United States. Diagnosis is often achieved after the onset of symptomatology (and subsequent investigation) or incidentally through staging performed for other causes. Because of this, the majority of gastric cancers found in the United States are often found at advanced stages of disease, with more than 50% of patients having regional or distant spread of disease at the time of diagnosis. Furthermore, physical examination for patients with gastric cancer is unremarkable in its early stages. Late stages of the disease may include a palpable abdominal mass, the presence of a periumbilic (Sister Mary Joseph's) or left supraclavicular (Virchow's) lymph node, or a pre-rectal mass resulting from tumor deposition in the rectovesical or retrouterine pouch (Blumer's shelf).

Endoscopy with biopsy of any suspicious manifestation is the first diagnostic modality used when gastric cancer is suspected. Endoscopic ultrasound (EUS) is used as an adjunct to further characterize the depth of tumor (T stage) as well as the presence of any suspicious or involved perigastric lymph nodes (N stage). Biopsy of suspected nodal metastasis may also be performed during EUS. EUS accuracy is operator dependent with wide ranging reported accuracies between 66% and 75%.

In the United States, reported utilization of EUS is around 25%. This is likely because of the increased reliance on high-quality cross-sectional computed tomography (CT) to characterize tumor depth and nodal involvement, as well as the presence or absence of any metastatic spread. EUS, however, may be most useful in the early stages of disease, to guide decisions regarding neoadjuvant therapy. Reported accuracy of CT scan versus EUS appears to be equivalent for locoregional staging for patients with gastric cancer; however, CT scans perform poorly in the detection of peritoneal disease because up to 50% of patients may have microscopic or macroscopic peritoneal disease despite a negative CT scan. As such, additional modalities such as positron emission tomography (CT and magnetic resonance imaging may all be diagnostic but are currently not routinely used in the diagnostic workup for patients with gastric adenocarcinoma.

Staging is most commonly based on the American Joint Committee on Cancer and International Union Against Cancer system that uses a traditional TNM system (Table 1). An eighth edition of this staging system was published in 2017 and was modified from the seventh edition based on Japanese and Korean data from the International Gastric Cancer Association. Compared to the seventh edition, patients with pN0s (0 to 1% regional metastatic nodes) and pN3s (16 or more regional metastatic nodes) were separated into different pathologic TNM stages to further improve the stratification of survival by stage of disease.

MULTIMODALITY THERAPY

Systemic Therapy

Even among patients with early stage disease, recurrence is common following resection alone. Based on several randomized clinical trials, neoadjuvant, adjuvant, and combined (neoadjuvant and adjuvant) systemic therapies are often used, and have been shown to provide a disease free and overall survival benefit. One of the most commonly used systemic therapy regimens originates from the British Medical Research Council's *MAGIC* (Adjuvant Gastric Infusional Chemotherapy) trial. This randomized trial compared perioperative epirubicin, cisplatin, and 5-fluorouracil (5-FU) with surgery alone for patients with stage II/III gastric or esophageal cancer (T3 or greater, N1 or greater). Chemotherapy given in the neoadjuvant setting offers the theoretic benefit of improved patient tolerance to therapy, ability to assess disease response in vivo, tumor downstaging/downstaging, improved resectability rates, and elimination of micrometastatic and asymptomatic disease. In this trial, perioperative chemotherapy resulted in an improvement in both progression-free and overall survival compared with the surgery alone group; however, only 42% of patients in the chemotherapy arm completed the full course of prescribed therapy. More recently, the *FLOT4-AIO* (Haustumoraff and Leucovorin versus Epirubicin, Cisplatin, and Fluorouracil or Capecitabine in Patients with Resectable Gastric or Gastro-esophageal Junction Adenocarcinoma) phase III trial showed an improvement in progression-free and overall survival among patients who received 5-FU, leucovorin, oxaliplatin, and docetaxel chemotherapy regimen versus epirubicin, cisplatin, and 5-FU or epirubicin cisplatin and Xeloda/capecitabine, as well as increased rates of pathologic complete regression, and completion of all intended therapies.

Chemoradiotherapy

In 2001, the Intergroup 0116 trial showed an improved overall and relapse-free survival among patients who received adjuvant 5-FU, leucovorin, and external beam radiation compared with patients who underwent resection alone. This study, however, has been criticized for poor standardization of surgical technique among study centers, with only 10% of patients undergoing a formal D2 lymphadenectomy (see the following section). Opponents of the trial argue that the benefit seen in the chemoradiation group may be due to "inadequate" surgery and suboptimal local control. Furthermore, only 64% of patients were able to complete the chemoradiation regimen because of intolerance and toxicity. To further evaluate the effect of adjuvant chemoradiation, the recently published *CRITICS* (Adjuvant Chemotherapy or Chemoradiotherapy in Resectable Gastric Cancer) trial compared perioperative chemotherapy (epirubicin, cisplatin or oxaliplatin, and capecitabine) versus preoperative chemotherapy (similar to that previously described) and adjuvant chemoradiation (external beam radiation, capecitabine, cisplatin) in patients who underwent curative-intent gastrectomy. The addition of chemoradiotherapy to the perioperative chemotherapy regimen did not improve overall survival. Moreover, roughly 60% of patients completed adjuvant therapy in both groups, potentially emphasizing the importance of neoadjuvant therapy in gastric cancer. Similarly, the *ARTIST* (Adjuvant Chemoradiation Therapy in Stomach Cancer) trial evaluated postoperative chemotherapy (capecitabine and cisplatin) with or without radiation and found no benefit in disease free or overall survival with the addition of adjuvant chemoradiation. A subgroup analysis of patients with nodal metastasis, however, did show an improvement in disease free survival among the patients who received adjuvant radiation.

Targeted Agents

Several targeted therapeutic agents have and are continually being developed for use among patients with advanced gastric cancer. These agents include monoclonal antibodies against PD-1/PD-L1 antibodies (nivolumab, pembrolizumab), anti-HER2 receptor therapy (trastuzumab, pertuzumab), anti-extracellular glomerular filtration rate antibodies (panitumumab), and antivascular endothelial growth factor antibodies (bevacizumab, ramucirumab), and to date have all shown mixed results among patients with advanced gastric cancer.

Surgery

Diagnostic Laparoscopy

As previously stated, a substantial proportion of gastric cancer patients who appear to have organ confined disease based on CT imaging may actually have peritoneal metastases despite a negative CT scan. Currently, diagnostic laparoscopy with biopsy and peritoneal washings for cytology provide the only modality to accurately assess the presence or absence of metastatic peritoneal disease, and has been found to change management in up to 40% of patients. As

such, diagnostic laparoscopy with cytology is indicated for all patients with a clinical stage T1b or higher.

If cytopathologic evaluation reveals malignant cells (indicating cytologic M1 disease), laparoscopy with cytology may be repeated following the completion of *pre-operative systemic* therapy to assess whether cytologically positive metastatic disease resolves. If no gross or cytologic peritoneal disease remains present, the patient should be treated with curative-intent gastrectomy. However, even in the presence of limited peritoneal disease and no solid organ involvement, recent data suggest an association with survival for resection combined with cytoreductive surgery and heated intraperitoneal chemotherapy (HIPEC), as discussed in the following section.

Primary Resection

Complete surgical resection is the only curative therapy for patients with gastric adenocarcinoma. Though no randomized data exist to guide management, retrospective studies suggest that gross margins of 2 to 4 cm are needed to increase the likelihood of microscopically negative margins. Numerous analyses suggest that positive margins independently predict worse outcomes following resection. Currently, National Comprehensive Cancer Network guidelines suggest a minimum gross margin of 4 cm. Management of a microscopically positive margin on final pathology remains controversial because literature evaluating outcomes following resection is limited. Currently chemotherapy, chemoradiation, or resection may be considered in this situation, depending on the type of preoperative therapy received. The extent of stomach

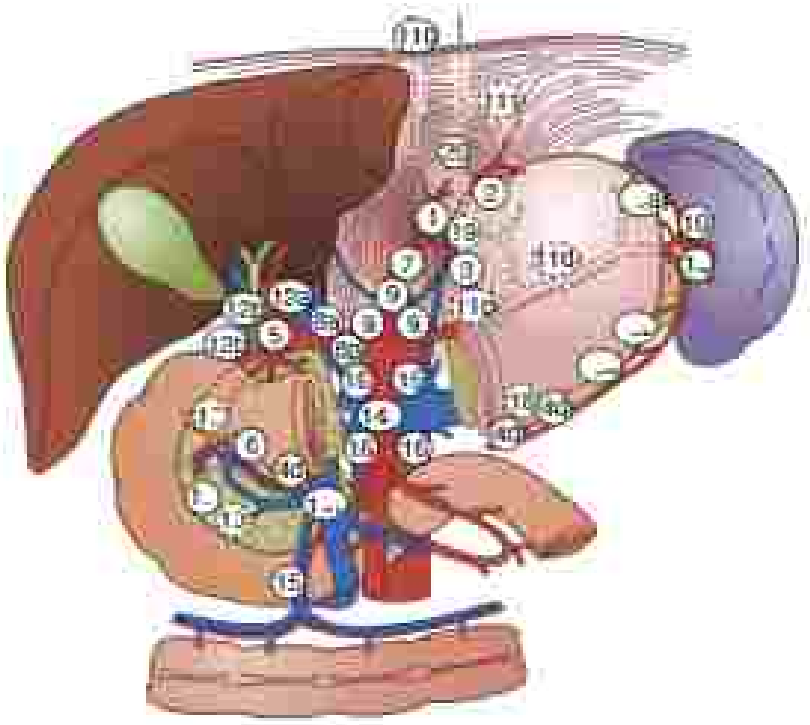

FIG. 1 Distribution of lymph node stations in gastric cancer

resection is determined by tumor location because a total or subtotal gastrectomy may each be used in the appropriate circumstances to achieve a microscopically negative margin. In select cases, consideration may be given to multivisceral resection, if safe and feasible.

Minimally Invasive Approaches

Advances in surgical technique, perioperative care, and operative technique have led to the increasing use of minimally invasive approaches in gastric cancer. Laparoscopic gastrectomy was first reported in 1994. Numerous observational studies and randomized trials have since evaluated the outcomes of laparoscopic and open approaches. In experienced hands, the laparoscopic approach has been reported to result in lower blood loss, quicker return of bowel function, shorter hospital stay, and fewer overall morbidity with comparable rates of operative mortality and total lymph nodes examined, at the expense of prolonged operative times. Although observational data suggest oncologic outcomes are equivalent, several ongoing trials are expected to address this question. The surgeon's level of experience is critical to successful outcomes following laparoscopic gastrectomy because studies suggest that 50 to 60 cases are required before proficiency may be achieved.

Robotic assisted gastrectomy was first reported in Japan in 2003 and has become increasingly used in specialized centers. Advantages of the robotic platform over laparoscopy include a three dimensional camera and magnification for improved visualization, and articulating instruments for improved dexterity and precision. Early literature suggests that in experienced hands, a robotic approach may achieve short term outcomes similar to laparoscopy, at the potential expense of prolonged operative times and increased costs. Current data suggest the learning curve for robotic gastrectomy is 20 to 25 cases in surgeons already proficient with advanced laparoscopy.

Lymphadenectomy

The extent of lymphadenectomy performed at the time of resection remains controversial. A standardized lymphadenectomy for gastric cancer was first published by the Japanese Research Society for Gastric Cancer in 1973 and was translated to English and more widely accepted in 1981. Lymph nodes are classified into 16 stations by their location (Fig. 1). The type of lymphadenectomy performed is defined by the proximity of harvested nodes to the stomach. A D1 lymphadenectomy includes perigastric nodes (stations 1 through 6), whereas a D2 lymphadenectomy also includes stations of the celiac axis (7 through 11), and a D3 lymphadenectomy includes celiac and paraaortic stations (7 through 16). Although a D2 lymphadenectomy was originally described to include a distal pancreatectomy and splenectomy, this led to significantly increased perioperative morbidity and mortality, and has largely been abandoned in favor of pancreas and spleen preserving approaches.

Historically, a more extensive lymphadenectomy has been performed in eastern countries, whereas western countries have favored more conservative approaches. To date, eight randomized trials have evaluated this topic: three comparing a D3 with D2 lymphadenectomy and five comparing D2 with D1 lymphadenectomy. None of the trials evaluating a D3 lymphadenectomy has reported a benefit in overall, disease specific, or disease free survival. Initial reports of trials evaluating a D2 versus D1 lymphadenectomy reported similar long term oncologic outcomes, largely influenced by the increased morbidity associated with pancreatectomy and splenectomy. However, recently published 15 year data from the Dutch Gastric Cancer Trial reported a significantly improved disease specific survival in patients receiving a D2 lymphadenectomy, and these findings have been confirmed by a Cochrane systematic review of published trials to date. Although numerous retrospective studies have reported associations between survival and increased number of resected nodes, these findings may in part be due to a reduction in understaging, or stage migration (i.e., the Will Rogers phenomenon). Currently, National Comprehensive Cancer Network guidelines recommend retrieval of at least 15 lymph nodes.

Operative Technique

Regardless of surgical approach, the core principles of operative technique remain constant. If a minimally invasive technique is planned, pneumoperitoneum is established in the standard fashion, via Hasson or Veress needle technique. For both laparoscopic

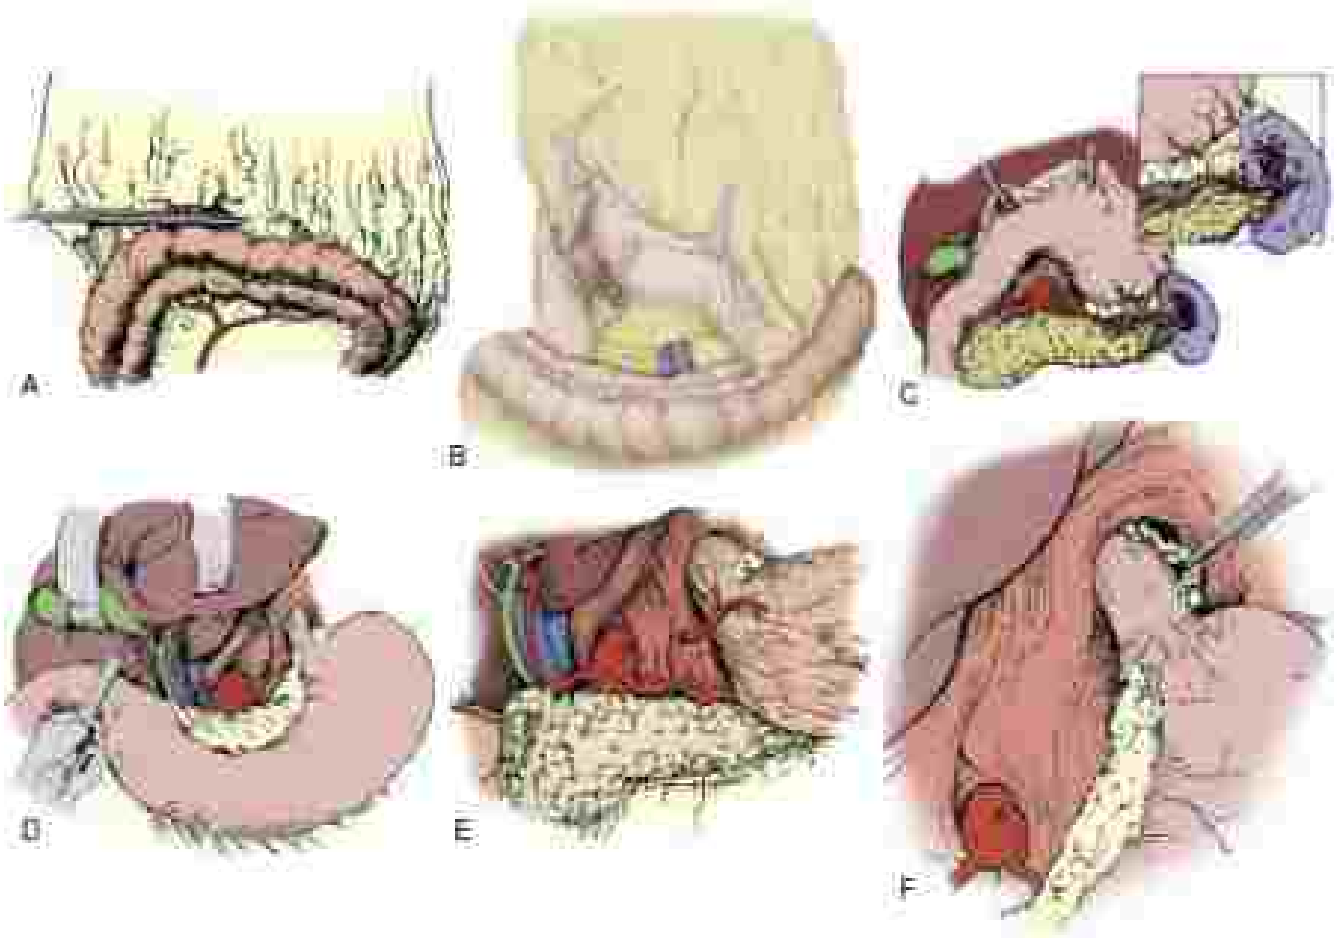

FIG. 2 (A) The avascular plane between the greater omentum and transverse mesocolon is defined. (B) The greater omentum is dissected off the colon along the avascular plane between the anterior and posterior sheaths of the transverse mesocolon. Resection is carried down to the level of the pancreas. (C) The lateral attachments of the stomach and short gastric vessels are divided. First, the splenic artery is dissected along the superior border of the pancreas. Next, these is dissected down to the level of the splenic hilus. (D) The duodenum is identified and divided with the gastrointestinal anastomosis linear stapler. (E) Distal dissection proceeds from the porta hepatis toward the celiac axis along the superior border of the pancreas. The left gastric artery is divided at its origin. (F) Final dissection continues along the right diaphragmatic crus and esophageal hiatus. The left pericardial nodes are taken during total gastrectomy.

and robotic approaches, five ports are most commonly used, with a central umbilical port and two ports right and left of the midline, although the sizes and configurations of ports vary by surgeon and technique.

Any operation should begin with a thorough exploration of the peritoneal cavity to evaluate for metastatic disease. Once the absence of metastatic disease is confirmed, the resection begins with dissection of the greater omentum off the transverse colon (gastrocolic ligament) (Fig. 2). The anterior sheath of the transverse mesocolon is dissected down to the pancreas. Left lateral omental attachments to the abdominal wall, splenic flexure, and spleen are divided, and the short gastric vessels are ligated and divided with ties or an energy device. The superior extent of dissection along the greater curvature toward the left crus is determined by the extent of stomach resection planned. Dissection of the greater omentum is continued rightward, separating the omentum from the hepatic flexure and mesocolon while controlling the gastroepiploic veins, keeping the omentum intact with the specimen. The duodenum is isolated and divided 1 cm distal to the pylorus. The left gastric artery is identified and ligated at the take-off from the celiac axis, and the associated lymph nodes are dissected en bloc with the lesser omentum and stomach, toward the right crus of the diaphragm. For tumors that are distally located on the greater curvature, the left gastric artery may be preserved. The lymph node bearing fibroadipose tissue of the porta hepatis, common hepatic artery, celiac axis, splenic artery, and superior pancreas is dissected, completing a D2 lymphadenectomy.

For a total gastrectomy, the esophagus is encircled and controlled, and the specimen is divided at the gastroesophageal junction. For a subtotal or distal gastrectomy, the stomach is divided transversely with a linear stapler at a site that allows for an adequate proximal margin. Frozen sections of the proximal and distal transection lines may be sent to confirm microscopically clear margins. For a total gastrectomy, gastrointestinal continuity is restored through creation of a Roux-en-Y esophagojejunostomy, often with roux limb of 50 to 60 cm in length to prevent bile reflux gastritis. If a subtotal gastrectomy is performed, reconstruction may be performed via a Roux-en-Y or Billroth II technique. Depending on the nutritional and functional status of the patient as well as any planned postoperative therapy, placement of a feeding tube may be considered.

Heated Intraperitoneal Chemotherapy

Even after curative intent gastrectomy, previous data suggested that patients with cytologic positive M1 disease carry a prognosis similar to patients with other forms of stage IV disease. In recent years,

however, several studies suggest that a select group of patients with limited peritoneal only disease, as well as an absence of solid organ metastasis, may achieve a survival benefit by undergoing aggressive cytoreductive surgery and HIPEC. Following cytoreductive surgery/HIPEC, a complete cytoreduction (minimal to no visible disease remaining) appears to be the most important factor in survival among gastric cancer patients with peritoneal disease. Furthermore, ongoing trials in Asia and Europe have evaluated intraperitoneal chemotherapy in the neoadjuvant and adjuvant settings with promising results.

Palliation

In western countries, one third of all patients with gastric cancer are found to have stage IV disease at the time of initial diagnosis. The prognosis of metastatic gastric cancer is poor, with median survival ranging from 4 months with best supportive care, to 12 months with palliative chemotherapy. As such, the management of this population must be individualized for a patient's symptoms, functional status, and prognosis. In appropriately selected patients, options for management in this population include best supportive care, palliative gastrectomy or bypass, chemoradiation, and systemic therapy.

In metastatic gastric cancer patients with aggressive tumor histology or poor functional status, the focus of care should be on symptom control and optimizing quality of life. Nausea may be addressed with antiemetic medications. Pain should be controlled through a multimodal approach. Bleeding is common and may be treated by endoscopy, angiography, or radiotherapy. Obstructive symptoms may be managed with endoscopic stent placement, venting gastrostomy, or radiotherapy, and, in select patients, palliative gastrectomy or gastrojejunostomy may be considered.

In patients demonstrating favorable tumor biology and good performance status, more aggressive treatments may be offered. Although controversial and subject to selection bias, recent retrospective studies and a systematic review suggest palliative gastrectomy may be associated with improved survival, particularly in younger patients with a single site of metastasis. Chemoradiation may also be considered in select patients who are radiotherapy naïve. Systemic therapeutic options include cytotoxic chemotherapy and targeted agents. Although two-drug chemotherapy combinations are preferred for a lower toxicity profile, three-drug regimens may be considered in medically fit patients with a robust performance status. Frequently used agents include 5-FU or capecitabine, cisplatin or oxaliplatin, docetaxel or paclitaxel, and epirubicin. Targeted agents shown to be effective in advanced gastric cancer include trastuzumab (anti-HER2; Trastuzumab for Gastric Cancer trial), ramucirumab (antivascular endothelial growth factor receptor 2), and panitumumab (anti-EGFR).

SUMMARY

Curative intent resection remains the mainstay of treatment for patients with operative gastric adenocarcinoma. A microscopically negative resection and an extended D2 lymphadenectomy provide the best outcomes for long term survival. Given the aggressive nature of the disease, management of patients with gastric adenocarcinoma necessitates a multidisciplinary approach so optimal treatment may include cytotoxic chemotherapy and possibly radiotherapy and/or targeted agents. Ongoing research will further help define the optimal regimen and timing of systemic therapy in combination with surgical resection in patients with locoregional disease and even limited metastatic disease.

Familial Gastric Cancer

Alex B. Blair, MD, and Mark D. Duncan, MD, FACS

Gastric cancer is a common cause of cancer worldwide, with more than 700,000 cancer related deaths yearly. Late diagnosis and limited effective therapeutic options are two prominent causes for a high associated mortality. As with most cancers, gastric adenocarcinoma is most commonly observed as sporadic disease with a multifactorial etiology. Multiple risk factors have been extensively studied, including gastroesophageal reflux disease, obesity, smoking, *Helicobacter pylori* infection, long term inflammation, and smoked foods. In addition to extrinsic environmental factors, emerging evidence supports a growing effect of inherited genetic predispositions in a subset of gastric cancers. *Familial gastric cancer* is a term used to describe families with two first- or second-degree relatives with gastric cancer before the age of 50 years or three first- or second-degree relatives independent of age. This aggregation of disease within families occurs in roughly 10% of gastric cancer cases.

There are many reports of presumed familial gastric cancer from as early as the famed French military leader Napoleon Bonaparte at the turn of the nineteenth century. Napoleon, his grandfather, father, four sisters, and a brother all died of gastric cancer, strongly suggesting familial clustering of disease. In 1998, Guilford *et al.* reported a high incidence of multigenerational diffuse gastric cancer affecting individuals at a young age within the indigenous Māori people of New Zealand. Germline mutations within the gene coding for the calcium dependent E-cadherin cell cell adhesion molecule (CDH1) was identified as a central mutation within this family responsible for their inherited gastric cancers (Fig. 1). A thorough knowledge of the molecular profile specific for familial gastric cancer is useful for clinicians in identifying individuals and family members at high risk who may benefit from early or preventative surgical intervention.

PATHOLOGY OF GASTRIC CANCER

The three most common primary gastric malignancies are adenocarcinoma (90%), lymphoma (4%) and gastrointestinal stromal tumor. Other primary malignancies such as carcinoid, squamous cell carcinoma, and angiosarcoma rarely occur. Gastric adenocarcinomas are then divided into broad histologic subtypes per the Lauren classification: intestinal and diffuse. The intestinal subtype is more commonly associated with extrinsic environmental risk factors and inflammation than the more aggressive diffuse form. Diffuse type

however, several studies suggest that a select group of patients with limited peritoneal only disease, as well as an absence of solid organ metastasis, may achieve a survival benefit by undergoing aggressive cytoreductive surgery and HIPEC. Following cytoreductive surgery/HIPEC, a complete cytoreduction (minimal to no visible disease remaining) appears to be the most important factor in survival among gastric cancer patients with peritoneal disease. Furthermore, ongoing trials in Asia and Europe have evaluated intraperitoneal chemotherapy in the neoadjuvant and adjuvant settings with promising results.

TABLE 1 Candidate Genes Associated With Familial Gastric Cancer

Associated Syndrome	Candidate Gene
Hereditary diffuse gastric cancer	*CDH1*
Hereditary nonpolyposis colorectal cancer	*MSH2, MLH1*
Li-Fraumeni syndrome	*P53*
Familial adenomatous polyposis	*APC*
MUTYH-associated polyposis	*MUTYH*
Peutz-Jeghers syndrome	*P53, STK11*
Gastric adenocarcinoma and proximal polyposis of the stomach	Unknown

gastric cancer is more likely to be a poorly differentiated, ulcerating, transmural lesion with higher lymphatic spread and is often associated with younger patients.

Genetic alterations are involved in all cancers as normal cells are transformed into a malignant state. A selection of genes is altered and leads to malignant transformation. In the majority of cases, these genes are altered at the tissue level by random errors in cellular processing. A proposed multistep model of carcinogenesis requires the accumulation of additional downstream genetic mutations to achieve the full neoplastic phenotype. Familial syndromes offer an inherited initial hit to this neoplastic process, thus markedly increasing the likelihood of eventual gastric cancer development (Table 1).

BOX 1 International Gastric Cancer Linkage Consortium Criteria for *CDH1* Genetic Testing

- Family with ≥2 or more cases of gastric cancer, with at least 1 being diffuse gastric cancer diagnosed before the age of 50 years
- 1 affected individual diagnosed with diffuse gastric cancer at age <40 years from a low-incidence population
- Personal or family history of both diffuse gastric cancer and lobular breast cancer, with 1 affected person age <50 years at the time of diagnosis
- Three confirmed diffuse gastric cancer cases in first- or second-degree relatives independent of age

Hereditary Diffuse Gastric Cancer

Hereditary diffuse gastric cancer is an autosomal dominant cancer predisposition syndrome associated with mutations in *CDH1* on chromosome 16q characterized by an increased risk of diffuse gastric cancer and lobular breast carcinoma. This was first identified in two large Maori families in New Zealand. *CDH1* has an important role in cell–cell adhesion; thus, the loss of function increases invasiveness and epithelial to mesenchymal transition. Individuals with a *CDH1* mutation are more likely to develop diffuse, aggressive, signet ring gastric adenocarcinoma and lobular breast carcinoma at an early age.

CDH1 testing is recommended based on the international gastric cancer linkage consortium (IGCLC) (Box 1). Their guidelines suggest testing in (1) patients with two family cases of gastric cancer with at least one being the diffuse subtype before the age of 50 or (2) one case of diffuse gastric cancer in an individual <40 or (3) a personal or family history of gastric cancer and lobular breast cancer in an individual <50 or (4) three confirmed diffuse gastric cancer cases in first- or second-degree relatives independent of ages. The IGCLC recommends against genetic testing in children; therefore, the earliest recommended age is 18, with qualifying asymptomatic family members typically undergoing testing in the second decade and at least 5 years before the earliest age of diagnosed familial gastric cancer. Familial testing is important because penetrance is quite high, with >80% of men and women developing gastric cancer and a 60% probability of developing lobular breast cancer in women. A family pedigree of a young patient with *CDH1* and gastric cancer treated at our institution is shared with their permission (Fig. 2).

An average age of 38 is reported for the development of gastric cancer; therefore, treatment for these individuals extends beyond increased surveillance to recommended prophylactic total gastrectomy. In those that decline surgery, annual endoscopic surveillance is offered starting at age 20 with multiple biopsies of any visible lesion and at least five random biopsies to each of the anatomical zones of the stomach. Unfortunately, endoscopy does a poor job of screening for tumor because of the difficulty identifying early disease of the diffuse gastric cancer subtype, which can infiltrate without endoscopically visual lesions.

Advanced hereditary diffuse gastric cancer presents as poorly differentiated diffuse carcinoma with signet ring cells invading widely and involving the entire thickness of the gastric wall. These ultimately have poor prognosis; thus, early prophylactic intervention is imperative and offered even if the carriers are asymptomatic. Prophylactic gastrectomy is a risk reduction gastrectomy given the high prevalence of microscopic carcinoma. Those that undergo prophylactic gastrectomy have excellent prognosis. The stomach of asymptomatic *CDH1* mutation carriers nearly always seem normal to the naked eye because of an absence of a mass lesion. Following prophylactic gastrectomy, however, close pathologic inspection reveals multiple foci of intramucosal (T1a) diffuse signet ring cell carcinoma ranging from 0.1 to 10 mm to the overwhelming majority of cases. A T1M0 malignancy was found in 92% of patients with *CDH1* mutations in a prospective series of prophylactic total gastrectomy. Of these patients, only 56% had a diagnosis preoperatively despite adequate endoscopic surveillance.

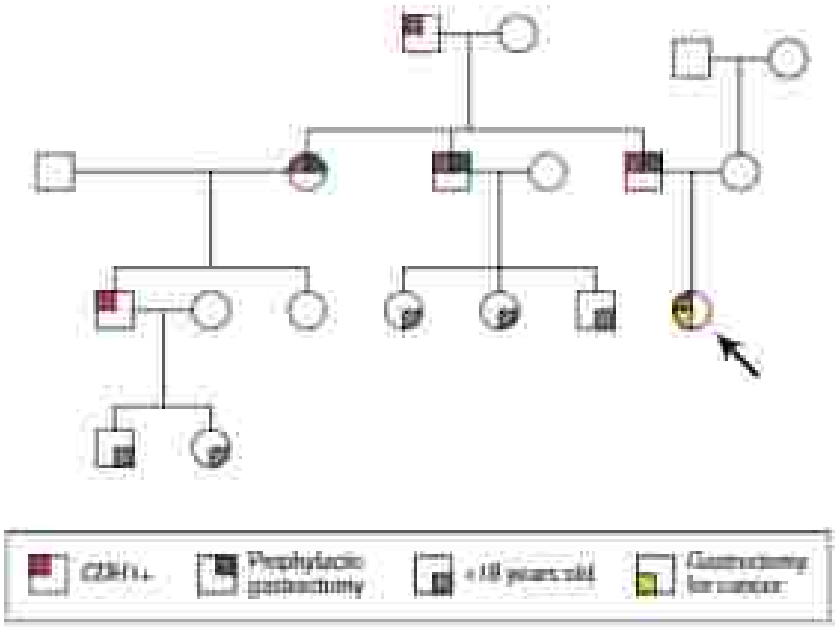

FIG. 2. Family pedigree of CDH1+ gastric cancer patient. The proband (arrow) developed diffuse gastric cancer at age 20 and underwent total gastrectomy at our institution. Subsequently family members underwent genetic counseling and testing with two prophylactic gastrectomies ultimately performed. At 15 yr. 3C months, all postgastrectomy individuals including the proband are alive and cancer free. Pedigree reproduced with patient permission.

Although distal gastric cancer was most common in the initial report of the Maori families, the identified diffuse foci are not restricted to any topographic region of the stomach and can be identified from cardia to the prepyloric region without specific clustering.

Because of the high lifetime risk of also developing lobular breast cancer, women with *CDH1* mutations are also encouraged to undergo yearly mammography and breast magnetic resonance imaging from age 35 onwards. Prophylactic mastectomy may also be an option, although data are insufficient. Although not meeting official IGCLC criteria, genetic testing for *CDH1* should be considered in cases of bilateral lobular breast cancer or a family history of two cases of lobular breast cancer at less than 50 years of age. Because of their shared risk, adequate knowledge of familial gastric cancer syndromes is imperative to not just the gastrointestinal surgeon, but those physicians managing breast malignancy as well. Although a *CDH1* mutation is only identified in 3% to 6% of lobular breast cancer patients, this still represents a significant number of individuals who would be counseled for prophylactic gastrectomy.

Hereditary Nonpolyposis Colorectal Cancer

Henry T. Lynch initially discovered two families predisposed to develop colorectal cancer (CRC) in the 1960s and deemed it hereditary nonpolyposis colorectal cancer (HNPCC). The development of cancers other than CRC, including gastric cancer, has been identified and thus the term Lynch syndrome has gained popularity. This is a highly penetrant, dominantly inherited familial cancer syndrome with a molecular phenotype of DNA microsatellite instability and accumulated DNA mismatch alterations resulting in carcinogenesis in several organs including the colon, rectum, uterus, ovaries, stomach, and hepatobiliary systems. Germline mutations in mismatch repair genes *MSH2* on chromosome 2p and *MLH1* on chromosome 3p cause 90% of the microsatellite instability observed in CRC from HNPCC families and are believed to play a role in inherited gastric cancers.

The Bethesda criteria are used to establish a diagnosis of HNPCC but do not include gastric carcinoma as a defining criterion. The criteria include (1) CRC diagnosed in an individual younger than 50 years of age; (2) presence of synchronous or metachronous CRC or other HNPCC related tumors, irrespective of age; (3) CRC with high microsatellite instability histology diagnosed at less than 60 years of age; (4) individuals with CRC with at least one first degree relative with CRC or HNPCC related tumor diagnosed at less than 50 years of age; and (5) individuals with CRC with at least two first or second degree relatives with CRC or HNPCC related tumor, irrespective of age. If an individual meets these criteria, they are referred for molecular and immunohistochemical testing for microsatellite instability because some individuals may meet the clinical criteria but are microsatellite stable on testing, which is an exclusionary characteristic.

Gastric cancer is found in carriers of Lynch syndrome at approximately 4% to 8% in patients with mutations in *MLH1* and 9% in those with mutations in *MSH2*. Gastric cancer with HNPCC is more commonly intestinal than the diffuse histologic subtype. Surveillance is recommended with upper gastrointestinal screening in individuals with HNPCC for whom a family history of gastric cancer is present or carriers of the *MLH1* or *MSH2* gene. Eradication of *H. pylori* infection in HNPCC patients is important to help reduce additional carcinogenic risk factors. Similar to familial adenomatous polyposis (FAP) and MUTYH associated polyposis (MAP), there is not a role for prophylactic gastrectomy and surgical intervention is restricted to the presence of confirmed gastric cancer.

Li-Fraumeni Syndrome

The gene *TP53* on chromosome 17p is a commonly studied tumor suppressor gene in many types of cancer. DNA damage to normal cells results in *TP53* mediated arrest and cell apoptosis; however, knock out of *TP53* prevents this and permits malignant transformation. Deletion or suppression of *TP53* is the most common genetic abnormalities found in more than two thirds of both inherited and noninherited forms of gastric cancer. Li Fraumeni syndrome (LFS) is associated with *TP53* mutations, thus encompassing several tumor types that generally develop before age 45 years. Malignancy risk with this mutation includes sarcoma, breast carcinoma, leukemia, and other neoplasms. Sarcoma before 45 years of age plus a first degree relative with cancer before this same age or another first or second degree relative with any cancer before this age or relative in this age with sarcoma at any age are the defining criteria of LFS. Gastric carcinoma is reported in 3% to 3% of LFS carriers and reported as early as 12 years of age with a median age of diagnosis of 36 years. Forty percent of families with *TP53* mutations present with at least one gastric cancer at ages significantly younger than sporadic gastric cancer.

The phenotypic diversity of LES complicates effective screening strategies. Periodic screening gastroscopy of LES carriers with at least one family member affected by gastric cancer should be considered. Early onset screening should be initiated at an early age.

Polyp-Associated Gastric Cancer Syndromes

Familial gastric cancer syndromes can be subclassified broadly into those prominently associated with polyps and those without. Benign neoplasms and polyps of the gastric mucosa are made up of multiple components including adenomatous, fundic gland, hyperplastic, inflammatory, and hamartomatous polyps. In general, the inflammatory, hyperplastic and hamartomatous polyps are considered benign, although occasionally malignant potential is appreciated. Gastric adenomatous polyps and fundic gland polyps are uncommon outside of familial syndromes and are more likely to behave as premalignant lesions. Despite displaying relatively modest rates of neoplastic development, these subsets of polyps are associated with a significantly increased life time risk of developing gastric adenocarcinoma and are thus approached with greater caution. A number of inherited cancer syndromes are characterized by a higher frequency of these polypoid lesions yielding an increased risk of gastric cancer.

FAP

FAP is an autosomal dominant disorder associated with the inactivation of the *APC* gene on chromosome 5q. APC is a gatekeeper gene for chromosomal instability and has many roles in development and carcinogenesis. Polyposis is a prominent phenotypic of this inherited mutation with more than 100 colonic and rectal adenomatous polyps a defining criterion. Adenomatous polyps are also manifested in the upper gastrointestinal tract in 50% to 80% of FAP cases. Gastric polyposis (>20 gastric polyps) may also be identified. In cases of gastric polyposis, the polyps are predominately located in the body/fundus, with adenomatous change most frequently identified near the body/antrum junction. Of interest, fundic gland polyps are more frequently observed in patients with attenuated FAP or confirmed *APC* mutation with less than 100 colonic polyps and later CRC disease onset. Although the overall risk of carcinoma is low (2%), individuals with familial polyposis have a much higher incidence of harboring dysplasia than sporadic gastric polyps (25%–40% vs <1%), with dysplasia risk directly proportional to polyp size. Dysplasia can be found in both adenomatous polyps and fundic gland polyps.

FAP patients are recommended to undergo prophylactic total proctocolectomy with ileal pouch anal anastomosis because of the high penetrance of early CRC cancer. No standard guidelines currently exist for gastric surveillance. The age of gastric manifestations is variable in FAP patients, although gastric adenocarcinoma is typically developed long after their colectomy. Current data suggest upper endoscopy initiated at 25 to 30 years of age and performed at intervals of 3 to 5 years with a decreased interval following finding of adenomatous polyps or dysplasia. Polyps larger than 1 cm should be removed to confirm the diagnosis and diminish the risk of malignant degeneration. If dysplasia is identified, low grade dysplasia is most common and the overall risk of carcinoma is low. Surgical intervention is typically reserved for patients with severe polyposis causing symptoms (i.e., bleeding) or in the case of confirmed malignancy on endoscopy. Hence, Prophylactic gastrectomy can be discussed for patients with FAP or attenuated FAP and displaying diffuse fundic gland polyps, large, or high grade dysplasia polyps.

MAP

MAP is an autosomal recessive polyposis syndrome phenotypically similar to attenuated FAP but demonstrating wild type APC. Mutations are identified in the *MUTYH* gene at chromosome 1p, a DNA glycosylase that excises misincorporated bases from DNA damage. Thus, loss of this protein function results in increased accumulation of DNA damage. Similar to FAP, MAP predominately affects the colon, but is also associated with CRC, breast, ovary, skin, and bladder carcinomas.

Gastric polyps are noted in just 11% of MAP cases at a median age of diagnosis of 49 years. These polyps include both adenomas and fundic polyps. The risk of cancer in these polyps is low, seen in just 2% of cases but diagnosed at a median age of 38. Duodenal polyps and malignancy are observed at higher rates, with malignancy in 12% of cases.

Endoscopic surveillance is the mainstay of treatment. Surveillance guidelines for families with MAP recommend upper endoscopy at age 25 to 30 years and then subsequently at intervals of 3 to 5 years. Screening and testing in minors are not recommended because of the low risk of gastric conversion to malignancy. Surgical intervention is reserved for cases of confirmed malignancy or symptomatic polyps. In patients with FAP or MAP, there is a significant risk of duodenal polyps and malignancy and thus continued surveillance following resection is required. Consideration of duodenal surveillance is prudent when undertaking reconstruction after gastrectomy in these patients. The authors have recommended a wider Roux en Y anastomosis with a deliberately shorter biliary pancreatic limb to facilitate subsequent endoscopic surveillance of the duodenal stump. We recognize this may lead to increased risk of bile reflux.

PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome (PJS) is an autosomal dominant disorder characterized by an association of multiple hamartomatous gastrointestinal polyps with mucocutaneous pigmentation and increased cancer risk, particularly for gastrointestinal and breast cancers. Polyps are found throughout the gastrointestinal tract, most commonly in the small bowel, colon, and stomach (70%, 80%, 69%, and 25%, respectively). Gastric polyps can involve the antrum and pylorus and can grow to large sizes, mimicking carcinoma. Because of their size, these polyps are occasionally associated with symptoms including bleeding, abdominal pain, intussusception, and even obstruction.

PJS is associated with *STK11* on chromosome 19p. Seventy percent of individuals with PJS also have germline mutations of the tumor suppressor gene *STK11* on chromosome 19p, providing a potential secondary driver for the typically benign hamartomas to the progression of adenocarcinoma. The role of these genes as initiators of gastric cancer is poorly defined but the association of gastric polyps and cancers implicates a potential role. Individuals with *STK11* mutations are more likely to develop gastric polyps and malignancies than the wild type counterparts. Gastric polyps are reported as early as 2 years of age with a median age of onset of just 16 years. Despite these early findings, gastric carcinoma transformation is rare and usually develops slowly after a long latency period of greater than 20 years. As a whole, gastric cancer is reported in 2% to 3% of Peutz-Jeghers families at a median age of approximately 40 years. Individuals with PJS are also at increased risk of developing cancer in multiple locations including the pancreas, breast, uterus, cervix, testis, ovary, and lung.

Because of their young age of development, endoscopic surveillance should be initiated early, with baseline endoscopy as early as 8 years with screening interval tailored based on the findings of the first endoscopy. In the absence of polyps, screening is reinitiated at 18 years of age with more rigorous yearly screening after the age of 30. Surgical intervention is uncommon and reserved for a confirmed finding of gastric cancer or symptomatic polyps refractory to conservative treatments.

GASTRIC ADENOCARCINOMA AND PROXIMAL POLYPOSIS OF THE STOMACH

Gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS) is an autosomal dominant syndrome with incomplete penetrance. The precise associated genetic mutation remains unknown at this time. Although FAP and MAP are defined primarily by their

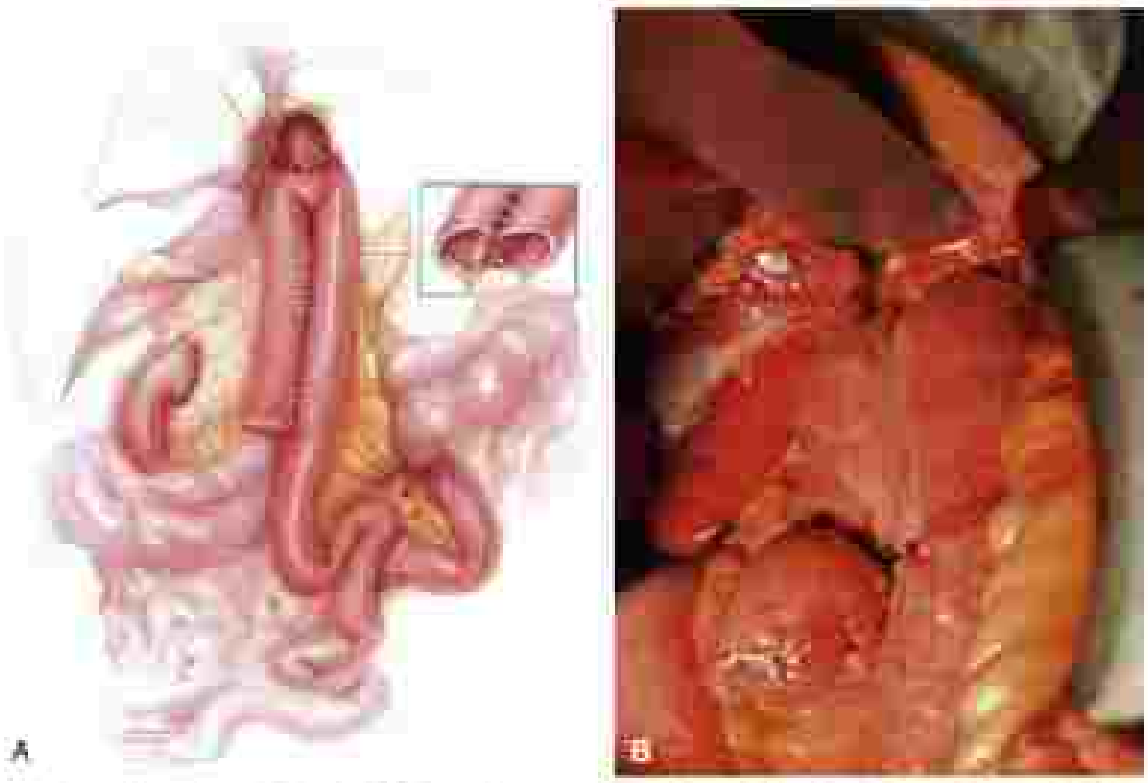

FIG. 3 Reconstruction and formation of jejunal pouch following total gastrectomy (from Cameron JL, Sandler C, Pitt HA, et al. Gastrointestinal Surgery, 6th ed. Philadelphia, PA: Elsevier; 2020).

CBC phenotype. GAPPS is associated with fundic gland polyposis with more than 100 polyps carpeting the proximal stomach while sparing the antrum, duodenum, and colon. Exclusion of other hereditable gastric polyposis syndromes and the use of proton pump inhibitors (which can induce benign gastric polyp formation) is necessary to confirm the diagnosis of this syndrome. GAPPS can also be diagnosed in cases of more than 30 gastric polyps in a first degree relative of another case. These polyps are predominately smaller than 1 cm and typically spare the lesser curvature of the stomach. Occasional hyperplastic and adenomatous polyps can be detected, although fundic gastric polyps represent the majority. These polyps can also display dysplasia and the development of intestinal type gastric adenocarcinoma. Dysplastic lesions have been described in those affected individuals as young as age 10, with adenocarcinoma occurring as early as age 30 years. Endoscopic surveillance can prove to be challenging with the large number of polyps and thus prophylactic gastrectomy should be considered. Considerations for gastrectomy timing are based on the limitations of endoscopic surveillance and patient specific risk of morbidity with prophylactic surgery.

Surgical Intervention

In patients with familial cancer predisposition syndromes in which gastric cancer is identified, surgical resection offers the only curative treatment. Initial workup is similar to that described in the previous gastric adenocarcinoma chapter. In short, following dedicated staging and patient selection, operative intervention is pursued with a goal for complete resection with margins of at least 5 cm from gross tumor. The most important prognostic indicators are lymph node involvement and depth of tumor invasion. The diffuse type are more common in familial gastric cancer; this histologic subtype is quite infiltrative and the cells can extend well beyond the tumor mass, thus margins beyond 5cm are typically recommended with frozen sections to confirm complete extirpation. More than 15 resected nodes are necessary for adequate staging, and a D2 or extended lymphadenectomy is then performed.

Prophylactic total gastrectomy is recommended for patients with *CDH1* mutations and other select familial cancer predisposition patients. The entire stomach must be excised to remove all at risk tissue. With total gastrectomy, we recommend the formation of an intestinal pouch if anatomically permitted (Fig. 3). This, in our opinion, leads to improved functioning in both the short and long term. The pouch functions as a reservoir, and ultimately, many patients eat almost normally (Fig. 4). Total gastrectomy should ideally be performed at high-volume centers with achievable low perioperative mortality rates, especially in these prophylactic patients. Radical lymph node dissection is not deemed necessary when gastrectomy is performed for prophylaxis, as lymph node metastases are highly unlikely. A D1 lymphadenectomy is considered adequate. Prophylactic gastrectomy can be performed laparoscopically or via a small upper midline incision based on the surgeon's preference, taking into consideration comfort with constructing an intestinal pouch.

Timing of prophylactic gastrectomy must be discussed in detail with at risk patients because personal preferences, family history, and age of diagnosis with cancer in relatives will all affect the decision. Because approximately 5% of clinically diagnosed diffuse gastric cancer in *CDH1* carriers occurs before the age of 30, preventive gastrectomy is typically recommended before the age of 30 in patients with *CDH1* mutations and at least 5 to 10 years before earliest age of gastric cancer in relatives.

Postoperative Physiologic Recovery

Although offering a cure, treatment is not completed with the surgical extirpation of disease. Physiologic postsurgical recovery must be taken into consideration. This important part of the surgical patient experience includes eating difficulty, weight loss, and potential postoperative complications and infections. Within the first month, all patients have difficulty with eating; thus, appropriate expectations of initial postoperative difficulties are imperative. It is not uncommon for these initial struggles to be associated with "buyer's remorse" in patients having prophylactic surgery who are normally without

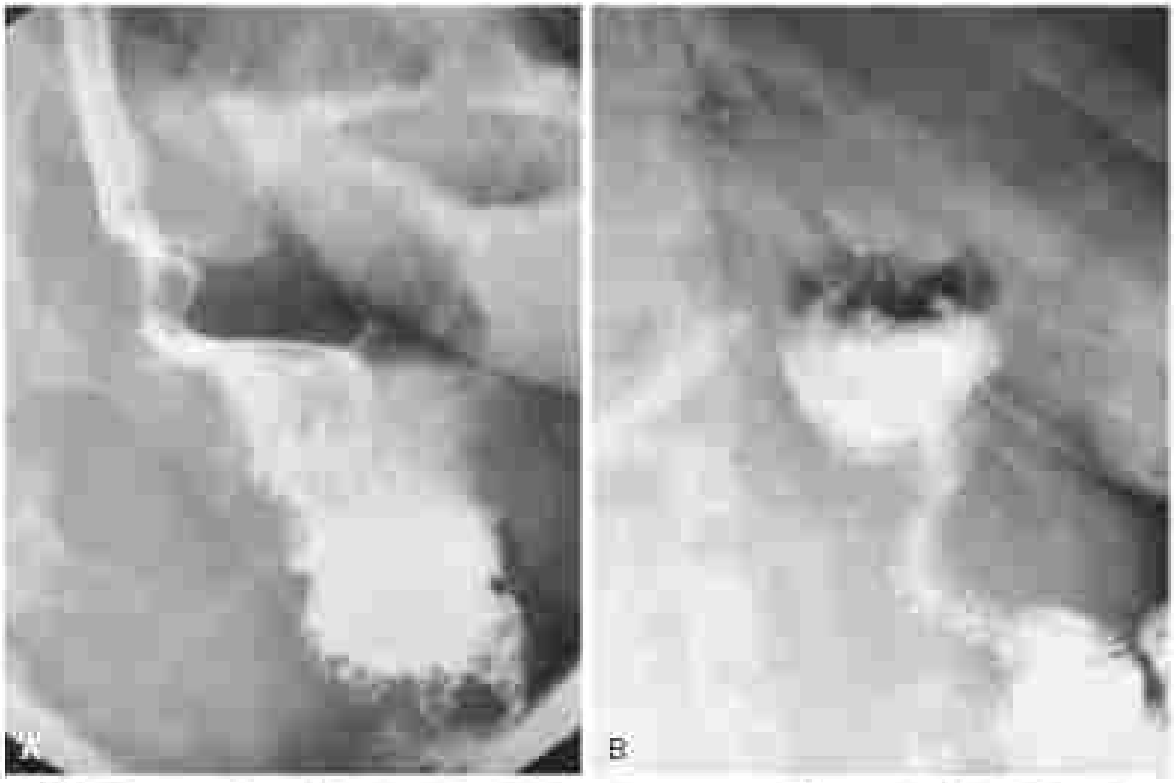

FIG. 4 Contrast swallow study in patient with prophylactic total gastrectomy now dilatory capacity of an inverted pouch.

symptoms and had no clinical disease. It is important to include a nutritionist in the treatment team counselling patients. Fortunately, there is usually improvement, particularly in the first 4 months but continuing throughout the first year. In our institutional series of prophylactic resections for *CDH1*, an initial 6-month weight loss of 12.5 kg was noted, which remained stable at 1 year. The majority of patients are eating well at 1 year and some patients report completely normal long term eating, including weight gain.

Gastric surgery changes how the stomach and intestines work, with different amounts and types of foods potentially causing nausea, diarrhea, or other symptoms. Dietary modifications and vitamin supplementation are necessary to maximize postoperative function and patient experience. Eating approximately six small meals and snacks throughout the day and drinking 30 to 60 minutes after, instead of with meals, can greatly improve tolerance. In the early postoperative period, our nutritionists recommend that meals should be made up of tender, soft, well cooked foods, high in protein and prepared without added fat. Foods high in sugar content, caffeine, dried beans, nuts, raw vegetables, and raw fruits should be limited, or avoided if particularly problematic. In patients who are doing better, a more liberal approach of eating smaller amounts of their own typical diet generally works well.

Because of changes in absorption, additional supplementation is necessary to meet daily requirements. This includes taking one to two multivitamins (including vitamin E) daily to provide iron, folic acid, thiamine, trace elements, and calcium. Calcium can be included in the multivitamin, or calcium citrate may be preferred at 1500 mg per day divided in three doses. Chewable and liquid vitamins are absorbed better than swallowed capsule or gummy forms. Vitamin B12 absorption is affected through loss of intrinsic factor, thus patients need regular supplementation after gastrectomy. This can be given either as a daily pill (1000 μg sublingually), or as a monthly injection (1000 μg intramuscularly), or rarely as a nasal spray (500 μg) weekly.

Other Malignancy Risks

It is crucial to recognize that gastric cancer is not the only malignancy with increased observed frequency for the majority of these syndromes and genetic mutations. For example, it is well recognized that HPNCC is associated with increased risks of colon cancer and thus appropriate colonoscopic surveillance is necessary. As previously mentioned, a *CDH1* mutation is associated with high rates of lobular breast cancer in women. It is important to identify these other malignancy risks on both sides of presentation and appropriately monitor and prevent malignancy of all types.

Appropriate Family Testing

Finally, these discussed syndromes are all inherited disorders, meaning the index patients directly cared for are not the only ones at risk. Appropriate genetic testing for family members is necessary to ensure that preventive care and surveillance are offered to all at risk. Genetic counseling is highly encouraged. Genetic counselors, working as part of the health care team, present and explain the often complex and confusing information about genetic risks, testing, and diagnoses. They also serve as patient advocates offering both pre- and positive counselling services to prepare patients and their families for testing results and implications. The advent of new, fast, and inexpensive, massive, parallel sequencing technologies is expected to increase the identification of potential oncogenes. With the growing availability and performance of genetic testing, mutations such as *CDH1* may be identified incidentally on a multigene panel in an individual without a relevant history of gastric cancer or lobular breast cancer. The true risks of these incidentally identified mutations are unknown. It is difficult to know the best recommendations; however, close surveillance is warranted and offering prophylactic surgery to appropriate candidates is reasonable.

As our understanding of familial gastric cancer and the associated putative genes improves, more at-risk patients will be identified earlier with an opportunity to offer surgical prevention of cancer.

Management of Gastrointestinal Stromal Tumors

Michael G. Heinz, MD, FACS

Gastrointestinal stromal tumor (GIST) is the most common sarcoma of the gastrointestinal tract and the most common sarcoma subtype overall; thus, a general surgeon should be familiar with the unique principles of management for this disease. Knowledge of the pathophysiology of GISTs has advanced rapidly over the past 2 decades. The cell of origin for GIST is the interstitial cell of Cajal, and in most cases, development of tumor appears to require oncogenic activation of a tyrosine kinase. Approximately 75% of GISTs bear activating mutations in *KIT*, with *PDGFRα* mutated in another 10%. The remaining group of wild-type *KIT* GISTs has continued to shrink because alterations have been discovered in *BRAF* and *NF1* genes in other patients. Since the description of a gain of function mutation in the *KIT* proto-oncogene in 1998, targeted therapy against GIST has been studied extensively. Imatinib mesylate (Gleevec), a tyrosine kinase inhibitor (TKI) of ABL, BCR-ABL, *KIT*, and platelet-derived growth factor receptor (PDGFR), has become a major component in the multidisciplinary management of patients with GIST.

Treatment of GIST with imatinib has been studied extensively. In patients with metastatic disease, imatinib prolongs median survival to more than 5 years from a historical median of 18 months. In the adjuvant setting, imatinib prolongs recurrence-free survival (RFS), and neoadjuvant imatinib therapy may improve resectability for tumors that are locally advanced or located in anatomically difficult areas (e.g., pelvis). Neoadjuvant imatinib may also downsize a tumor to permit an organ-preserving resection. Imatinib therapy has also expanded the role of surgical therapy for metastatic GIST. The ability to estimate the risk of recurrence in GIST patients increasingly is refined. In addition to traditional stratification using tumor size, mitotic index, and organ site, specific mutations in *KIT* have a significant bearing on tumor behavior and sensitivity to TKIs. Although targeted therapy plays a major role in the management of patients with GIST, surgery remains the only potentially curative therapy for GIST.

CLINICAL PRESENTATION

GIST is typically a disease of adults, with a median presenting age of approximately 60 years, with a slight male predominance. The incidence of GIST is estimated to be approximately 6000 new cases per year in the United States. According to autopsy studies, the incidence of occult micro GISTs, smaller than 1 cm, is much higher. Although GIST may arise anywhere from the esophagus to the rectum, the stomach is the most common site (~50%), followed by small bowel (25% to 35%). The majority of small bowel tumors are found in the jejunum and ileum, with a minority (<10%) arising in the duodenum. Rare sites of GIST include the rectum, colon, esophagus, and extraintestinal/indeterminate locations. The median size of GIST at presentation is 5 to 7 cm, although tumors may grow to excess of 30 cm. GISTs may produce clinical symptoms (e.g., early satiety, nausea, weight loss, postprandial pressure, bloat) induced by a large space occupying tumor. Often, GISTs are discovered incidentally by endoscopy or imaging during the workup for other conditions or at the time of unrelated surgery. Patients with large GISTs may experience pain or a palpable mass. Although GIST is not a mucosa-based tumor and grows from the muscular layer of the gut wall, it still may be accompanied by occult or overt gastrointestinal bleeding in up to one-quarter of patients as a result of direct tumor erosion of the underlying mucosa. Careful endoscopy is necessary to reveal small punctate areas of mucosal ulceration resulting from GIST. Bleeding from tumor rupture into the peritoneal cavity is rare, but is a negative prognostic factor and may lead to life-threatening hemorrhage. Metastasis typically involves the liver or peritoneal cavity. Lymph node involvement, occurring less than 5% of patients, is rare in adult GIST and usually reflects direct tumor extension.

Pediatric GIST, often associated with succinate dehydrogenase deficiency, exhibits a different biology compared with adult GIST. This disease is indolent and shows female predominance with multifocal disease, frequent lymph node metastasis, and imatinib resistance. Familial GIST involving germline mutation of *KIT* or *PDGFRα* mutations is rare. Typically, the tumors are multifocal and indolent. GIST can occur rarely in association with the Carney triadakis syndrome (GIST and paraganglioma), Carney's triad (GIST, paraganglioma, and pulmonary chondroma), or neurofibromatosis type 1 (GIST, neurofibroma, glioma, and malignant peripheral nerve sheath tumor).

Workup

Computed tomography (CT) of the abdomen and pelvis with oral and intravenous contrast is the imaging test of choice for the initial evaluation of GIST. A typical GIST appears as an enhancing mass arising in the wall of the stomach or intestine. GISTs may be grossly categorized as exophytic, endophytic, or mixed dumbbell shape (Fig. 1). Large masses may exhibit heterogeneous enhancement resulting from necrosis or areas within the tumor. Small GISTs may not be visible on CT, depending on the distention of the bowel or stomach and whether oral contrast was administered. A large hypervascular GIST arising from the lesser curvature of the stomach may be misinterpreted as a primary liver tumor. Determining whether adjacent structures are involved by large tumors can be difficult because of a loss of plane interfaces on CT; however, most GISTs are found to be mobile

As our understanding of familial gastric cancer and the associated putative genes improves, more at-risk patients will be identified earlier with an opportunity to offer surgical prevention of cancer.

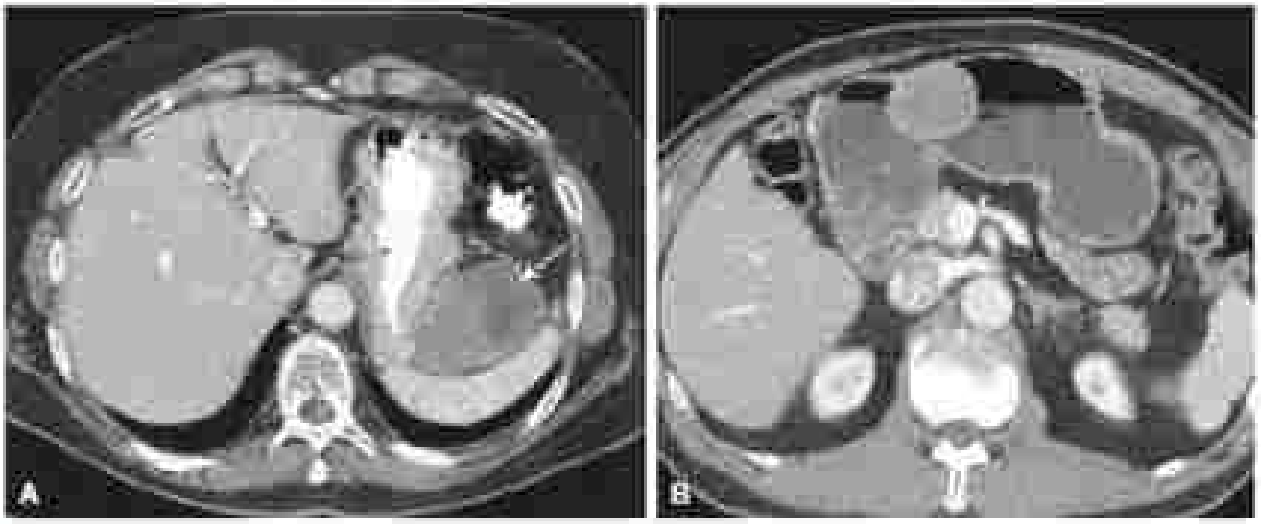

FIG. 1 Contrast-enhanced computed tomography scan of a patient with a gastrointestinal stromal tumor (GIST). (A) The most common appearance on neoplastic on axial imaging. (B) Endophytic GISTs of the stomach are less common but may be associated with higher rates of intestinal erosion and bleeding.

at the time of operation and do not require multivisceral resection. Although GISTs are typically glucose avid on [^{18}F] fluoro-2-deoxy-D-glucose positron emission tomography, this test is not necessary in the initial evaluation and should be reserved for assessment of metastatic disease when there is heterogeneity of response to TKIs.

Some GISTs are detected initially by endoscopic evaluation by the presence of a submucosal mass or a small punctate mucosal ulceration. Endoscopic ultrasound with fine needle aspiration (FNA) is highly sensitive and will reveal a population of spindle cells that stain positive for CD117 (KIT) on immunohistochemistry. Endoscopic ultrasound FNA may help differentiate GIST from other tumors involving the stomach or duodenum such as leiomyoma, lymphoma, or adenocarcinoma that would require different treatment considerations. For indeterminate tumors that would require potentially morbid operations (e.g., tumors involving the gastroesophageal junction, periampullary duodenum, or rectum), several biopsy attempts to establish an accurate diagnosis may be necessary to recommend the optimal sequence of intended treatments with resection and targeted therapy. If the radiologic appearance of a tumor involving the stomach or small bowel is typical of GIST, biopsy is not necessarily required. Percutaneous biopsy of a small bowel GIST is never recommended as it risks peritoneal dissemination.

Risk Stratification

Three clinicopathologic parameters have been shown to independently predict risk of recurrence after complete resection of primary GIST: tumor size, mitotic rate, and tumor site. Size greater than 5 cm; tumors larger than 5/50 high powered fields; and nongastric site are poor prognostic variables. Several different risk stratification systems have been developed based on these variables (Table 1). A nomogram that incorporates all three criteria (Fig. 2) provides an individualized estimate of 3- and 5-year RFS after complete resection of a primary GIST and can provide selection criteria for adjuvant imatinib.

Identification of the specific *KIT* or other gene (e.g., *PDGFR*, *SDH*) mutation in GIST, either after resection or even preoperatively from FNA cytopathology, provides useful information regarding responsiveness to targeted therapy and progression free survival after resection. Specific mutations are associated with tumor biology and most importantly tumor response to imatinib therapy. Three-quarters of tumors harbor a *KIT* mutation, and mutations of exon 11 are the most common, encompassing 67% of all GISTs. Among exon 11 mutations, codons 557 and 558 are hot spots for mutation, and tumors with deletions of this part of the gene are more likely to metastasize or recur as compared with point mutations or insertions in this area. *KIT* exon 9 mutations (about 10% of all GISTs) typically arise in nongastric tumors and carry unfavorable biology. Meta-analysis of two large trials of imatinib in metastatic unresectable GIST showed that patients with exon 9 mutations require higher dose imatinib for response (800 mg vs 400 mg daily). PDGFRα mutant tumors, representing 10% of GISTs, are almost always gastric based and display comparably indolent biology. However, the most common PDGFRα mutation to exon 18 (D842V) imparts imatinib resistance.

SURGERY FOR PRIMARY DISEASE

Indications

Resection is the mainstay of treatment for the majority of patients with GISTs. National Comprehensive Cancer Network guidelines recommend that GISTs larger than 2 cm *should* be resected in patients who are *otherwise* acceptable candidates for surgery. Asymptomatic, uncomplicated small GISTs smaller than 2 cm may be observed with surveillance imaging.

General Technical Aspects

At the time of surgical exploration, whether open or laparoscopic, the peritoneal surface and liver should be surveyed for metastatic disease. Exophytic anterior and greater curvature gastric tumors are immediately apparent. Posterior gastric tumors require mobilization of the stomach, which is facilitated by retracting the left lobe of the liver to the right and entering the lesser sac thru the greater omentum or gastrocolic ligament. Small intramural, or intraluminal gastric tumors that are not easily identified externally during laparoscopy, can be localized with intraoperative endoscopy with a gastroscope. Duodenal tumors beyond the first portion require an extensive Kocher maneuver and possibly mobilization of the ligament of Treitz. Ileal and jejunal tumors are identified best by carefully running the small bowel from the ligament of Treitz to the terminal ileum.

After the primary tumor is identified, all manipulations should be done with great care because these tumors are friable, especially after neoadjuvant treatment. During laparoscopic surgery, manipulation is achieved best by handling only tissue adjacent to the tumor (i.e., no touch technique). Tumor rupture, whether spontaneous or iatrogenic, is associated with almost inevitable peritoneal recurrence. Likewise, GISTs recruit large arterial and venous collateral blood

TABLE 1 Risk Classification for Primary GIST According to Mitotic Index, Tumor Size, and Tumor Site

Tumor Parameters			Risk of Disease Progression (% of Patients)		
Mitotic Index	Size	Stomach	Duodenum	Jejunum or Ileum	Rectum
≤5 per 50 HPF	≤2 cm	None	None	None	None
	>2 to ≤5 cm	Very low (1.9%)	Low (8.3%)	Low (4.3%)	Low (8.3%)
	>5 to ≤10 cm	Low (3.4%)	Insufficient data	Moderate (24%)	Insufficient data
	>10 cm	Moderate (10%)	High (34%)	High (52%)	High (57%)

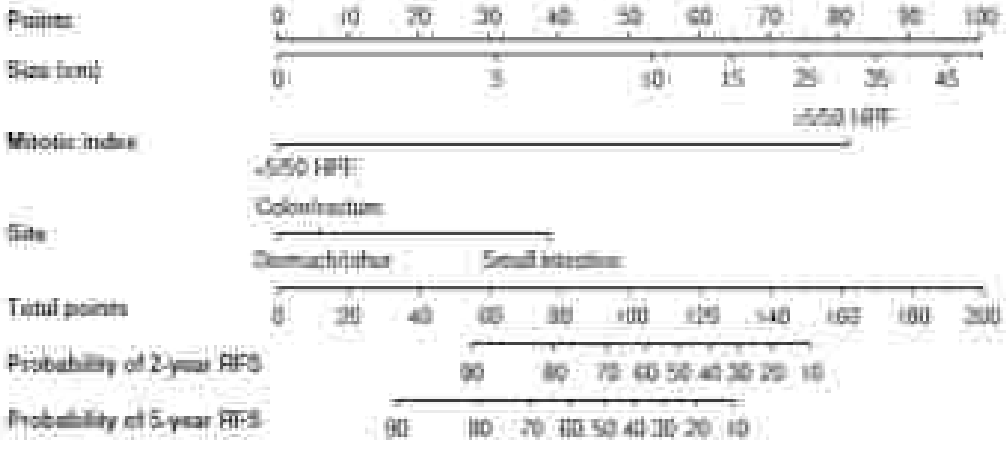

FIG. 2 Nomogram for predicting 2- and 5-year recurrence-free survival (RFS) after resection of primary gastrointestinal stromal tumor. Points are assigned based on tumor size, mitotic index, and site by drawing a vertical line from each row to the "points" row. The sum is then located in the "total points" row, and a vertical line is drawn to the "probability" rows to estimate RFS. HPF, high-powered field. (Modified from Gold JS, Gönen M, Gutiérrez A, et al. Development and validation of a prognostic nomogram for recurrence-free survival after complete surgical resection of localised primary gastrointestinal stromal tumour: a retrospective analysis. Lancet Oncol. 2009;10(11):1045–1052.)

wounds, and careful dissection is required to prevent the potential for significant blood loss. During laparoscopic surgery, retrieval of the specimen should be done with a plastic specimen retrieval bag to prevent tumor seeding. Although GISTs usually displace and do not invade adjacent organs, any tissue surface that is densely adherent to the tumor should be at least partially resected en bloc.

Site-Specific Considerations

Several fundamental principles and site-specific considerations exist for the resection of GIST. Complete resection of GIST does not require wide margin clearance or formal lymphadenectomy. Complete (R0) resection is the goal, but data from 819 primary GISTs 3 cm or larger resected in the American College of Surgeons Oncology Group Z9000 and Z9001 trials showed no difference in RFS in the 72 (8.8%) patients who had microscopically positive (R1) margins compared with those who underwent R0 resection. Gross circumferential resection margins of 1 cm will ensure an R0 resection.

Exophytic tumors with a narrow stalk or those on the greater curvature or fundus of the stomach can be removed easily by laparoscopic wedge partial gastrectomy using surgical staplers without compromising the lumen of the stomach.

A unique technique of tumor excision with a small negative margin (usually 1 cm) under direct visualization using cautery is useful for gastric GISTs (Fig. 3). Direct visualization and excision facilitate safe resection while preserving gastric capacity and minimizing luminal narrowing in more difficult areas, such as the pyloric antrum, incisura, lesser curvature, or gastroesophageal junction (GEJ). GISTs involving the GEJ should attract attention for neoadjuvant imatinib for tumor downsizing before resection, and open surgery is preferred for tumors along the posterior aspect of the GEJ (Fig. 4). Tumor resections from the lesser curvature of the stomach will require careful dissection to preserve vagal nerve integrity. When the vagal trunks cannot be preserved, pyloroplasty or pyloromyotomy should be performed.

Total gastrectomy or esophagogastrectomy is rarely necessary but may be required for sizable tumors involving a large area of the lesser gastric curvature or GEJ, respectively. Massive tumors may be adherent to the spleen, distal pancreas, or colon, necessitating en bloc resection. When neoadjuvant preoperatively preferred lies with

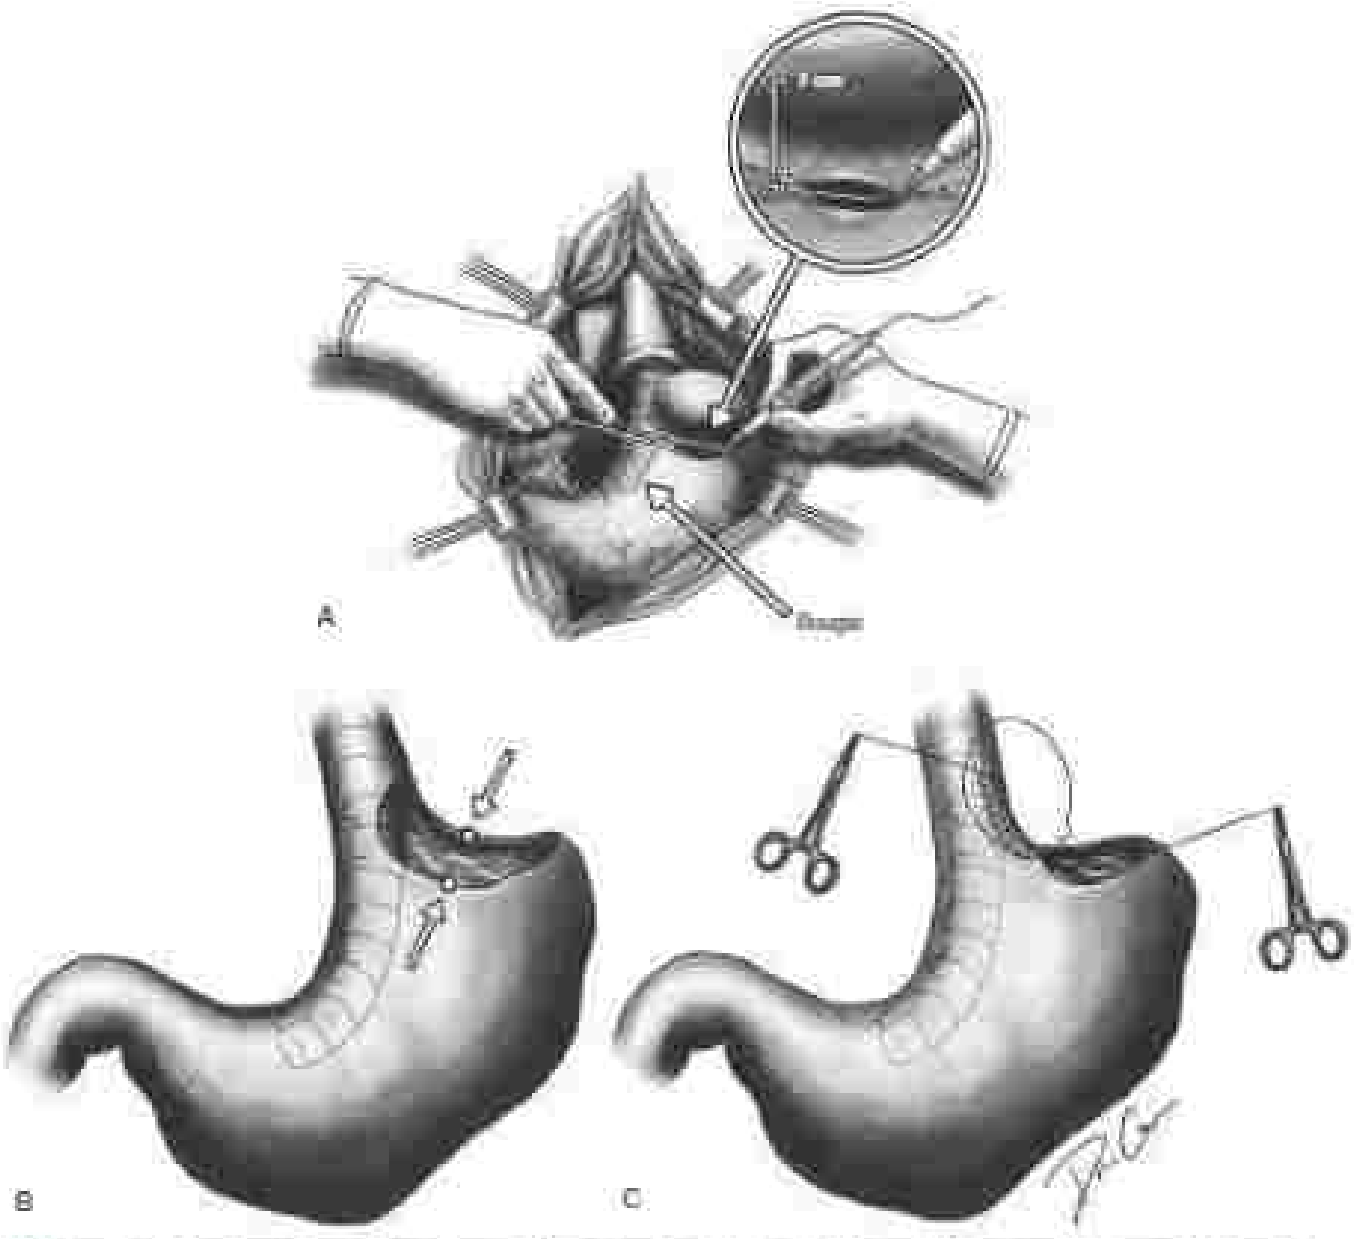

FIG. 3. Resection of a large gastrointestinal stromal tumor at the gastroesophageal junction. (A) After making a gastrotomy with marking the tumor is resected with a 1–cm margin. (B) The defect is then sewn closed (C) over a large bougie placed in the esophagus to prevent narrowing. (Courtesy Cleveland Clinic)

neoadjuvant imatinib to accomplish tumor downsizing and demarcation before an attempt at organ preserving resection.

The next most common site of GIST is the small bowel. Jejunal and ileal tumors can be removed easily with either open or laparoscopic techniques. Management of duodenal GISTs may be complicated because of relationships with the pancreas and bile duct. Consideration for neoadjuvant imatinib should occur for any duodenal GIST where pancreaticoduodenectomy is deemed necessary for complete resection. Small GISTs not involving the peri-Vaterian duodenum can be resected without pancreatectomy. Periampullary GISTs involving the medial duodenal wall usually require pancreaticoduodenectomy even after neoadjuvant imatinib. Small GISTs arising from the lateral wall of the second portion of duodenum can usually be excised. The duodenal defect can be closed with suture duodenorrhaphy without compromising luminal caliber. Alternatively, the duodenal defect can be anastomosed to a Roux limb. Tumors in the third or fourth portion of the duodenum can be managed with segmental duodenectomy followed by primary duodenojejunostomy.

Rectal GISTs are rare but are much more common than colonic GISTs. Neoadjuvant imatinib treatment should be offered to patients with large rectal GISTs to accomplish tumor downsizing and sphincter preservation. Small GISTs involving the lower rectum can be excised transanally with possible need for transanal endoscopic proctoscopic surgery.

NEOADJUVANT IMATINIB

For nonmetastatic GISTs, neoadjuvant imatinib treatment should be considered for tumors that are locally advanced and require major multivisceral resection. Neoadjuvant imatinib may also allow tumor downsizing that could facilitate operative resection. Although change in metabolic activity is evident by [18F] fluoro-2-deoxy-D-glucose

positron emission tomography imaging within days of imatinib exposure, objective tumor downsizing may take many weeks or even several months on imatinib treatment. Treatment response is more reliably assessed by comparing tumor density and dimensions, particularly when evaluating early tumor response (Fig. 5). After initiation of neoadjuvant imatinib, a follow up contrast enhanced CT should be obtained within 8 weeks. Surveillance imaging is typically obtained at 3 month intervals thereafter. Beyond 6 months of neoadjuvant imatinib therapy, further tumor downsizing is unlikely to be observed. Unlike most cytotoxic chemotherapy regimens used in the neoadjuvant setting, neoadjuvant imatinib and other TKIs can be continued up until the time of surgery without compromising wound healing or causing immunosuppression.

ADJUVANT IMATINIB

The initial large-scale studies of imatinib in metastatic unresectable GIST were highly successful. These studies realized a dramatic improvement in survival from a historical median of 18 months to beyond 5 years. However, demonstrating similar improvement in survival from adjuvant imatinib after complete surgical resection has been more difficult. Randomized adjuvant trials designed with crossover treatment arms have demonstrated that placebo-treated patients who develop recurrence are usually salvaged with imatinib therapy and resection and survive for extended periods. The American College of Surgeons Oncology Group Z9001 study was a phase III multicenter prospective randomized trial of imatinib compared with placebo for 1 year after resection of primary GISTs of at least 3 cm size regardless of mitotic index. The study was stopped early at interim analysis when significantly improved RFS survival was noted in the imatinib group (98% vs 83% at a median follow-up of 19.7 months). Long-term follow-up of these patients revealed that relapse occurred within 5 years after completing the 1 year of prescribed imatinib (Fig. 6). After 54 months of follow-up, the RFS curves of the placebo and imatinib treatment arms converged. Imatinib seems to be effective in controlling but not eradicating residual microscopic disease. Interestingly, the majority of improvement in RFS from imatinib was observed primarily in the patients with exon 11 deletions, but not other mutations.

The SSG XVIII study was a phase III randomized study designed to compare the benefits of 1 versus 3 years of adjuvant imatinib.

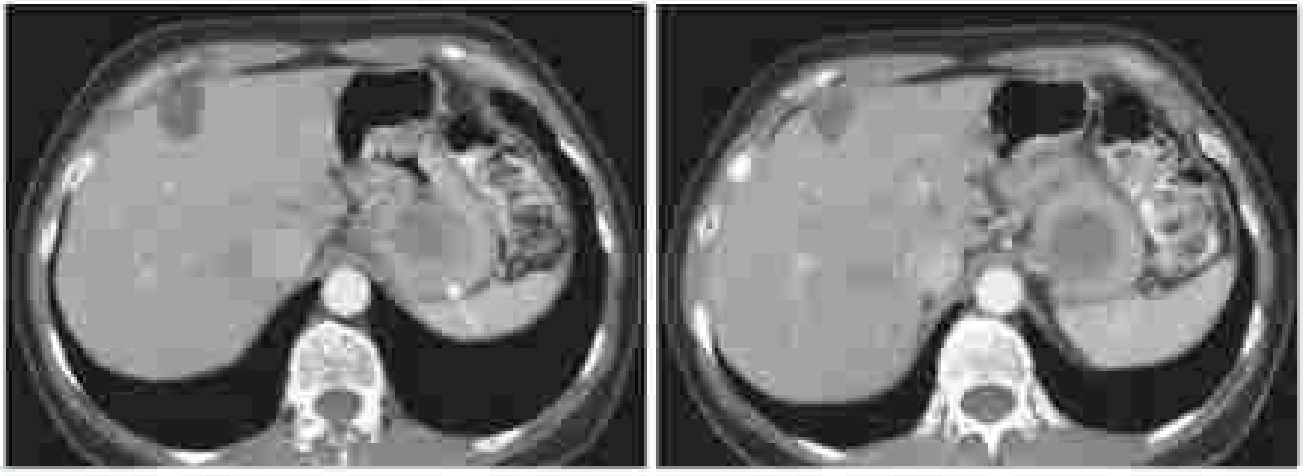

FIG. 4 Contrast-enhanced computed tomography scan of a patient with a gastric gastrointestinal stromal tumor that is endophytic in nature and located along the posterior aspect of the gastric cardia just 3 cm beyond the gastroesophageal junction (arrow). Open excision with nature gastrectomy is recommended for tumors in this location.

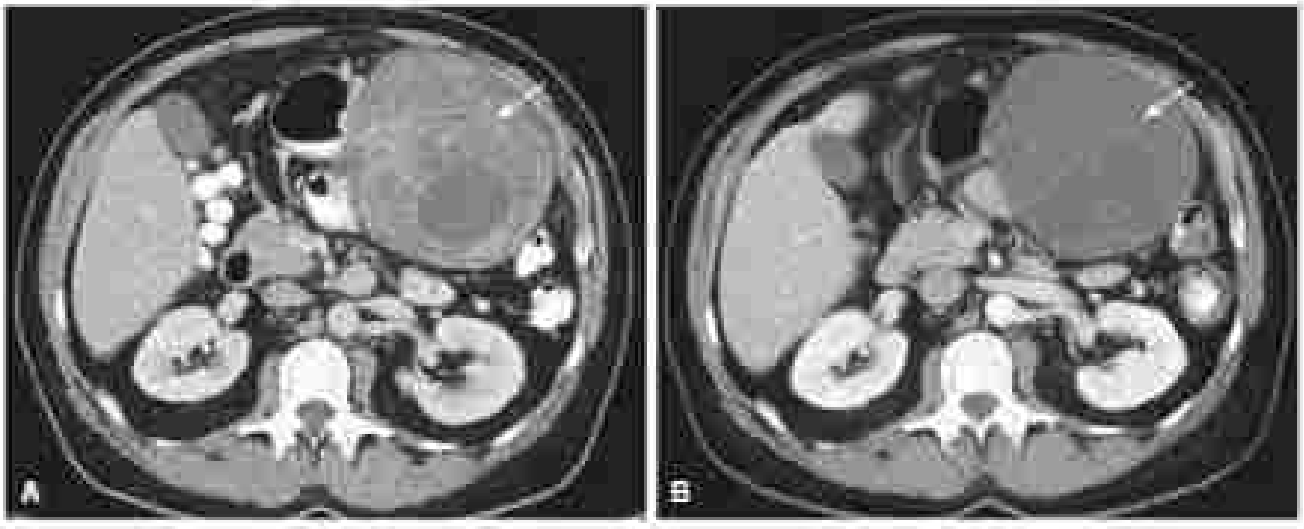

FIG. 5 Initial tumor response to neoadjuvant imatinib is best assessed by changes in tumor density. (A) A large gastric gastrointestinal stromal tumor was treated with imatinib for 8 weeks. (B) After treatment, computed tomography showed similar size (maximal dimension 12.6 cm pretreatment, 11 cm post-treatment), but decreased density. The patient eventually underwent an uncomplicated wedge partial gastrectomy and pathology showed RECIST treatment response.

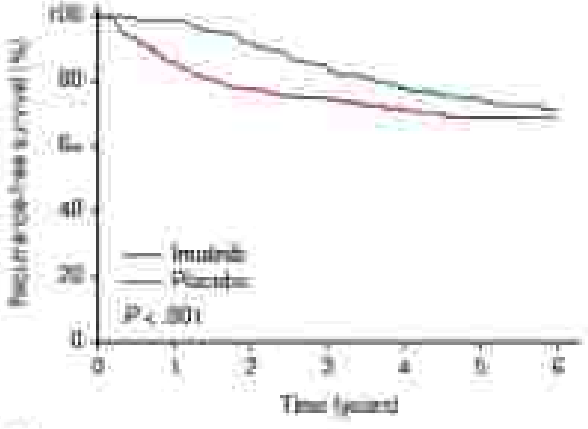
this study showed improved 5-year RFS (90% vs 69%), with a slight improvement in overall survival (92% vs 82%). The PERSIST-5 (Efficacy Study of Imatinib Therapy for the Treatment of Myelofibrosis Irrespective of Baseline Cytogenetics-5) trial was a phase II single-arm study of 5 years of adjuvant imatinib after resection of primary GISTs at high risk for recurrence (any site ≥2 cm with ≥6 mitoses/50 high-powered fields or any nongastric GIST ≥5 cm). Five years of imatinib treatment for this group of GIST patients was effective in preventing recurrence in those with sensitive *KIT* gene mutations.

RECURRENT, METASTATIC, AND RESISTANT DISEASE

First-line imatinib therapy will usually induce an objective partial tumor response in the majority of patients who develop recurrent disease after resection for GIST. However, the median time to disease progression with imatinib therapy alone is on the order of 24 months



No. at risk							
Imatinib 400 mg	359	256	151	230	199	143	74
Placebo	354	278	243	218	186	132	64

FIG. . Recurrence-free survival in patients with primary gastrointestinal stromal tumor of 3 cm or greater after complete resection, randomized to 1 year of adjuvant imatinib versus placebo. (*Modified from* Corless CL, Ballman KV, Antonescu CR, et al: Pathology and molecular biology correlates with long-term outcome after adjuvant therapy of resected primary GI stromal tumor: the ACOSOG Z9001 trial. J Clin Oncol 2014;32:1563.)

and often reflects the development of secondary mutations in *KIT*. Resistance to imatinib may be detected during radiographic surveillance with the appearance of an enhancing nodule(s) within a previously lucent tumor. Despite accumulation of further *KIT* mutations, treated GISTs that have become resistant to imatinib will often show partial response to second lines of TKIs (e.g., sunitinib, regorafenib). However, second- and third-line TKI therapy affords smaller benefits with regards to progression-free survival on the order of 3 to 6 months.

Patients with recurrent or metastatic GIST should be imaged on a 3-month basis. Operative resection can be considered when tumor resistance becomes apparent. Survival benefit from surgical therapy in these two situations is realized only in carefully selected patients with limited burdens of disease. Patients with partially responsive GISTs after TKI therapy will experience improved survival after surgery compared with patients who develop either rapid or multifocal tumor resistance patterns. Patients with multifocal sites of tumor resistance during TKI therapy should be referred for clinical trials.

Resection or ablation of hepatic GIST metastases should be planned to clear all detectable sites of tumor with attention to parenchymal preservation of the liver remnant. Resection of peritoneal GIST metastases may require removal of adjacent organs. After resection of hepatic or peritoneal metastases, adjuvant TKI therapy should be continued indefinitely or until tumor recurrence develops.

CONCLUSIONS

GISTs most commonly arise from the stomach or small intestine and are caused by activating mutations in the *KIT* or *PDGFRα* genes. GIST is a heterogeneous disease that may present as a clinically indolent micrometer or a rapidly progressive malignancy with widespread metastases. Surgery for GIST requires a no-touch technique to avoid tumor rupture and spillage. Tumor locations along the alimentary tract dictate the specific aspect of surgical therapy that will provide complete tumor clearance. Operative resection of larger tumors and tumors located at difficult anatomic locations may be facilitated by neoadjuvant imatinib therapy. Risk for tumor recurrence is independently predicted by tumor size, mitotic rate, and site of disease. Specific mutations of *KIT* help to predict responsiveness to TKI therapy. Adjuvant imatinib should be used in patients at high risk for disease recurrence predicted by individualized nomograms. Resection of recurrent or metastatic GIST should be considered for patients with limited burdens of disease who are responding to TKI therapy or demonstrate only focal tumor resistance. An algorithm for multimodality therapy of GIST is shown in Fig. 7.

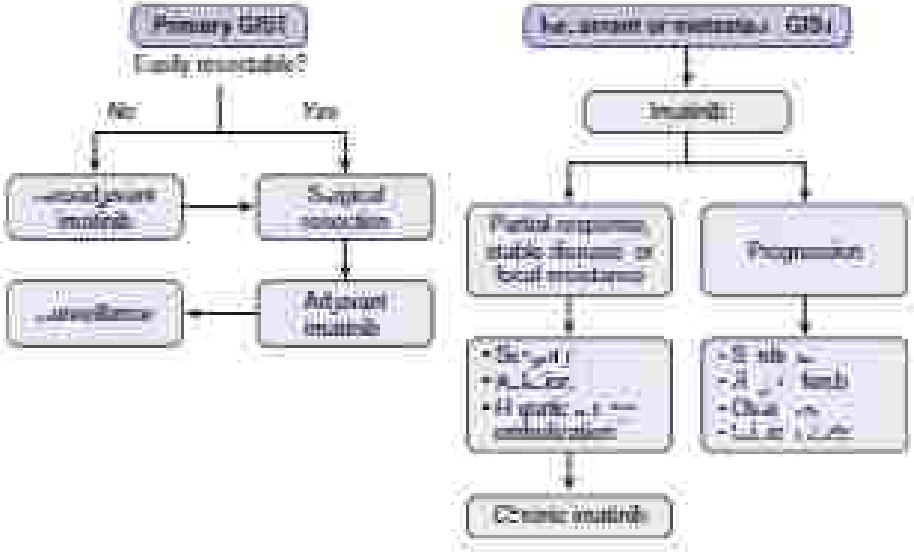


FIG. 7 Schematic approach to patients with gastrointestinal stromal tumor (GIST). For locally advanced primary tumors treated with adjuvant imatinib, tumor assessment should be performed by computed tomography (CT) at 4 weeks to document response to therapy. If GIST nomogram predicts a high or intermediate risk of recurrence, adjuvant imatinib (*) should be continued for at least 3 years; possibly chronically. Surveillance after resection of GIST should include a CT of abdomen and pelvis every 3 or 6 months for 3 to 5 years and then annually. TKI, tyrosine kinase inhibitor. Management of Morbid Obesity

Andrew P. Rogers, MD, and Anne O. Lidor, MD, MPH

The prevalence of morbid obesity continues to increase in the United States and throughout the world. In the United States, >5% of adults are classified as either overweight or obese, up 10% in the past generation. The majority of that increase is in the obese population (body mass index [BMI] >30 kg/m^2), with more than 6% being severely obese (BMI >40 kg/m^2). This trend is seen across the age spectrum, as the prevalence of obesity (>95% BMI for age and sex) in children and adolescents has tripled since 1970.

Although initial forays into weight loss surgery had high complication rates and poor long-term results, advances in technology and technique have led to a surge in surgical interventions for morbid obesity. Recent studies have shown bariatric surgery to be superior to intensive medical management for both weight loss and all-cause mortality for the morbidly obese patient, even when perioperative morbidity and mortality are included. As of 2014, more than 200,000 surgical weight loss procedures are performed annually in the United States. The majority of these are sleeve gastrectomy (58.2%), with Roux-en-Y gastric bypass (18.2%) and revisions (13.9%) comprising most of the rest. Gastric bands have greatly fallen out of favor (3.4%, down from 35.4% 5 years prior), owing to their poor outcomes and higher complication rates.

Surgical intervention may achieve weight loss either by restriction of caloric intake (gastric band and sleeve gastrectomy), intestinal malabsorption of calories (duodenal switch), or a combination of restriction and malabsorption (gastric bypass). Weight loss surgery also has been demonstrated to have significant metabolic and neurohormonal effects (independent of restriction and malabsorption), which also may play an important role in the beneficial effects of these procedures.

Patient Selection

The National Institutes of Health issued a consensus statement in 1991 regarding the effectiveness of bariatric surgery and patient selection criteria. A patient is considered a candidate for bariatric surgery if his or her BMI is 40 kg/m^2 or greater or between 35 and 40 kg/m^2 if an obesity-related comorbidity (i.e., diabetes, hypertension, sleep apnea) is present. Candidates should demonstrate prior unsuccessful attempts at nonsurgical weight loss, including dietary intervention, pharmacologic therapy, or behavioral modification. Realistic long-term outcomes and expectations should be set before surgical intervention, and the patient should be an appropriate operative candidate from a perioperative perspective. Relative contraindications include inability to comply with postoperative requirements, active alcohol or substance abuse, and uncontrolled psychiatric disease.

Preoperative evaluation should involve a multidisciplinary team, including a dietician and a mental health professional familiar with bariatric surgery. It is critical to obtain a complete history of prior weight loss attempts and behavior history around food intake. Preparation for postoperative behavior modifications and examination of social support is also important to success. Patients should be required to attend a multidisciplinary preoperative education program. Participation in postoperative support group meetings also is encouraged. As experience builds, the age for which surgical intervention is appropriate continues to grow; adolescents and those older than age 70 are now routinely undergoing bariatric surgery.

Operative Procedures

Most bariatric surgical procedures are performed laparoscopically, with a hospital length of stay of 48 hours or less. Open surgery may be necessary and planned for patients who undergo revision surgery, those with prior extensive abdominal operations, or patients with a high BMI (>70).

Perioperatively, all patients should receive appropriate antibiotics as well as subcutaneous unfractionated or low molecular weight heparin to help minimize venous thromboembolic complications. Patients are typically in steep reverse Trendelenburg position and must be supported with a footboard and arms and legs secured. Initial laparoscopic entry to a morbidly obese patient can be difficult. We have found that the safest way to enter is to the left upper quadrant with direct vision, using a device that allows visualization of the abdominal wall layers during entry with a 0-degree laparoscope. Once proper placement is confirmed, the abdomen then can be insufflated and the remaining laparoscopic trocars placed.

Laparoscopic Vertical Sleeve Gastrectomy

Laparoscopic vertical sleeve gastrectomy (LVSG) is the most recent of the bariatric surgery procedures to be introduced (Fig. 1) and is the most commonly performed weight loss operation in the United States. The LVSG is restrictive; the lateral aspect of the stomach is removed to create a sleeve-like tube or reservoir. Because the fundus produces the pro-appetite hormone ghrelin, its removal also gives this procedure a neurohormonal mechanism of action. Although not

Management of Morbid Obesity

Andrew P. Rogers, MD, and Anne O. Lidor, MD, MPH

The prevalence of morbid obesity continues to increase in the United States and throughout the world. In the United States, >5% of adults are classified as either overweight or obese, up 10% in the past generation. The majority of that increase is in the obese population (body mass index [BMI] >30 kg/m^2), with more than 6% being severely obese (BMI >40 kg/m^2). This trend is seen across the age spectrum, as the prevalence of obesity (>95% BMI for age and sex) in children and adolescents has tripled since 1970.

Although initial forays into weight loss surgery had high complication rates and poor long-term results, advances in technology and technique have led to a surge in surgical interventions for morbid obesity. Recent studies have shown bariatric surgery to be superior to intensive medical management for both weight loss and all-cause mortality for the morbidly obese patient, even when perioperative morbidity and mortality are included. As of 2014, more than 200,000 surgical weight loss procedures are performed annually in the United States. The majority of these are sleeve gastrectomy (58.2%), with Roux-en-Y gastric bypass (18.2%) and revisions (13.9%) comprising most of the rest. Gastric bands have greatly fallen out of favor (3.4%, down from 35.4% 5 years prior), owing to their poor outcomes and higher complication rates.

Surgical intervention may achieve weight loss either by restriction of caloric intake (gastric band and sleeve gastrectomy), intestinal malabsorption of calories (duodenal switch), or a combination of restriction and malabsorption (gastric bypass). Weight loss surgery also has been demonstrated to have significant metabolic and neurohormonal effects (independent of restriction and malabsorption), which also may play an important role in the beneficial effects of these procedures.

Patient Selection

The National Institutes of Health issued a consensus statement in 1991 regarding the effectiveness of bariatric surgery and patient selection criteria. A patient is considered a candidate for bariatric surgery if his or her BMI is 40 kg/m^2 or greater or between 35 and 40 kg/m^2 if an obesity-related comorbidity (i.e., diabetes, hypertension, sleep apnea) is present. Candidates should demonstrate prior unsuccessful attempts at nonsurgical weight loss, including dietary intervention, pharmacologic therapy, or behavioral modification. Realistic long-term outcomes and expectations should be set before surgical intervention, and the patient should be an appropriate operative candidate from a perioperative perspective. Relative contraindications include inability to comply with postoperative requirements, active alcohol or substance abuse, and uncontrolled psychiatric disease.

Preoperative evaluation should involve a multidisciplinary team, including a dietician and a mental health professional familiar with bariatric surgery. It is critical to obtain a complete history of prior weight loss attempts and behavior history around food intake. Preparation for postoperative behavior modifications and examination of social support is also important to success. Patients should be required to attend a multidisciplinary preoperative education program. Participation in postoperative support group meetings also is encouraged. As experience builds, the age for which surgical intervention is appropriate continues to grow; adolescents and those older than age 70 are now routinely undergoing bariatric surgery.

Operative Procedures

Most bariatric surgical procedures are performed laparoscopically, with a hospital length of stay of 48 hours or less. Open surgery may be necessary and planned for patients who undergo revision surgery, those with prior extensive abdominal operations, or patients with a high BMI (>70).

Perioperatively, all patients should receive appropriate antibiotics as well as subcutaneous unfractionated or low molecular weight heparin to help minimize venous thromboembolic complications. Patients are typically in deep reverse Trendelenburg position and must be supported with a footboard and arms and legs secured. Initial laparoscopic entry to a morbidly obese patient can be difficult. We have found that the safest way to enter is to the left upper quadrant with direct vision, using a device that allows visualization of the abdominal wall layers during entry with a 0-degree laparoscope. Once proper placement is confirmed, the abdomen then can be insufflated and the remaining laparoscopic trocars placed.

Laparoscopic Vertical Sleeve Gastrectomy

Laparoscopic vertical sleeve gastrectomy (LVSG) is the most recent of the bariatric surgery procedures to be introduced (Fig. 1) and is the most commonly performed weight loss operation in the United States. The LVSG is restrictive; the lateral aspect of the stomach is removed to create a sleeve-like tube or reservoir. Because the fundus produces the pro-appetite hormone ghrelin, its removal also gives this procedure a neurohormonal mechanism of action. Although not

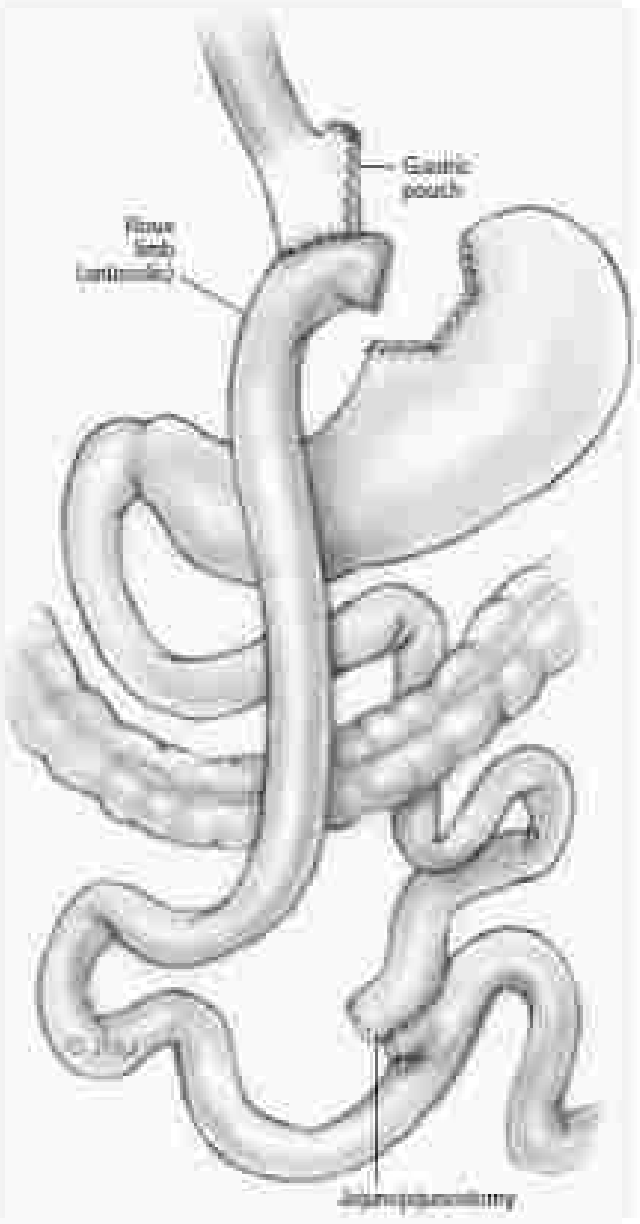

FIG. 2 Antecolic antegastric Roux-en-Y gastric bypass. (Courtesy Carlos Jacobo, copyright Johns Hopkins University)

roversible, LVBG; can be converted into a Roux-en-Y gastric bypass or duodenal switch if greater weight loss is desired.

The LVBG typically is performed with four trocars (various combinations of 5, 12, or 15 mm). With the liver retracted with the Nathanson retractor (Cook Medical), the short gastric vessels are divided along the greater curve of the stomach. An energy sealing device (such as a LigaSure or Harmonic scalpel) (Covidien) typically is used to accomplish this. A 40F bluntly tip bougie is placed in the stomach and directed along the lesser curve. The stomach is divided at the greater curvature, beginning 4 cm proximal to the pylorus. Appropriately sized staple loads are used adjacent to the 40F bougie and extending to the angle of His. The staple line is oversewn or an absorbable buttress material can be used with the staples to assist with hemostasis. To test the integrity of the staple line, an endoscopic air leak or liquid dye infused through an orogastric tube can be used.

The partial gastrectomy specimen is removed through one of the larger trocar sites. Care should be taken to repair the fascial opening of this enlarged trocar site to prevent postoperative herniation. An upper gastrointestinal contrast study is performed only if clinically indicated.

Laparoscopic Roux-en-Y Gastric Bypass

Gastric bypass (Fig. 2) is the second most common bariatric procedure performed in the United States. Numerous reports have shown that gastric bypass results in durable long-term weight loss and remission of metabolic disease with a reasonably low complication rate.

A 45-degree angled laparoscope is inserted above the umbilicus, and the operation is performed using a total of five laparoscopic trocars (three 12 mm and two 5 mm). The omentum and transverse colon are retracted cephalad until the ligament of Treitz is visualized. The jejunum then is transected approximately 40 cm distal to the ligament of Treitz with an appropriately sized stapler cartridge. The mesentery is divided with either a stapler or an energy sealing device. The proximal biliopancreatic limb of jejunum then is anastomosed to the distal segment of jejunum 75 to 100 cm distal to the point of division. We perform this anastomosis in a side-to-side fashion using linear stapler cartridges. The resulting mesenteric defect is closed with a running permanent suture to help minimize the risk of internal hernia.

The patient is then placed in steep reverse Trendelenburg position, and the gastric pouch is created. The left lateral segment of the liver is retracted using a Nathanson through a subxiphoid 8 mm puncture. The peritoneal attachments at the angle of His are dissected to expose the left crus, followed by the base area of the gastrohepatic ligament to allow entry the lesser sac. Division of the neurovascular bundle on the lesser curve side of the stomach just distal to the left gastric artery and vein is accomplished using a gray vascular cartridge. Multiple appropriately sized 45-mm stapler cartridges then are used to transect the stomach up to the angle of His, creating a vertically oriented, 20 mL proximal gastric pouch. Any bleeding staple lines are controlled easily with clips or suture ligation.

We typically bring the Roux limb up to the gastric pouch in an antecolic antegastric orientation. This has been shown to reduce the incidence of internal hernias and is simpler to perform than a retrocolic retrogastric approach. The side of the Roux limb is sutured to the gastric pouch staple line. A small enterotomy is made just proximal to the end of the Roux limb, a similarly sized gastrotomy is made in the pouch for the placement of the linear stapler. The stapler is loaded with a 45-mm cartridge to create the gastrojejunostomy, using only the first 30 mm of the staple cartridge. After the stapler is fired, a stay suture is placed on the lesser curve (right) side of the opening, and the suture then is used to retract the anastomosis to the left and anterior, thereby exposing the posterior side. A running 2-0 suture is placed posterior on the left side and commonly ran to the stay suture on the right side to which it is tied.

A 32F, blunt, round and bougie then is passed from the mouth through the gastrojejunal anastomosis and into the Roux limb. The bougie can be seen through the opening that was formed after the stapler was removed. A stay suture is placed at the halfway point of the opening between the end stay sutures. This stay suture and the stay suture on the left (angle of His side) are used to elevate the tissue so that the 45-mm length blue load cartridge can be used to close the openings. The stapler is brought down on tip of the bougie while the tissue to be transected is retracted. This firing will close most of the opening, and the small remaining defect on the right side is closed readily with a 2-0 suture. The gastrojejunostomy is completed by running a 2-0 suture to cover the entire anterior portion in a second layer. The resultant anastomosis is approximately 15 mm in diameter. A leak test can be performed by clamping the Roux limb just distal to the anastomosis and insufflating air (via endoscope or stapler's tube), whereas the gastric pouch and anastomosis are submerged in saline. The use of a circular stapler to create the gastrojejunostomy is also an acceptable and widely used method by many bariatric surgeons.

The mesenteric defect then is closed between the Roux limb mesentery and the transverse mesocolon, up to the transverse colon (Petersen's defect). If clinically indicated, a Gastrografin swallow study is performed on postoperative day 1 or 2 to check for leakage or obstruction.

Laparoscopic Adjustable Gastric Band

The laparoscopic adjustable gastric band (LAGB) has seen a decrease in the frequency of use since the advent of the sleeve gastrectomy. Although the band is reversible and does not carry a risk of anastomotic or staple line leak, it has fallen out of favor as more data have been collected regarding complications. In addition, the sleeve gastrectomy is comparably easy to complete. In addition, the band requires multiple postoperative adjustments in the first year after surgery and success depends more on patient compliance than the durability of the bypass. Studies have suggested inferior long-term weight loss compared with other operative options.

The LAGB procedure (Fig. 3) is performed routinely via the pars flaccida technique, with four various-sized trocars. The liver is retracted with a Nathanson retractor. Dissection is performed bluntly at the angle of His, freeing up attachments for later insertion of the band. The gastrohepatic ligament adjacent to the lesser curve of the stomach is then divided with electrocautery. The right crus is identified, and the anterior peritoneal tissue is divided. If a hiatal hernia is identified, reinforcement of the hiatus is important, either anteriorly or posteriorly, to discourage further herniation once the band has been placed. Two graspers are used to carefully dissect the plane of tissue posterior to the gastroesophageal junction to provide a tunnel for the LAGB.

An articulating dissector then is placed from the right crus toward the angle of His. The dissector arm then is flexed to create a right angle and locked into place. The adjustable band is placed into the abdomen through the 15-mm trocar in the left upper quadrant. The band is secured to the articulating dissector and brought around the

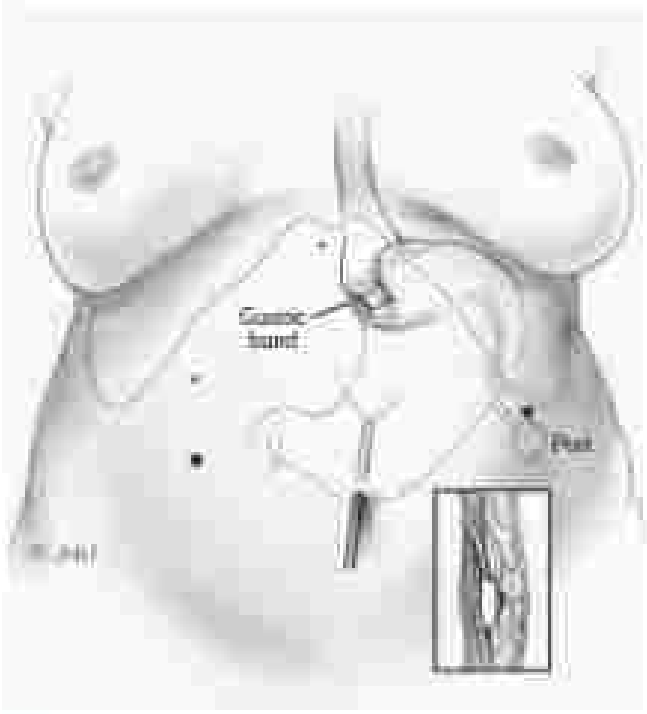

FIG. 3 Laparoscopic adjustable gastric band (courtesy Ethicon Endosurgery, Cincinnati, Ohio). (Adapted from Nguyen NT, Slone JA: Laparoscopic bariatric surgery: current perspectives and new developments, *Adv Surg* 43:1–30, 2009.)

stomach while the instrument is withdrawn. The band then is locked into place with an approximate 45-degree angle toward the patient's left shoulder. A minimum of two sutures then are placed from the fundus to the proximal gastric tissue around the band to secure the band into place. This reduces the possibility of band migration or herniation. It is important to ensure that the balloon portion of the band has not been compromised while either placing the band or suturing it into position.

The band tubing is brought out through the left upper quadrant port and secured externally to the subcutaneous injection port. When securing the port to the fascia, the surgeon must clear a sufficient space along the rectus sheath. After hemostasis has been achieved in the pocket, the port can be sutured or deployed into position while care is taken to leave the majority of the tubing in the abdomen. Finally, the port can be tested via Hubert needle to ensure that the tube and band are functional and not kinked or malpositioned.

Though the band has fallen out of favor, it is still important to maintain familiarity with the procedure because revision is increasingly necessary. If planning to remove the band, it is necessary to remove the band, tubing, and subcutaneous port. Conversion from a laparoscopic band to either a gastric bypass or sleeve gastrectomy is relatively straightforward and may be done at the time of the band removal or at a subsequent operation if scarring at the time of the initial operation is not severe.

Laparoscopic Duodenal Switch With Biliopancreatic Diversion

The laparoscopic duodenal switch with biliopancreatic diversion (DS-BPD) is primarily a malabsorptive operation that involves gastrectomy of the pylorus and creation of a short, 100-cm final "common channel" (Fig. 4). The DS-BPD is the least common bariatric procedure performed because of its surgical complexity and potential for severe malabsorptive nutritional deficiencies.

This procedure can be performed in a single operation or in two stages if the patient has a high BMI (>70). The first stage is similar to LSG, with the creation of a gastric sleeve. After approximately a

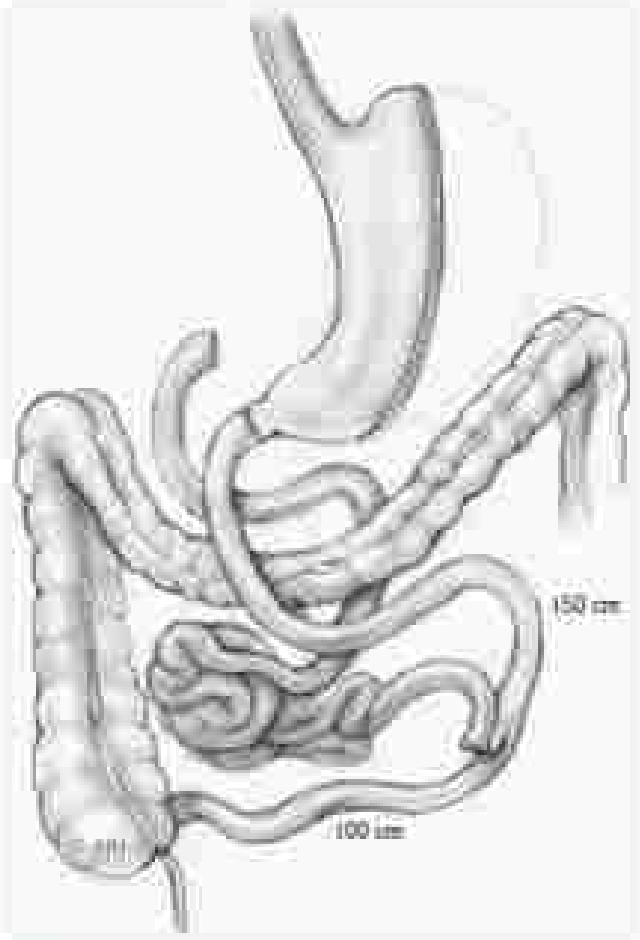

FIG. 4 Ascending duodenal switch with biliopancreatic diversion. (Courtesy Carmen Lorenzo, copyright John Hopkins University)

1-year period of weight loss, the patients can be converted to DS BPD and the malabsorptive second stage performed. This is performed by dividing the small bowel 250 cm from the ileocecal valve. The proximal end of bowel then is anastomosed to the distal ileum 100 cm from the cecum.

The patient then is placed in steep reverse Trendelenburg position and the liver is retracted. If the sleeve gastrectomy portion has not been performed previously, then partial gastrectomy proceeds as previously described. The duodenum is then divided approximately 3 to 4 cm distal to the pylorus with a 60 mm linear stapler. The Roux limb is directed in an antecolic fashion, and a side-to-side anastomosis is performed with the duodenum. An air leak or dye test can be performed to check for leaks at the stomach staple line and new duodenal jejunal anastomosis. Finally, the mesenteric defect then is closed between the Roux limb mesentery and the transverse mesocolon.

POSTOPERATIVE CARE AND SHORT-TERM OUTCOMES

After any of the bariatric procedures, patients are seen in follow-up at 2 weeks to ensure that they are well hydrated, tolerating oral intake, and without wound complications. They are then seen at 3, 6, 12, 18, and 24 months and annually thereafter to follow weight loss and nutritional issues. Patients are encouraged to meet with dietitians and remain with their support groups indefinitely.

For 1 month after surgery, patients are all maintained on a high-protein puree consistency diet; after that, they gradually are advanced to solid food. They also receive multivitamins, calcium, and vitamin B12 supplements. This is especially important for patients with gastric bypass and DS BPD who are at higher risk for malabsorption and possible malnutrition. Supplemental iron always is considered for menstruating women.

Weight loss after gastric bypass and DS BPD occurs primarily in the first to 18 months after surgery and averages approximately 70% and 80% excess weight loss, respectively. Sleeve gastrectomy typically has less excess weight loss, on average 50% over a 2- to 3-year period. Recent 5-year follow-up data suggest that this difference may decrease over time and ultimately may not be clinically significant.

Overall complication rates after bariatric surgery are less than 15% in most reports. As with most surgeries, there are early and late complications for bariatric surgery. Early or perioperative complications include bleeding, anastomotic leakage, and deep venous thrombosis. The mortality rate is less than 1% and is usually attributable to a pulmonary embolus or sepsis from anastomotic leak. Persistent unexplained tachycardia higher than 120 beats/min may be an early sign of sepsis; an appropriate workup should be considered.

Vitamin B12, calcium, iron, vitamin D, and protein deficiencies can occur within the first year or longer after surgery. Rigorous monitoring of nutrition status is necessary. Vitamin B1 deficiency also can occur in patients with protracted vomiting after surgery; these patients may experience extremity paresthesias and confusion. Lower extremity weakness and paresthesias also can be seen with vitamin B12 deficiency. Anastomotic stenosis and obstruction at the gastrojejunostomy in the first few months after surgery occur in less than 5% of patients after gastric bypass and usually can be managed with endoscopic dilation.

LONG-TERM OUTCOMES OF BARIATRIC SURGICAL INTERVENTION

Cohort data have shown bariatric surgical intervention to have a lower all cause mortality than intensive medical management for patients with morbid obesity. This association holds true regardless of the type of surgical intervention. Compared with maximal medical therapy, surgical intervention also improved outcomes for the treatment of type 2 diabetes, hypertension, sleep apnea, and dyslipidemia. There is no difference seen in hospitalization rates and major cardiac events, suggesting that postsurgical complications are not a higher burden than complications seen from existing comorbidities in patients treated medically.

Overall surgical complication rates for sleeve gastrectomy versus bypass are similar. The rates of reoperation are also similar, but the reasons for reoperation differ depending on the index operation. Gastroesophageal reflux may be worsened with sleeve gastrectomy. In the presence of significant reflux, a hiatal hernia, or esophageal metaplasia, sleeve gastrectomy should not be the operation of choice. There exists no consensus as to the role of preoperative esophagogastroduodenoscopy, although we routinely perform endoscopy to rule out metaplasia should the patient admit symptoms of reflux.

Internal hernias are a complication seen only in gastric bypass and duodenal switch because there is no small bowel mesentery or mesenteric window associated with sleeve gastrectomy. Patients should be counseled as to this possibility and a sleeve gastrectomy may be preferred in the absence of reflux disease in patients prone to hernia formation, adhesive disease, or with extensive prior abdominal surgery.

Ultimately, the decision as to which surgical intervention to undertake is complex and should be made in consult of the individual patient and in conjunction with the patient's goals. Regardless of the method chosen, there remains significant variation in response to surgical intervention, an area of active investigation in the field.

urine output, or orthostasis may be manifestations of the dehydration associated with gastric losses in SBO but may also point to signs of ischemia or perforation. The clinician should be especially suspicious of ischemia when patients present with fever, altered mental status, or other toxic signs. Although bacterial translocation from the intraluminal compartment has been shown to be a possible cause of the systemic inflammatory response, systemic signs should be considered a sign of strangulation or ischemia until proven otherwise. These indications should urge the surgeon in the operating room immediately.

Abdominal inspection should begin by noting any surgical scars and ruling out abdominal wall or groin hernias as causes of mechanical obstruction. The hallmark of the physical examination in a patient with SBO is abdominal distension, especially in the context of old surgical scars. There is a direct relationship between the severity of abdominal distension and the proximal nature of the SBO, with distension being worse in more proximal obstructions (duodenum/jejunum); however, it is important that patients with a closed-loop obstruction may display little to no abdominal distension. Basic characteristic signs of abdominal auscultation note "high pitched tinkling" sounds that may become more muffled as the bowel progressively distends and may become absent when peritonitis ensues in the setting of impending or acute bowel ischemia. Although these auscultative findings are worth noting, they are generally not reliable as independent markers of the grade of obstruction or likelihood of ischemia. Percussion may reveal tympany throughout the abdomen; however, dullness to percussion may be present over fluid-filled bowel loops. Pain to light percussion, local tenderness or guarding, are signs of peritonitis and merit exploration. Rectal examination is mandatory because it can identify fecal impaction, rectal masses, blood, or the rare obturator hernia, all of which would critically alter management.

DIAGNOSIS AND WORKUP

After a thorough history and physical examination, laboratory values and imaging can aid in identifying which patients require urgent operation or have failed conservative therapy. Recent data have shown the accuracy of predictive models that use clinical/radiographic parameters to evaluate the likelihood of postoperative complications or the likelihood that the SBO will require operation for bowel resection. We use the following clinical and radiographic factors in our decision making regarding operation for SBO[6–12]:

Laboratory Studies

No single laboratory finding definitively rules out bowel ischemia or perforation; however, laboratory values can aid in characterizing the severity of the presentation and helping determine which patients should be taken directly to the operating room. Basic laboratory values for serum sodium, potassium, chloride, blood urea nitrogen, and creatinine/glomerular filtration rate can aid in the diagnosis and management of dehydration. Although patients may have a metabolic alkalosis as a result of persistent vomiting, metabolic acidosis can be a sign of bowel ischemia or malperfusion in other organs. Lactic acidosis has a sensitivity of up to 100% in the diagnosis of intestinal ischemia, but is a late finding and clinicians should be careful not to undertriage patients without a lactic acidosis. The lack of a lactic acidosis should not be used as a decision point in avoiding operation because it carries a specificity of approximately 48%. A C-reactive protein level greater than 7 mg/L and leukocytosis level higher than 10×10^9 have been used in predicting ischemia and correlate with the need for bowel resection. Other studies have demonstrated that a high serum procalcitonin levels can be useful in predicting the failure of conservative management; a serum procalcitonin threshold of 0.5 ng/mL or greater was found to have an 83% positive predictive value and 91% negative predictive value for bowel ischemia at operation.

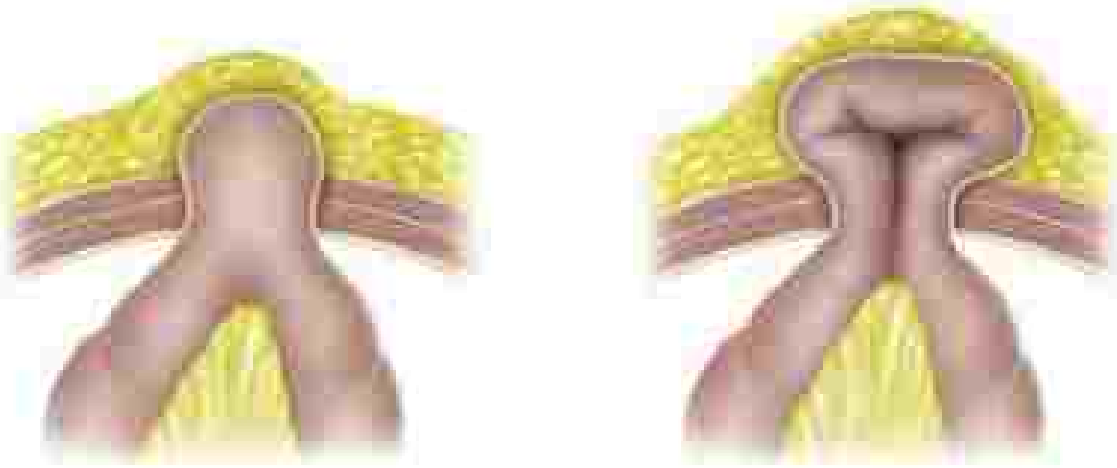

FIG. 1 [illegible]

BOX 2 Clinicoradiologic Parameters Associated with Bowel Ischemia/Need for Bowel Resection

History/physical
- Pain lasting more than 6 days
- Rebound or guarding on abdominal examination

Laboratory
- C-reactive protein >75 mg/L
- Procalcitonin > [illegible] ng/mL
- Leukocytosis >10 × [illegible]
- Lactic acidosis

Computed tomography
- Presence of >50 mL of free fluid
- Free fluid density >[illegible] HU
- Reduced bowel wall enhancement
- Intramural hemorrhage
- Pneumatosis
- Portal venous gas
- Bowel wall thickening >3 mm

Imaging

Plain radiography is generally obtained as a first step in imaging a patient with suspected SBO. Although not as sensitive or specific as computed tomography (CT), it is cheap, easily accessible, expeditious, and may obviate the need for CT in the presence of free intraperitoneal air (Fig. 2). When flat and upright plain films are obtained, radiography carries a 67% sensitivity and 63% specificity for diagnosing SBO. The most specific findings for SBO on plain radiographs are dilated small bowel loops greater than 3 cm along with decompressed distal loops, air-fluid levels, and a paucity of gas in the colon (Fig. 3). A "gasless abdomen" represents filling of bowel loops with sequestered fluid resulting from obstruction and should not mislead a person to underestimate the severity of SBO because of a lack of air-fluid levels (Fig. 4). A "string of pearls" sign can be seen on upright or decubitus radiographs as an obliquely oriented linear row of air bubbles in the abdomen; these represent small pockets of gas along the superior wall of the small bowel that are trapped between the plicae circulares. In the event of an abdominal catastrophe or hemodynamic instability, the surgeon can forgo radiography and proceed directly to the operating room.

In a stable patient, a CT scan with intravenous contrast can help to provide a valuable picture of the patient with SBO. The CT scan can identify the etiology of the SBO (e.g., hernias, tumors, malrotation),

FIG. 2 Plain upright radiograph demonstrates free intraperitoneal air under the right hemidiaphragm in a patient with small bowel obstruction and bowel perforation.

the degree of obstruction being if partial or complete, the potential location of the obstruction by identifying transition points, and can identify markers of ischemia, perforation, or necrosis. The sensitivity and specificity of CT scans in identifying SBO are greater than 90%. Although the use of oral in conjunction with intravenous contrast is useful in differentiating partial versus complete obstruction by evaluating the passage of oral contrast into decompressed bowel segments, omission of oral contrast facilitates the identification of areas of where the bowel wall demonstrates decreased or delayed enhancement, an important marker of bowel ischemia. The low attenuation gas and fluid within the obstructed lumen generally provide adequate contrast relative to the normally enhancing bowel wall which can be obscured by high attenuation oral contrast material.

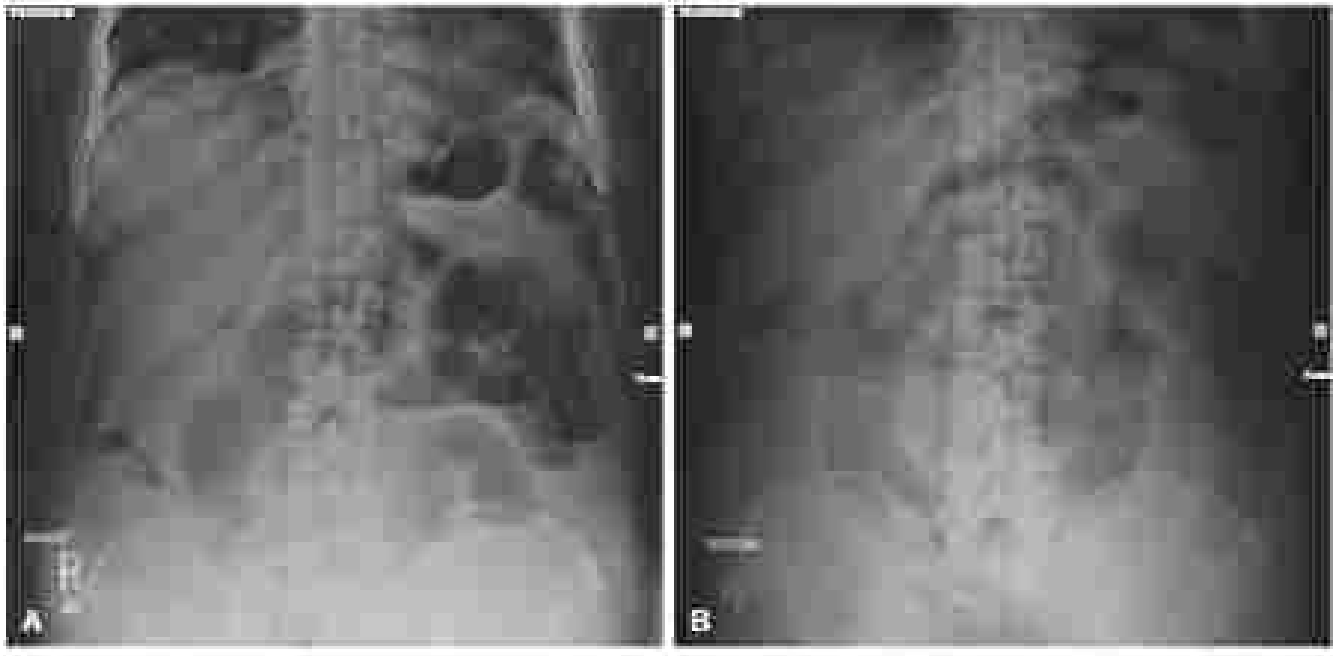

FIG. 3 Plain abdominal upright radiographs of a patient with a complete small bowel obstruction. (A) Differential air fluid levels and upright films. (B) Dilated loops of small bowel with no evidence of colonic gas.

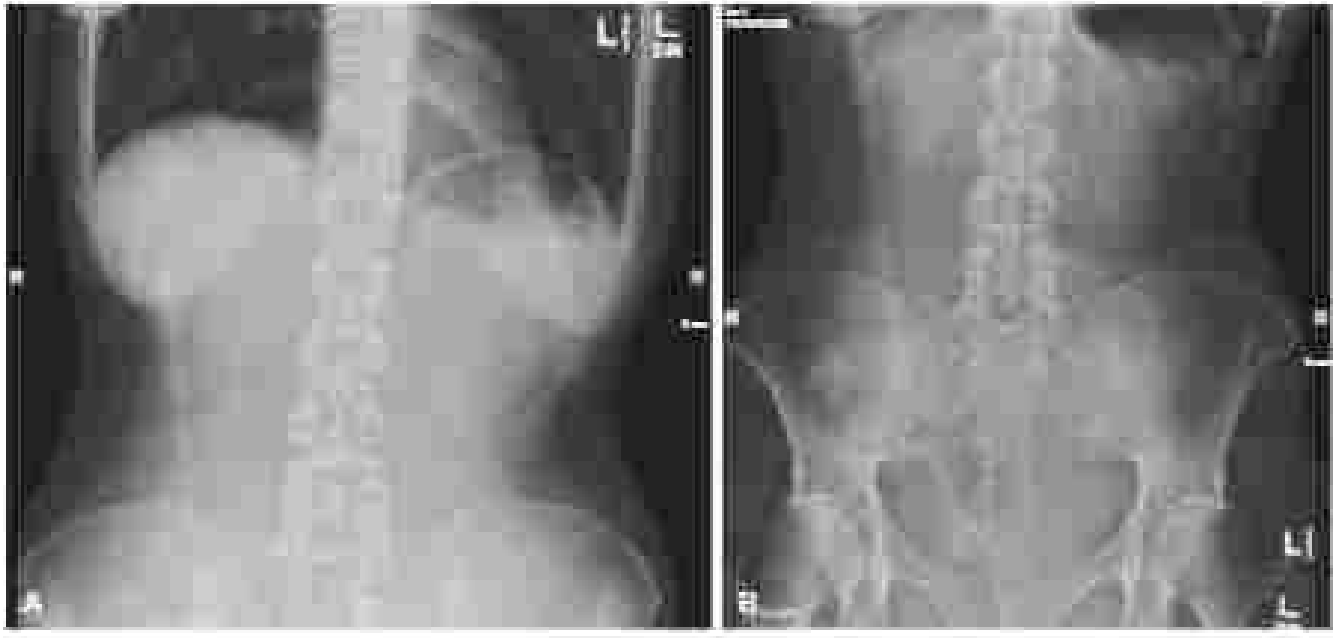

FIG. 4 Abdominal radiograph demonstrates a "gallus abdomen" in the upper (A) and lower (B) abdomen of a patient with small bowel obstruction.

As with radiography, the hallmark of SBO on CT is dilated (>3 cm) proximal small bowel with decompressed distal small bowel and colon. One advantage of CT is the increased ability to identify the transition point or zone where the dilated bowel transitions to decompressed bowel, highlighting the site of obstruction (Fig. 5). The location of obstruction on CT correlates with the location at the time of surgery approximately 70% of the time, making this a potentially useful guide to surgical approach. It is noteworthy, however, that the presence of a transition point on CT does not accurately identify patients in need of surgery nor does it identify patients who will fail operative management and should not be used as a major criterion in influencing operative versus nonoperative management.

Because physical examination and laboratory evaluation alone are not sufficient to rule out ischemia, CT is widely relied on for this role. In patients with proven bowel obstruction, the sensitivity for detecting ischemia ranges from 75% and 100%, and the specificity ranges from 67% to 98%. A high index of suspicion when interpreting CT scans is key. A number of studies have identified radiologic parameters that recognize patients at high risk for ischemia or in need for bowel resection. High density intraperitoneal free fluid (>10 HU) in one retrospective series was predictive of the need for surgical intervention in patients with SBO (sensitivity 53%, specificity 82.5%). Interperitoneal free fluid of more than 500 mL or volume expansion of fluid density, and a reduction in small bowel wall contrast

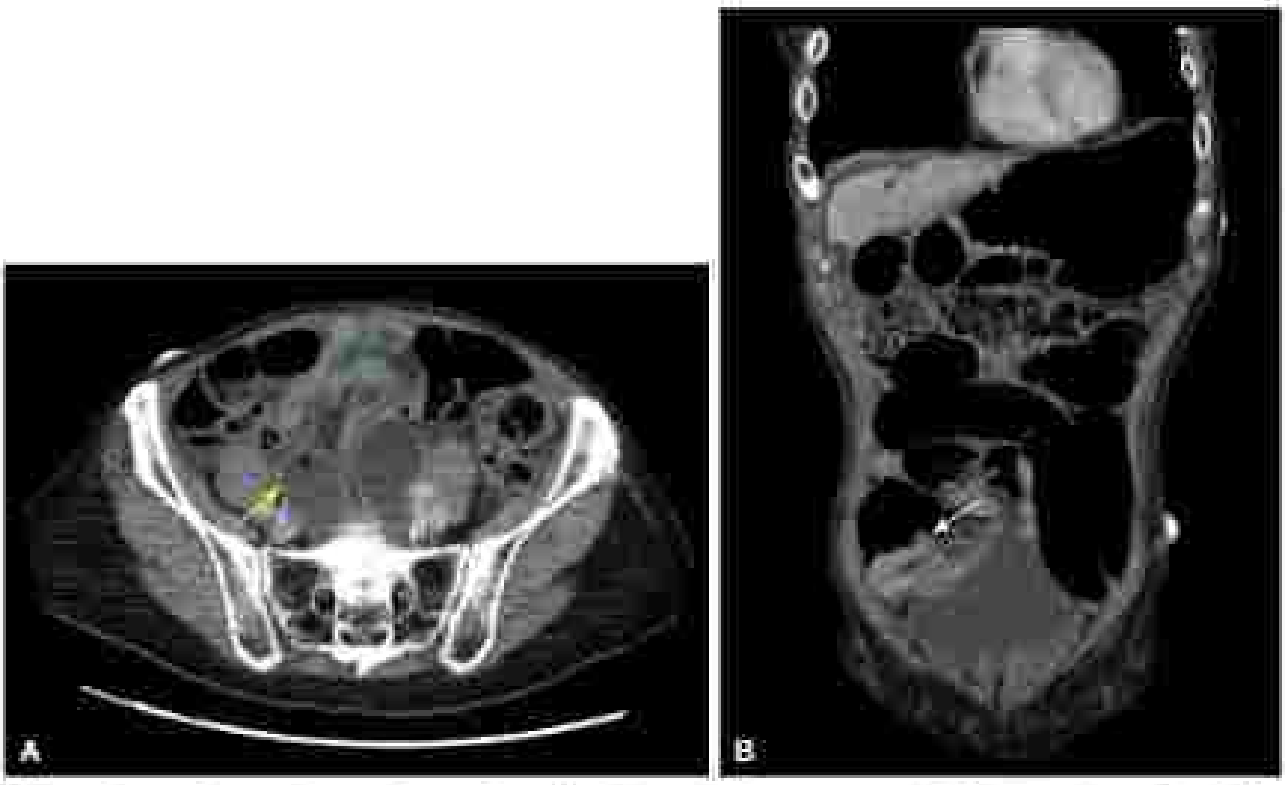

FIG. 5 Computed tomography scan demonstrating a complete small bowel obstruction with a transition point. (A) Axial image shows dilated small bowel loops (*, *) with adjacent decompressed small bowel loops (arrow, arrowhead) in the anterior abdomen. (B) Coronal image demonstrates the transition point (arrow).

FIG. 6 Computed tomography scan demonstrates bowel wall thickening in a patient with a complete small bowel obstruction.

enhancement are strongly associated with bowel manipulation in SBO. Other important CT findings that are associated with ischemia include bowel wall thickening greater than 3 mm (Fig. 6), mesenteric edema or fluid, decreased bowel wall enhancement, "target sign" (hyperenhancement of the mucosa relative to the remainder of the bowel wall), pneumatosis, or portal venous gas.

An important type of obstruction that may be difficult to identify on CT but is a surgical emergency is the closed loop obstruction. Closed loop obstructions are a type of complete obstruction in which an intestinal loop is obstructed at two adjacent points, generally by adhesion or volvulus, creating a segment with no proximal or distal outlet that is at high risk for impending strangulation (Figs. 7 and 8). This requires prompt identification and surgical intervention. Classically, on CT, the incarcerated small bowel can be seen as fluid filled distended loops with a U shape configuration, a corresponding radial distribution, with stretched and thickened mesenteric vessels converging toward the point of obstruction; there may also be a swirling of the mesentery. Other signs include the "beak sign" or two collapsed adjacent loops.

NONOPERATIVE MANAGEMENT

Absent signs of ischemia or intra-abdominal catastrophe, a trial of conservative management is typically preferred in most patients. The mainstays of nonoperative management are bowel rest, nasogastric decompression, and fluid therapy, with serial abdominal examinations. Nasogastric decompression is achieved with a Salem sump tube that is flushed regularly to ensure patency. Prospective studies failed to show the superiority of long nasointestinal tubes over nasogastric tubes. Fluid management should be dictated by electrolyte correction, replacement of missed oral intake leading to presentation, replacement of nasogastric tube losses, as well as urine output as guided by a Foley catheter for patients in whom urine output cannot be accurately measured. Patients with SBO warrant prompt surgical consultation and admission to a surgical service. A review of more than 100,000 admissions for SBO demonstrated that 73% are managed by a medical attending and 27% are managed by a surgical attending, and that being on a medical service was independently associated with a longer length of stay, greater inpatient costs, a higher rate of 30-day readmission, and a delay in time to surgical intervention.

In the setting of adhesive SBO, the success of nonoperative management ranges from 65% to 80% in retrospective series. During a trial of nonoperative therapy, a change in the status of a patient to

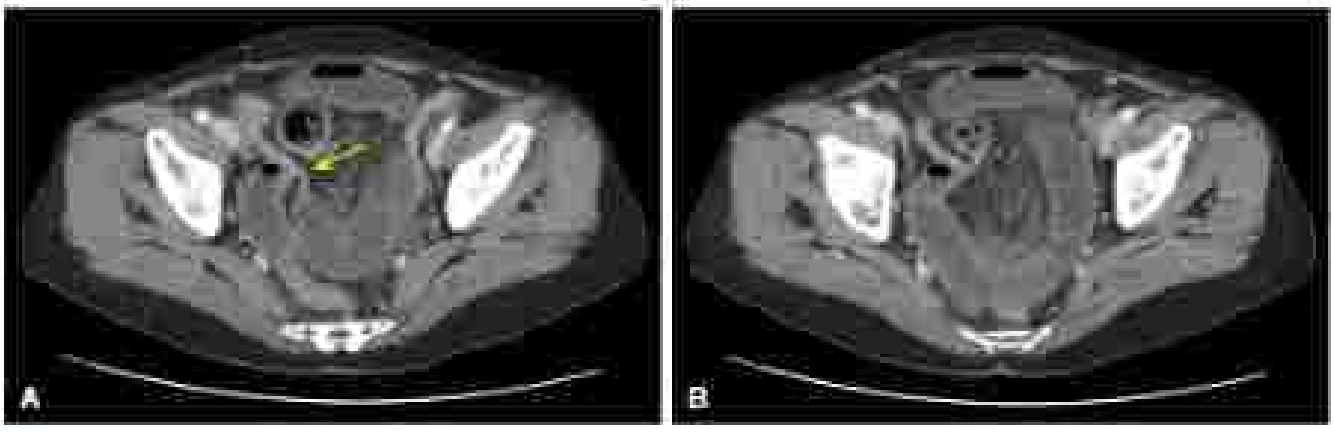

FIG. 7 Computed tomography images of a patient demonstrating findings consistent with a closed-loop obstruction. (A) One clear transition point is visible adjacent to (B) a second transition point can also readily be discerned. The intervening bowel loop is distended.

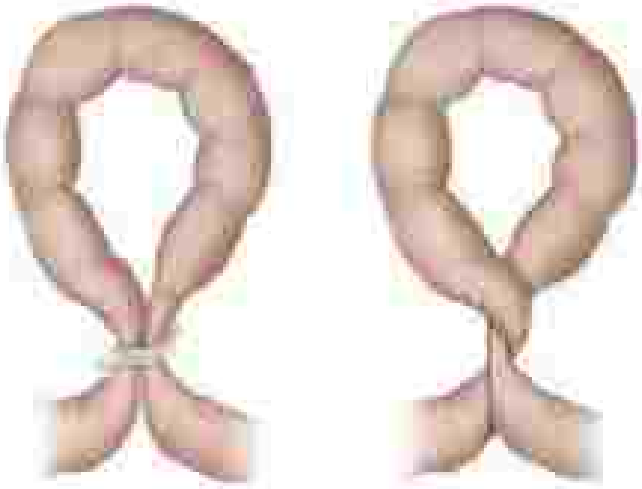

FIG. 8 Illustration of a closed-loop obstruction. Adhesive bands can cause an obstruction at two adjacent segments of bowel (left). A volvulus caused by twisting of a segment of bowel (right) is also a common cause of closed-loop obstruction.

indicate a complete obstruction should prompt surgical intervention. The use of serial abdominal radiography is of little use in guiding management, and we find that following the abdominal examination and nasogastric tube output are more informative to treatment decisions. That being said, an abdominal radiograph 24 hours after an initial CT with water soluble contrast that shows contrast reaching the colon demonstrates the likely resolution of the SBO. Failure of contrast to reach the colon in 24 hours should be noted because it is predictive of failure but should not stand alone to dictate operative decision making.

Although the decision to proceed with surgical therapy is dictated by the overall clinical status of the patient, a delay in operation is associated with a substantial increase in morbidity and mortality. The appropriate duration of nonoperative therapy varies widely in the literature. The World Society of Emergency Surgery recommends a period of 72 hours and the Eastern Association for the Surgery of the Trauma guidelines recommend a period of 3 to 5 days of conservative management. Failure to resolve after 72 hours of conservative therapy is highly predictive of nonoperative failure. In our practice, we generally observe patients for a period of 72 hours, but the decision to operate is individualized based the etiology of the SBO and the patient's clinical status. For example, patients with obstructions secondary to Crohn's disease may require a longer period of medical optimization and parenteral nutrition.

OPERATIVE MANAGEMENT

Once the need for surgery has been determined, the remaining challenge consists of choosing the appropriate approach.

Open laparotomy has been and continues to be the dominant surgical strategy for SBO when compared to laparoscopy, with approximately 70% to 80% of SBOs being treated via laparotomy. In the case of an open approach, a midline laparotomy provides adequate access for entry into the abdominal cavity. Care must be taken to avoid bowel injury during abdominal entry by being cognizant of bowel that may be adherent to abdominal wall, especially if in the setting an area of previous scar. Preferentially entering the abdomen in virgin areas far from previous incisions and going from "known" to "unknown" can help mitigate the risk of bowel injury during entry. If a clear transition point is visible and consistent with CT imaging, it is not necessary to perform a complete lysis of adhesions; however, it is important to confirm the bowel can be run distally to the ileocecal valve to ensure that there is no downstream obstruction. If an abdominal wall or inguinal hernia is the cause of the obstruction and is in need of mesh repair, absent any spillage or contamination, a synthetic mesh is appropriate. In the case of spillage, contamination, or iatrogenic injury, if a mesh is required, biologic mesh should be used. After lysis of adhesions, the bowel should be thoroughly inspected for injuries. Perforations or iatrogenic injuries that are larger than 50% of the bowel lumen necessitate resection. Smaller injuries can be repaired primary. We prefer a two layered repair with a full thickness, braided, absorbable suture followed by a seromuscular Lembert suture; however, a one layer repair is also appropriate. Importantly, when primarily repairing the bowel, bites should be taken transversely so as not to narrow the bowel lumen.

Perforated or clearly ischemic bowel should be resected. If the viability of an intestinal segment is uncertain, the surgeon may choose to temporarily close the abdomen and re-explore in 24 to 48 hours to definitively determine bowel viability. A Doppler scan can also be used to determine blood flow. The technique of leaving the patient with an open abdomen is also useful in cases of hemodynamic instability or abdominal catastrophe. In this case, the surgeon can resect the necrotic bowel and leave the patient to discontinuity, returning for a definitive assessment when the patient can tolerate the procedure. If a small bowel mass is encountered as the reason for an SBO, an oncologic resection should be performed. This should include a 5- to 10 cm margin as well as resection of the associated lymph nodes. In this case, rather than cutting the mesentery to the small intestine close to the bowel wall, the mesenteric resection should follow a triangular shape, with the apex of the triangle pointing to the base of the mesentery. At the conclusion of the operation, ensure the patient has a functioning nasogastric tube and manually confirm its position prior to fascial closure.

More recently, there has been a substantial increase in the volume and proportion of SBOs that are treated with the laparoscopic approach. In multiple retrospective case-matched series, laparoscopy is associated with shorter procedure times, shorter hospitalization, and less postoperative complications when compared with open surgery. Small studies have suggested that the use of laparoscopy may result in the lower incidence, extent, and severity of adhesions to parietal surfaces, but no trial evidence has shown that this translates to a decrease in the recurrence of SBO. Some retrospective studies have suggested that the laparoscopic approach may be associated with a higher incidence of bowel interventions (resection/repair), which may be a surrogate for iatrogenic injury; however, the data on this topic remain sparse and divided. In our experience, we will start an operation for SBO laparoscopically if there is a suspicion that there is a single adhesive band as the cause of obstruction, which can be easily lysed, or if the bowel appears sufficiently decompressed on imaging to allow enough visibility and maneuverability for laparoscopy.

We prefer an open Hasson approach away from any previous surgical scars to minimize the risk of bowel injury during entry into the abdomen. When running the bowel laparoscopically to identify the transition point, beginning distally at the ileocecal valve where the bowel is decompressed and working proximally toward the ligament of Treitz, mitigates the risk of grasping potentially delicate dilated bowel that is more prone to injury with light manipulation. When it is necessary to handle dilated segments, care must be taken to avoid iatrogenic injuries from the laparoscopic graspers. In the case that a small bowel resection is necessary, we prefer performing an extracorporeal anastomosis because dilated and fluid-filled bowel loops will cause some level of intra-abdominal spillage during anastomosis creation, whether it be stapled or hand sewn, that will be difficult to control even in the most experienced hands. Although the enthusiasm for laparoscopic SBO management is growing, the ultimate goal of the procedure is to complete the necessary operation safely and efficiently with minimal morbidity to the patient. The safety of the patient and the ability to complete the necessary surgical tasks always supersede maintaining a minimally invasive approach.

CONCLUSION

SBO represents a spectrum of disease that ranges from the mild, self-limiting symptoms of a partial obstruction to bowel necrosis that necessitates urgent surgical intervention. Although a large proportion of obstructions can be managed nonoperatively, surgeons will continue to face the difficult challenge of deciding on whom to operate, when to operate, and which approach to use. A high index of suspicion in those at risk for bowel ischemia with the aid of clinical, laboratory, and imaging findings helps surgeons identify patients with subtle or atypical presentations. Although open surgical intervention is the dominant surgical strategy for SBO, laparoscopy has demonstrated safety and efficacy and should be considered.

Management of Crohn's Disease of the Small Bowel

Heather L. Yeo, MD, MHS, MBA, MS, and
Fabrizio Michelassi, MD

The incidence of Crohn's disease is increasing worldwide. Currently, the US Centers for Disease Control and Prevention estimate its incidence at 201 in 100,000 adults, the highest in industrialized countries. Within 10 years of diagnosis, nearly one-half of all patients require surgical management; however, surgery is not curative and many patients require multiple surgical procedures and complex surgical care throughout their lifetimes.

Crohn's disease is a chronic inflammatory disease that can occur anywhere along the gastrointestinal tract, with the terminal ileum being the most commonly affected site. The inflammation affects the full thickness of the gastrointestinal tract and can lead to development of strictures, perforations, hemorrhages, fistulas, or malignant transformations. The pathophysiology is unknown, although research points to dysregulated gut mucosal immune responses to environmental triggers in genetically predisposed individuals. The clinical course is characterized by unpredictable cycles of disease activity and quiescence, making it difficult to manage.

The presentation of Crohn's is varied and follows three main disease phenotypes: fibrosing, fistulizing, and inflammatory. The fibrosing phenotype is characterized by intestinal strictures and manifests itself with abdominal pain, possibly diarrhea, and partial or complete intestinal obstructions. The fistulizing phenotype presents with fever, abscess, or fistulas, whereas the inflammatory phenotype manifests itself with a painful, tender mass. The broader spectrum of signs and symptoms may include hematochezia, anemia and weight loss, fatigue, nausea and vomiting, malnutrition, vitamin deficiency, and growth failure in the young. Many of the symptoms are nonspecific; other gastrointestinal diseases such as infectious gastroenteritis, appendicitis, and diverticulitis must be ruled out.

The diagnosis depends on a detailed history, including family history, and a complete physical examination. Imaging, both radiologic and endoscopic, is critical to confirm the diagnosis, map its extent, and eventually follow the course of the disease. Computed

More recently, there has been a substantial increase in the volume and proportion of SBOs that are treated with the laparoscopic approach. In multiple retrospective case-matched series, laparoscopy is associated with shorter procedure times, shorter hospitalization, and less postoperative complications when compared with open surgery. When it is necessary to handle dilated segments, care must be taken to avoid iatrogenic injuries from the laparoscopic graspers. In the case that a small bowel resection is necessary, we prefer performing an extracorporeal anastomosis because dilated and fluid filled bowel loops will cause some level of intra-abdominal spillage during anastomosis creation, whether it be stapled or hand sewn, that will be difficult to control even in the most experienced hands. Although the enthusiasm for laparoscopic SBO management is growing, the ultimate goal of the procedure is to complete the necessary operation safely and efficiently with minimal morbidity to the patient. The safety of the patient and the ability to complete the necessary surgical tasks always supersede maintaining a minimally invasive approach.

CONCLUSION

SBO represents a spectrum of disease that ranges from the mild, self-limiting symptoms of a partial obstruction to bowel necrosis that necessitates urgent surgical intervention. Although a large proportion of obstructions can be managed nonoperatively, surgeons will continue to face the difficult challenge of deciding *on* whom to operate, when to operate, and which approach to use. A high index of suspicion in those at risk for bowel ischemia with the aid of clinical, laboratory, and imaging findings helps surgeons identify patients with subtle or atypical presentations. Although open surgical intervention is the dominant surgical strategy for SBO, laparoscopy has demonstrated safety and efficacy and should be considered.

Management of Crohn's Disease of the Small Bowel

Heather L. Yoo, MD, MHS, MBA, MS, and
Fabrizio Michelassi, MD

The incidence of Crohn's disease is increasing worldwide. Currently, the US Centers for Disease Control and Prevention estimate its incidence at 201 in 100,000 adults, the highest in industrialized countries. Within 10 years of diagnosis, nearly one half of all patients require surgical management, however, surgery is not curative and many patients require multiple surgical procedures and complex surgical care throughout their lifetimes.

Crohn's disease is a chronic inflammatory disease that can occur anywhere along the gastrointestinal tract, with the terminal ileum being the most commonly affected site. The inflammation affects the full thickness of the gastrointestinal tract and can lead to development of strictures, perforations, hemorrhages, fistulae, or malignant transformations. The pathophysiology is unknown, although research points to dysregulated gut mucosal immune responses to environmental triggers in genetically predisposed individuals. The clinical course is characterized by unpredictable cycles of disease activity and quiescence, making it difficult to manage.

The presentation of Crohn's is varied and follows three main disease phenotypes: fibrosing, fistulizing, and inflammatory. The fibrosing phenotype is characterized by intestinal strictures and manifests itself with abdominal pain, possibly diarrhea, and partial or complete intestinal obstructions. The fistulizing phenotype presents with fevers, abscess, or fistulae, whereas the inflammatory phenotype manifests itself with a painful, tender mass. The broader spectrum of associated symptoms may include hematochezia, anemia and weight loss, fatigue, nausea and vomiting, malnutrition, vitamin deficiencies, and growth failure in the young. Many of the symptoms are nonspecific, other gastrointestinal diseases such as infectious gastroenteritis, appendicitis, and diverticulitis must be ruled out.

The diagnosis depends on a detailed history, including family history, and a complete physical examination. Imaging, both radiologic and endoscopic, is critical to confirm the diagnosis, map its extent, and eventually follow the course of the disease. Computed

tomography enterography or magnetic resonance enterography are the radiologic tests of choice. Upper and lower endoscopy provides direct observation and tissue for histopathologic diagnosis. Capsule endoscopy can be used for examination of the small bowel in the absence of strictures but is rarely necessary with modern radiologic examinations. At initial presentation, around 40% of patients manifest terminal ileal disease, 30% have colonic disease, 10% have duodenal and jejunal disease, 10% have perianal disease, and 20% have disease in more than one anatomic location.

MULTIDISCIPLINARY MANAGEMENT

Optimal management of Crohn's disease occurs within the expertise of a multidisciplinary team that comprises gastroenterologists, surgeons, radiologists, pathologists, nutritionists, specialty nurse clinicians of stoma nurses, social workers, and associated specialties as needed. Complex cases should be reviewed within this context and treatment plans should be formulated after consideration of multidisciplinary team input. Although not curative, surgery is critical in the management of the disease for many patients. Where applicable, patients should be considered for clinical trials.

MEDICAL MANAGEMENT

The majority of patients present with mild to moderate disease or spend long periods with their disease in clinical remission. For this early disease, treatment with 5-aminosalicylates or budesonide, depending on disease location, is a standard of management. Patients with severe disease are usually treated more aggressively with early introduction of immune modulators or biologic therapies. Acute flares are treated with corticosteroids and then, once in remission, patients are advised to start maintenance therapies.

The medical treatment of Crohn's disease has advanced significantly in the last decade with the introduction of anti–tumor necrosis factor biologic agents. Some early data suggest that biologics reduce mucosal healing. This observation has led many to change management with biologics used upfront rather than after more conventional treatments have failed.

Several longitudinal cohort studies suggest that biologics therapies may alter the course of disease and lessen the need for surgical treatment. It is likely that the reduction of local inflammation and possible mucosal healing induced by biologics may be effective in eliminating the need for surgical treatment in milder forms of the disease. Yet, there is no evidence that they are as effective in the more aggressive forms.

INDICATIONS FOR SURGERY

Overall, the goals of surgical treatment are alleviating symptoms and improving quality of life, while preserving bowel length. Obstructive and septic complications are the most common indications for surgery in small bowel Crohn's disease. Intestinal obstructions are usually partial or high grade and, in the absence of findings consistent with an acute abdomen, they can usually be resolved with bowel rest, time and supporting measures. The most common septic complication necessitating surgery is a perforation with an inflammatory abscess after appropriate percutaneous drainage of the abscess and a course of intravenous antibiotics, the diseased segment requires resection in most cases. Inflammatory masses with failure of medical management require surgical treatment as well. Most fistulae are not an indication for surgery unless they cause repeated urinary tract infections (enterovesical fistulae), sexual embarrassment (enterovaginal fistulae), or challenges with personal hygiene (enterocutaneous fistulae). Rare indications for surgery include free perforation, hemorrhage, and cancer. Cancer may manifest indirectly as a complete intestinal obstruction that does not resolve spontaneously with bowel rest and supportive measures as described previously.

The presence of disease at multiple sites along the gastrointestinal tract may make operative decisions more complex but does not alter the basic recommendations for treatment.

PREOPERATIVE PLANNING

Preoperative Medications

It is well established that the chronic, long-term use of steroids (a common practice of the past, which should not be performed nowadays) has a deleterious effect on wound healing and increases the risk of postoperative infectious complications. Whether the preoperative use of short-term steroids or antimetabolites increases the risk of postoperative complications is controversial. Nevertheless, it makes sense to try to reduce the dosage of these medications to the extent possible, but this is not feasible in the majority of patients because symptoms quickly recur. If a patient comes to surgery on steroids, perioperative steroids supplementation may be necessary to avoid acute adrenal insufficiency.

The recent widespread use of biologics has raised similar questions on their influence on postoperative outcomes. The literature is mixed, with some studies showing no effect and others showing a modest increase in postoperative infectious complications, especially if surgery occurs within 2 months from the last dose. In view of these reports, it is advisable to schedule the surgery, if at all possible, 2–3 or 8 weeks from the last dose.

In patients with long-term steroid treatment or biologics, consideration should be given to an intestinal diversion at the time of surgery especially if the patient has experienced weight loss, shows malnutrition, or has hypoalbuminemia. In these cases, the preoperative discussion with the patient should include also mentioning the formation of a temporary stoma.

Timing

Although not curative, surgery is critical in addressing complications of the disease and improving the patient's quality of life. Yet, determining the optimal timing of surgery may prove to be difficult in a chronic disease that alternates flares to periods of relative quiescence and in a lifelong disease in which surgical interventions should be minimized for patient convenience and to avoid the dreaded consequence of a shorter bowel. Emergency procedures are fortunately seldom necessary because free perforation, generalized sepsis, and acute gastrointestinal hemorrhage are rare. Every effort should be made to transform urgent conditions to elective situations. A complete bowel obstruction can usually be resolved with bowel rest, time, and supporting measures; an abscess should undergo percutaneous drainage and a course of intravenous antibiotics. In the presence of a large phlegmonous mass, bowel rest and total parenteral nutrition may be required to reduce the local inflammation, make a challenging procedure less so and avoid placing undiseased bowel at risk.

The most difficult situation is represented by a patient who is not doing well yet has not developed a clear complication of the disease. This situation, commonly called failure of medical treatment, refers to recognizing that medical treatment has failed to restore the patient's quality of life and surgery is necessary. Unfortunately, the desire to avoid surgery, the temptation of continuing or changing medical treatment in the hope of a miraculous response, and the chronicity of the condition that masks the overall worsening of the patient's general condition from day to day all conspire against a decision in favor of surgery. Waiting too long can lead to operating on a sicker patient who is more malnourished. As discussed earlier, the decision should be made carefully with a multidisciplinary team of surgeons and gastroenterologists.

Nutritional Status and Preoperative Preparation

Once a decision regarding elective surgery has been made, the patient's current health status must be evaluated to initiate preoperative planning. The patient's general medical condition must be considered and maximized. If nutritional deficits exist, and time allows, nutritional improvement should be pursued. This can be done in consultation with a nutritionist as enteral nutrition supplementation is preferred to parenteral when possible.

An enhanced recovery after surgery protocol should be initiated. Standard oral mechanical and antibiotic bowel preparation should be performed preoperatively unless the patient has a long-term, high-grade obstruction. In these cases, a prolonged period of clear liquid diet only, in combination with oral antibiotics just before surgery, is recommended. All patients should be given standard prophylactic intravenous antibiotics just before surgery. Fluid and electrolyte imbalances and any existing profound anemia also should be corrected before surgery. If a diversion is possible, a stoma site should be selected in the least inconvenient location on the anterior abdominal wall and marked preoperatively.

TECHNICAL CONSIDERATIONS OR SURGICAL INTERVENTION

Key to management of these patients is accurate preoperative planning, but often selecting the appropriate procedure cannot be decided until a thorough intraoperative examination is performed. The entire small bowel from the ligament of Treitz to the ileocecal valve should be carefully assessed. This can be done via laparotomy or laparoscopy. Special attention should be paid to all Crohn's related processes: strictures, phlegmonous masses, abscesses, and fistulae should all be documented. We recommend creating a "roadmap" and using that to plan the operation. The ultimate goal in addressing complications of the disease, alleviating symptoms, and improving quality of life while preserving bowel length through a safe procedure. Surgical techniques that can be used include: strictureplasty, intestinal resection, intestinal bypass, abscess drainage, fistula repair, diversion, or a combination of all these techniques.

A thorough preoperative discussion with the patient is critical, particularly in cases with extensive disease or cases that will require intervention in multiple intestinal segments. The possible nutritional effects of intestinal loss, as well as the possible role of a stoma should be discussed. The more information the patient and family understand regarding the plan, the better.

COMMON PROCEDURES FOR SMALL BOWEL CROHN'S

Bowel-Sparing Procedures

Bowel sparing procedures are covered in depth in another chapter. A brief mention is made here to put them in perspective with other surgical procedures for Crohn's.

From 20% to 30% of small bowel Crohn's disease can be managed with a strictureplasty as the only surgical procedure or in association with additional strictureplasties or bowel resection(s). Short isolated segments of stricture are appropriate for a Heineke-Mikulicz (3–7 cm) or a Finney (7–15 cm) strictureplasty. Longer segments or chain of like formations should be considered for a side to side isoperistaltic Michelassi strictureplasty. Multiple different strictureplasty techniques can be used in conjunction with simultaneous bowel resections in a patient with multifocal disease in an attempt to preserve intestinal length.

After opening the diseased segment in preparation for a strictureplasty, it is important to inspect the mucosa to rule out underlying pathology. If there are any suspicious abnormalities, a biopsy should be obtained for frozen section to rule out cancer or dysplasia because this will also rule out the use of strictureplasty in favor of a bowel resection.

Heineke-Mikulicz Strictureplasty

The most commonly used and simplest strictureplasty is the Heineke-Mikulicz strictureplasty. After isolating the diseased segment, two stay sutures are placed on either side of the structured area. A longitudinal enterotomy is then made along the antimesenteric border of the small bowel across the stricture and extended for 2 cm into the normal bowel on either side. The enterotomy is then closed in a transverse fashion in one or two layers.

Finney Strictureplasty

The Finney strictureplasty is used for medium length strictures up to 10 to 15 cm. The diseased bowel is folded on itself at the half point. A row of interrupted sutures is placed between the two loops of the folded bowel and a longitudinal U shaped enterotomy is made. The back wall of the enterotomy is closed in a continuous fashion and then continued anteriorly. A second layer of seromuscular sutures is then placed anteriorly.

Side-to-Side Isoperistaltic Strictureplasty (Michelassi Strictureplasty)

The Michelassi strictureplasty is used to preserve bowel in long segment disease or in areas with multiple strictures close to each other. The bowel is transected at the midpoint of the diseased segment. The proximal loop is then moved over the distal loop so they are lying in an isoperistaltic side to side manner. A back row of 3-0 sutures is used to approximate the two loops all the way to the end. A longitudinal enterotomy is performed on both loops and the intestinal ends are spatulated. The inner suture lines are performed in a continuous fashion with absorbable sutures and the anterior layer is inverted with an outer layer of nonabsorbable 3-0 sutures.

Bowel Resection

A bowel resection is the most common surgical procedure in Crohn's disease. Division of the intervening mesentery may be challenging because of its thickness and friability. In this situation, it is advisable to obtain proximal control with a vascular clamp across the vascular pedicle providing blood supply to the diseased loop. A vessel sealing energy source can then be used to seal and transect the mesentery with care. Partial and slow release of the vascular clamp allows vessels may need to be ligated with figure of eight 2-0 braided sutures. The use of the vascular clamp transforms a challenging situation to a manageable one. Attempting to blindly clamp the thickened mesentery while bleeding without previously obtaining proximal control can make things much worse. Surgeons should be cautious of thickened and inflamed Crohn's mesentery, particularly if it extends all the way into the retroperitoneum. Bleeding in this situation can be treacherous and can put the patient at risk of substantial blood loss and injuries to adjacent bowel and retroperitoneal structures.

Stoma

Occasionally a large inflammatory mass does not respond to treatment with fasting and total parenteral nutrition. In these cases, surgery may be necessary, but the surgeon may be confronted with a very challenging situation in which multiple internal loops of small bowel are found densely adherent to the inflammatory mass. A resection is not advisable because it would sacrifice a large amount of normal intestine; instead, a carefully constructed proximal stoma may provide the patient the appropriate time to let the inflammatory mass regress for an easier procedure at a later time when the normal loops of bowel can be safely dissected off the mass and preserved.

ANATOMIC CONSIDERATIONS

Duodenum

Duodenal disease manifests itself with delayed gastric emptying, nausea, and epigastric fullness resulting from one or multiple strictures along its course. Balloon dilation can be attempted especially in the presence of a single, short stricture. When surgery becomes necessary, strictureplasty techniques are preferred to bypass. Isolated strictures in the first, second, and third portions of the duodenum are usually amenable to a Heineke-Mikulicz strictureplasty, whereas strictures in the fourth portion of the duodenum may require a Finney strictureplasty with the first loop of the jejunum.

Bypass is used when strictureplasty is not feasible either because the length of a stricture or because of multiple strictures. Most

commonly this is accomplished with a gastrojejunostomy. Before the procedure, it is advisable to perform a gastric pH study. In the presence of an acid milieu, a vagotomy is added to the bypass to minimize the risk of postoperative marginal ulceration. In the presence of a neutral or near-neutral milieu, the vagotomy is omitted for fear that it may contribute to dumping and diarrhea. If the structures to be bypassed are distal in the inferior genu of the duodenum, a duodenojejunal bypass should be considered between the second portion of the duodenum and the jejunum. This configuration avoids the risk of a marginal ulcer and the need for a vagotomy.

The gastrojejunostomy can be performed in either an antecolic or retrocolic fashion and the anastomosis can be hand sewn or stapled. The anastomosis is typically performed using the most dependent part of the stomach on the greater curve. The most proximal loop of jejunum that can be brought up to the greater curve is used. A posterior row of interrupted sutures is placed to approximate the stomach and the small bowel. A 5-cm gastrojejunostomy is then constructed with a continuous inner layer of 3-0 absorbable suture and is reinforced with a front row of interrupted nonabsorbable sutures.

Small Bowel

Small bowel disease should be cared for with bowel-preserving procedures if at all possible or with bowel resection or stoma followed by bowel resection (see the previous section). Occasionally, small bowel disease develops into other hollow viscera. In the presence of an enteroenteric fistula located in the loop of bowel to be removed, the intestinal resection will remove the fistula en bloc. If the fistula connects with a normal loop of small or large bowel, the fistula can be divided and the defect in the small bowel can be debrided and closed primarily, ensuring the lumen of the bowel is not be compromised. In this case, a limited resection of the target loop of bowel needs to be performed as well. The diseased bowel is then, of course, resected. If the fistulized organ is the bladder, the opening should be debrided and closed in multiple layers if at all possible. Sometimes an intervening wall abscess makes closure difficult or impossible, even after debridement from chronic inflammation. Whether a closure is feasible or not, a urinary catheter is left in place for decompression for 7 days, after which a cystogram should be performed to check on the integrity of the bladder wall before removing the urinary catheter. If the fistulized organ is the vaginal cuff in a patient after a hysterectomy or the abdominal wall, all is necessary is the drainage of any intervening abscesses and debridement.

The most challenging operative situation is diffuse and complex jejunoileitis. In this situation, the surgeon is faced with many epienteral sites separated by inches of normal and possibly dilated bowel for a considerable length of small bowel. Deciding what needs resection, what can be managed with strictureplasty, and what can be left alone requires careful consideration, judgment, and a precise knowledge of the symptoms and complications that brought the patient to surgery. The most important consideration to remember in these cases is that surgery is not curative in Crohn's disease but merely palliative; hence, the surgeon needs to know what symptoms/complications need to be palliated/addressed. In addition, the most important directive at surgery is to carefully examine the entire bowel from ligament of Treitz to ileocecal valve, documenting the findings in a roadmap, which then becomes the basis of a comprehensive, individualized plan of action.

The extent of the disease does not necessarily mandate an open procedure. The diseased segments can be eviscerated progressively segment by segment, however, if there is any concern or struggle with stability, an open procedure may be preferable.

Terminal Ileum

Isolated disease of the terminal ileum is the most common site requiring surgery and accounts for nearly one half of all patients referred for surgical intervention. Most commonly, these patients present with obstructive symptoms or septic complications with or without fistula. Management is usually based on an ileocolic resection, although stricturoplasty can be used on limited anastomotic strictures of the anterior ileum after a previous ileocolectomy.

When the ileocolectomy is performed laparoscopically, the pneumoperitoneum is created through a trocar placed in a periumbilical or umbilical position. Once the pneumoperitoneum is established, a 30-degree laparoscope is placed through the umbilical port and two additional 5-mm ports are inserted in the left upper and left lower quadrants, respectively. The terminal ileum and cecum can then be mobilized in a medial to lateral or lateral to medial approach. The vascular pedicle is then sealed and transected with an energy device. If the pedicle is thickened and friable all the way to the base, it is advisable to take it under direct vision through an extension of the umbilical trocar incision. An ileocolic anastomosis can then be performed in a number of ways, hand sewn or stapled, and in a number of configurations, end to end, side to side, or end to side. The senior author prefers a hand sewn end to end anastomosis. A new anastomosis, the antimesenteric side to side hand sewn anastomosis or a Kono S anastomosis, is being studied to validate claims that it is associated with milder endoscopic recurrence at 3 and 12 months postoperatively and much lower incidence of recurrence in need of resection in the first 5 years postoperatively.

POSTOPERATIVE CARE

The enhanced recovery after surgery protocol should be continued postoperatively with narcotic-sparing analgesia. A nasogastric tube is typically not necessary. Patients are discharged once there is clear evidence of sufficient bowel function to maintain hydration independent of intravenous fluids and adequate pain control on oral medications. If a patient has a stoma, discharge can only occur after the patient has learned how to take care of the appliance and the stoma output is under control (usually <1000 mL/24 hours). At discharge, patients are given information regarding warning signs of complications and given a quick and clear pathway back to the team should any concerns arise.

POSTSURGICAL MEDICAL MANAGEMENT

It is well known, and even assumed, that Crohn's disease will recur, and that at a microscopic level it will do so early at the anastomotic site. Recently, the American Gastroenterological Association has published guidelines on the management of Crohn's disease after resection suggesting early postoperative medical therapy in high-risk groups and observation for low-risk patients. In those patients suffering from reduced bowel length affecting nutrition, the recent Food and Drug Administration approval of teduglutide (Gattex) for short bowel syndrome offers great promise.

Use of Strictureplasty in Crohn's Disease

Mark A. Talamini, MD, MBA, and
[illegible] D'Hoore, MD, FRCS, FASCRS

Crohn's disease (CD) is an inflammatory disease that establishes full thickness inflammation in the gastrointestinal tract that is chronic with acute exacerbations. It can afflict any site along the gastrointestinal tract, but most commonly initiates in the terminal ileum. Surgery for CD does not cure, but rather treats difficult symptoms as an adjunct to effective medical therapy. However, surgery takes center stage in managing the most troubling complications of CD. The transmural inflammation of the bowel wall in CD will lead to abscess formation, enteroenteral fistula, enterocutaneous fistula, perforation, and stricture in many patients. Stricture formation most commonly becomes symptomatic when it occurs in the small bowel.

The baseline surgical treatment of symptomatic CD has been resection of the involved bowel with either restoration of intestinal continuity or a stoma. Resection removes the Crohn's diseased tissue, which is believed to have specific advantages for the patient. Strictureplasty has been considered a less preferred, or backup, option, inferior to resection, used only when bowel preservation for the patient predominates as a consideration. That thinking is changing. Based on circumstances, strictureplasty should be considered an equal first treatment option, rather than the reserve option for many patients.

OVERVIEW

Strictureplasty carries the significant advantage of avoiding the loss of gastrointestinal length. Some speculate that relieving the obstruction via strictureplasty (Box 1), thereby resulting bowel content stasis, can by itself contribute to resolution of inflammation in the involved bowel. Strictureplasty requires some fundamental differences in approach and technique. The suturing is to abnormal bowel, and the anastomotic surfaces that are joined frequently involve diseased inflamed tissue. In CD resection, the margins are typically grossly unresolved, as suturing is to normal bowel. The minimally invasive evolution in surgery has moved a great deal of inflammatory bowel surgery to a laparoscopic approach. A complicated strictureplasty procedure involves suturing of difficult tissue with thick, less mobile mesentery, making a laparoscopic technique more difficult and less attractive. Nevertheless, the advantage of bowel preservation in a disease in which many patients will undergo multiple operations is important and attractive.

INDICATIONS AND CONTRAINDICATIONS

The etiology of bowel stricture formation is most likely related to repeated episodes of inflammation, resolution, and remodeling of the bowel wall, leading to replacement of the normally pliable tissue with a thickened, unpliable bowel wall segment that, over time, narrows the lumen. This leads to obstructive symptoms. The time course of this process varies from patient to patient and may be modified by medications such as steroids, immunomodulators, or biologics, including tumor necrosis factor-α antagonists and integrin blockers. Over time, the involved segment of bowel may become less responsive to increasingly aggressive medical management, and surgical intervention will become necessary for obstructive symptoms.

Strictureplasty can be undertaken throughout the small bowel but has been less frequently used in the colon, because the concern for neoplasm is increased (Box 2). Strictureplasty should not be used in the presence of active sepsis or significant acute inflammation, such as phlegmon or abscess, or in the face of generalized peritonitis. Fistula of the involved bowel is also a relative contraindication (Box 3). Under these circumstances, the increased risk of suturing and joining infected badly inflamed tissue does not appear warranted. However, strictureplasty might still play a role in another diseased segment in conjunction with a fistula at another site. Obviously, if there is concern regarding tumor, the segment must be resected using oncologic principles. Severe malnutrition mitigates against strictureplasty because of the increased demand for effective tissue healing.

PREOPERATIVE PREPARATION

The importance of team management of patients with CD cannot be overemphasized, with the surgeon and the gastroenterologist as the critical (but not the only) team members. Today, because of the effective armamentarium of medical therapy, the overwhelming balance of surgery is elective and not emergent. Therefore the balance between the patient's symptoms, their "readiness" for surgery, and their medical therapy profile all play heavily into decisions regarding surgery. Any septic focus should be controlled with antibiotics, percutaneous drainage, or both. Nutritional status should be evaluated, and patients who are nutritionally compromised should undergo nutritional repletion by a liquid enteral diet, if needed, to reverse their catabolic state before surgery with an aim to reduce postoperative complications.

Optimal surgical outcome requires careful preoperative evaluation and planning. The scope and nature of the patient's past and current disease activity should be evaluated and documented. Obtaining a thorough history of prior operations and operative reports to help full to understand the patient's current anatomy. Colonoscopy should be performed to determine whether there is any colonic disease that might require surgical treatment. Any colonic stricture must undergo biopsy to rule out the possibility of malignancy. Although colonic strictureplasty may be considered if there is a real need to preserve colonic length, the risk of an occult malignancy in a colonic stricture is relatively high, and resection should be the preferred procedure. The extent of small bowel disease should be defined before surgery. Magnetic resonance enterography (MRE) is the gold standard today to assess structural anatomy and inflammatory state. MRE provides key information regarding the state of inflammatory versus mechanical stricturing; primarily inflamed strictures are more likely to respond to medical therapy. Computed tomography enterography, often with water as the contrast agent, is also useful. Together these provide an effective map of the distribution of disease activity, as well as any unsuspected enteroenteral fistulae, contained perforations, and an overall estimate of small bowel length. Preoperative stoma site marking should be considered as well, particularly in patients likely to possess surgical challenge based on preoperative assessment.

INTRAOPERATIVE EVALUATION

The first step in any CD abdominal procedure is to exhaustively assess the state of disease. The bowel should be examined laparoscopically or via laparotomy, with the preoperative imaging in mind, matching the imaging findings to the visual appearance of the bowel. The prime question being considered during this evaluation is whether affected strictured segments are candidates for strictureplasty, will require resection, or can be left alone in the case of just fat creeping with no bowel wall effects. The small bowel usually betrays the presence of any CD by the presence of creeping fat, wall thickening, and mesenteric thickening. Additionally, any abscesses or fistulae must also be addressed in the surgical plan. The colon is more subtle; mucosal disease can be present with the external wall looking normal.

BOX 1 Surgical Objectives in CD Surgery

Preoperative Objectives

- Maximize or exhaust nonsurgical treatment options before surgery
- Surgical intervention should be limited to the treatment of symptomatic complications of CD
- Evaluate nutritional status before surgery
- Consider supplemental nutrition to improve nutritional status before surgery when nutritional status is poor

Intraoperative Objectives

- Spare bowel length
- Utilize alternative strategies to resection when appropriate to preserve sufficient length of the remaining bowel and minimize the propensity for short bowel syndrome
- Spare the ileocecal valve when possible
- Biopsy any suspicious ulcers or mucosa for malignancy

BOX 2 Indications for Strictureplasty

- Diffuse involvement of the small bowel with strictures
- Prior small bowel resection greater than 100 cm
- Rapid recurrence of CD with obstruction
- An obstructing, chronic small bowel stricture without associated sepsis

BOX 3 Contraindications to Strictureplasty

- Albumin level <2 g/dL
- Free or contained perforation of the bowel associated with the stricture
- Phlegmonous inflammation, internal fistula, external fistula involving affected site
- Stricture close in proximity to a resection site
- Multiple strictures within a short segment in a patient who has not had prior small bowel resections or in a patient with sufficient small bowel length
- Any stricture with pathologic evidence of dysplasia or malignancy

STRICTUREPLASTY TECHNIQUES

Strictureplasty techniques can be categorized as short, intermediate, and long (Table 1 and 2). Short strictureplasty technique applies to strictured segments 7 cm or less, usually using a Heineke-Mikulicz type technique. Intermediate strictureplasty is used for segments between 7 and 15 cm, using a Finney type strictureplasty. Longer strictureplasty is usually indicated in situations where a length of bowel has close multiple tight strictures over a longer length of bowel. In these instances, the Michelassi side-to-side strictureplasty is indicated.

SHORT STRICTUREPLASTY

Short strictures (<7 cm) are best dealt with using a strictureplasty technique derived from the Heineke-Mikulicz pyloroplasty performed for pyloric stenosis. A Heineke-Mikulicz type strictureplasty (Fig. 1) is performed by first placing two 3-0 sutures, either unabsorbable or absorbable, on the side of the bowel at the midportion of the stricture to act as stay sutures. The surgeon then creates an antimesenteric longitudinal incision with electrocautery. This incision divides the stricture and should be carried out at an equal distance of 2 cm proximally and distally into normal, thin-walled, nonthickened bowel (Box 4). For ease of closure, it is essential that the longitudinal incision stays truly on the antimesenteric border. The mucosal surface of the affected and neighboring bowel are then evaluated. Mucosal biopsies of the stricture for frozen section analysis are obtained to rule out the presence of dysplasia or malignancy. This is especially important if an ulcer is noted. With a first segment open, neighboring segments can also be evaluated. One method is to thread a well-lubricated Foley catheter in the lumen of the bowel to another affected segment. The balloon is then inflated and gently pulled through affected bowel to gauge the

TABLE 1 Stricture Length and Recommended Strictureplasty Technique

Stricture	Recommended Technique
Short (<7 cm)	Heineke-Mikulicz
Intermediate (7 to 20 cm)	Finney
Long (>20 cm)	Side-to-side isoperistaltic

TABLE 2 Technique Used in Meta-analysis, Including 4538 Strictureplasties

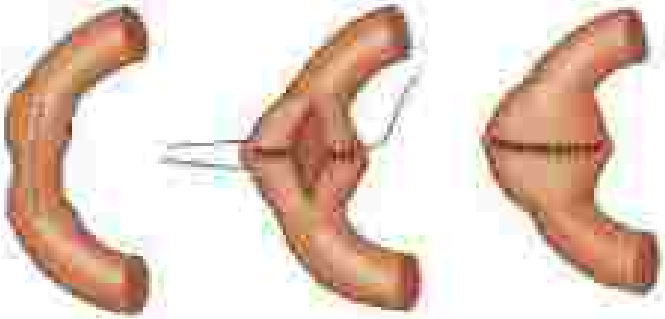

FIG. 1 Heineke-Mikulicz strictureplasty on an isolated stricture. A single-layer suturing technique is performed to close the longitudinal enterotomy transversely, maximizing an anastomotic lumen.

BOX 4 Strictureplasty Operative Strategy

- Extend incision 1 to 2 cm beyond the diseased segment
- Biopsy any suspicious ulcers and mucosa to exclude carcinoma
- Obtain excellent hemostasis
- Closure with an absorbable or nonabsorbable suture in a one- or two-layer fashion
- Label resection at strictureplasty site with metallic clip

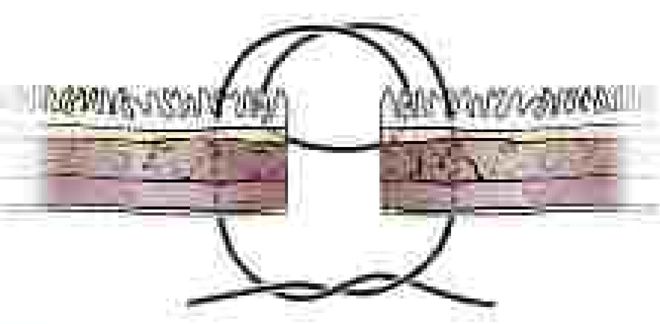

FIG. 2 Modified Gambee stitch. [illegible] Modified Gambee stitch [illegible] *Am J Surg* [illegible]

size and tightness of the closure. For closure, the stay sutures are pulled perpendicular to the long axis of the bowel (as in Fig. 1). Then the enterotomy is closed in one or two layers. A single suture technique particularly suited to strictureplasty is the modified Gambee stitch (Fig. 2). This single layer technique ensures appropriate approximation of the mucosa and serosa, while leaving the blood supply intact between sutures. In the instance of a two-layer closure, a running absorbable inner layer and an interrupted Lembert nonabsorbable suture outer layer is used. This transverse closure strictureplasty technique is ideal for short strictures, but not for longer segments.

It is important to obtain excellent hemostasis. Bleeding from a strictureplasty site is one of the most common and troubling potential postoperative complications. Labeling the mesentery at each strictureplasty site with radiopaque metal clips may assist with discriminating between multiple sites in the event of postoperative hemorrhage. Selective mesenteric angiography with intraarterial vasopressin infusion will control most episodes of bleeding. If bleeding continues despite conservative medical therapy, the metallic clips may help localize the bleeding strictureplasty site and prevent the need to open all of the strictureplasty sites to localize the bleeding at the time of surgery. Alternatively, India ink blue dye can be injected at the time of selective mesenteric angiography for intraoperative localization.

The Heineke-Mikulicz strictureplasty can be performed laparoscopically. With effective suturing skills, the surgeon can simply perform the procedure with intracorporeal suturing technique. However, Crohn's tissue is notoriously unforgiving, making the technical aspects critical. If the mesentery allows, the affected segment can be delivered through a small laparotomy and the sutures placed under direct vision.

INTERMEDIATE STRICTUREPLASTY

The Finney strictureplasty (named after the Finney pyloroplasty) resembles a side-to-side anastomosis (Fig. 3). This strictureplasty may be useful in a patient with a medium-length stricture (7 to 20 cm) or for a segment with multiple short strictures closely grouped together with intervening dilated short segments of bowel. The bowel is folded at the stricture, with the normal proximal and distal bowel brought alongside one another. If a hand-sewn technique is used, there are two options. First, if the strictured area is mildly stenotic and the bowel is of reasonable quality, the entire stricture may be opened along the antimesenteric border, and a hand-sewn, essentially side-to-side anastomosis may be performed along the length of the enterotomy (Finney strictureplasty, Fig. 3). Second, if the stricture is too tight or the bowel is not suitable for suturing, then a true side-to-side anastomosis between the proximal and distal normal bowel can be performed, leaving the strictured segment in place as a short bypassed segment (Jaboulay strictureplasty, Fig. 4). Similarly, if a stapling device is used, a side-to-side anastomosis can be fashioned between the normal proximal and distal bowel, leaving the strictured segment in continuity. There is some concern with the Jaboulay

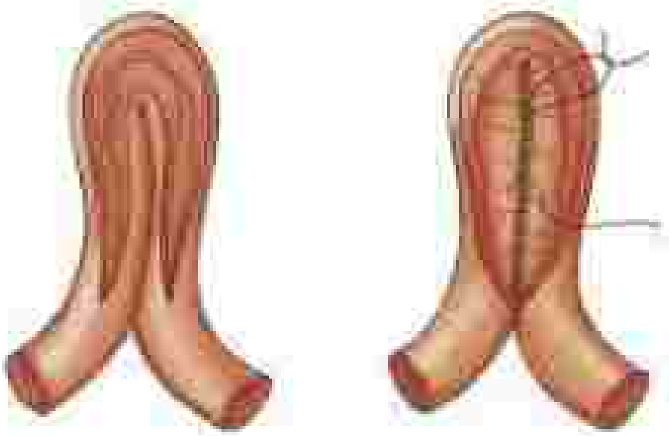

FIG. 3 A Finney strictureplasty can be used for the treatment of a long stricture. [illegible]

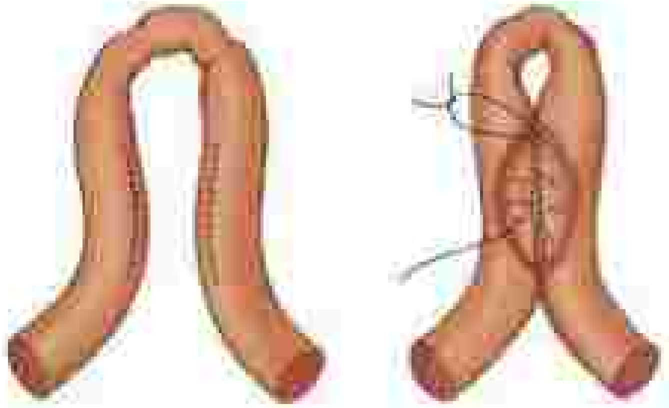

FIG. 4 Jaboulay strictureplasty can be used to bypass a stricture that is too narrow or a stricture in which the bowel is not suitable for suturing.

strictureplasty technique in that it results in a bypassed segment. Although the segment is short, there are potential long-term ramifications, including bacterial overgrowth and malignant degeneration.

In patients with two strictures in close proximity, a modification of the Heineke-Mikulicz strictureplasty technique has been created. The bowel is entered on the antimesenteric border, and both strictures are divided, as is the normal intervening segment. The resulting long enterotomy is closed transversely (Fig. 5).

When the bowel is markedly dilated proximal to a short stricture, the size discrepancy between the proximal and distal normal bowel often precludes a Heineke-Mikulicz-type strictureplasty. In these cases, a Moskel-Walske-Neumayer strictureplasty can be performed (Fig. 6). This strictureplasty technique is essentially a Y-to-V advancement flap closure of the stricture. The stricture is opened along the antimesenteric border in a Y-shaped enterotomy, with the Y portion in the dilated bowel just proximal to the stricture. The strictured segment is then pulled apart, and the antimesenteric segment of the proximal dilated bowel is advanced into the strictured area and closed in a transverse fashion, with one side of the closure being normal bowel along the entire length and the other being the two strictured bowel edges.

Although it is possible to perform the necessary intracorporeal suturing to perform these more challenging procedures laparoscopically, most surgeons will accomplish these procedures

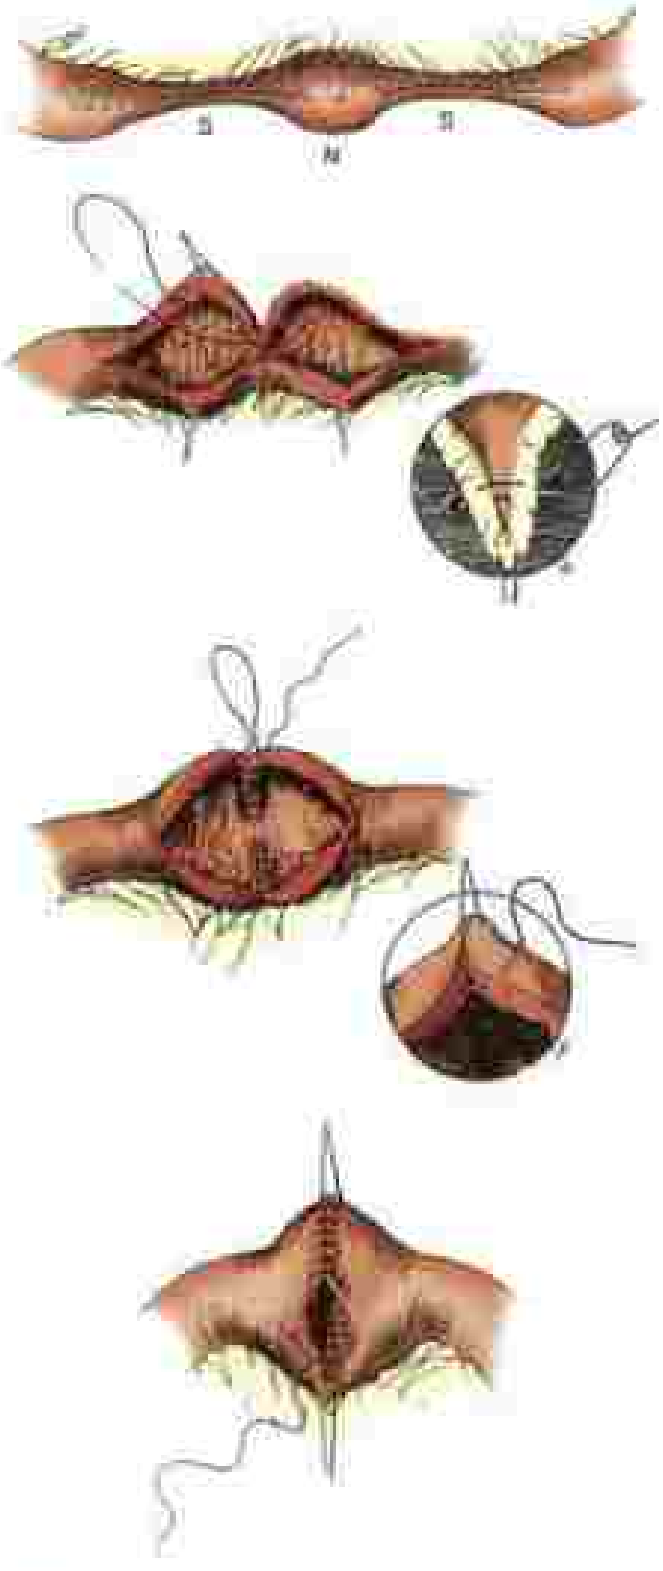

FIG. 3 Modified Heineke-Mikulicz strictureplasty can be used for two short segment strictures that are close to one another with a normal or dilated segment of bowel between them.

FIG. 4 Modified Heineke-Mikulicz strictureplasty is used when there is a significant or a difference between the proximal and distal bowel segments adjacent to a short stricture. Instead of a longitudinal incision, a U-shaped enterotomy is performed and then closed in a transverse fashion.

LONG STRICTUREPLASTY

The side-to-side strictureplasty as described by Michelassi et al. and is applicable for long, multiple strictures in a segment of small bowel. This is a unique, versatile procedure. A long segment of bowel that would result in a proximal, extensive resection can be retained as a side-to-side isoperistaltic strictureplasty. In this technique, the segment is completely divided transversely at the midpoint of the strictured segment. Unlike other strictureplasty techniques, the proximal and distal limbs are then transected perpendicular to the long axis of the bowel to produce the two segments of bowel to be overlapped and positioned side-to-side along the entire length of the divided segments. If possible, the dilated segments of one of the bowel segments ends is lined up with strictures in the other segment. Both strictured segments are opened along the anti-mesenteric border and the anti-mesenteric faces of bowel are sewn one to the other in an isoperistaltic fashion. The lowered suturing technique is an outer layer of interrupted sutures with an inner layer of running absorbable suture. Once the divided loops are approximated with limbers interrupted sutures, the bowel is opened longitudinally at the antimesenteric location. The inner layer is then constructed with a two-layer continuous suturing technique. The stricture is completed with interrupted nonabsorbable suture connecting the inner layer. This technique does not result in bypassed segments of bowel.

Colonic strictureplasty has limited utility because the colon is not essential for nutrient absorption and an isolated colonic stricture has a low incidence of harboring an occult malignancy. However, in some patients in whom preservation of colonic mucosal surface area is of utmost importance, such as a patient with short bowel syndrome, a colonic strictureplasty may be performed.

RESULTS

Increasingly large studies and meta-analyses support the view that strictureplasty is at least equivalent to resection for the treatment of Crohn disease. A University of Toronto group reported a large series of 901 strictureplasty procedures over 5 years from 1982 to 2002. Most patients underwent 1 to 2 operations, including the strictureplasty

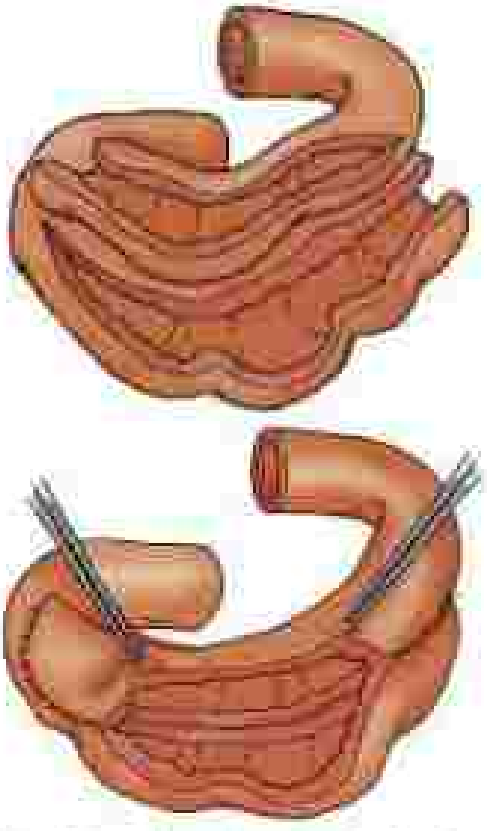

FIG. 7 Side-to-side isoperistaltic strictureplasty is used for a long segment of involved bowel that would require resection because of multiple non-stricture structures. The involved bowel is divided in the middle of the segment, and in a mirrored pattern of orientation to allow the two segments to lie side by side one another and laid side to side in an isoperistaltic fashion. An enterotomy is performed with the two cut edges closest to one another closed in a back wall and the others closed in the front wall. (From Kennedy GT, Zaghiyan K, Fleshner PR, et al. Strictureplasty for Crohn's disease made simple. J Am Coll Surg. 2016;223(1):197.)

procedures over 25 years. Outcomes measures reported were short-term complications, surgery free survival, need for further surgery, and quality of life. Median follow-up was 94 months. On multivariate analysis, only one factor was related to the need for further surgery: the patient's age at the time of the first strictureplasty. Quality of life measures were also impressive. The authors conclude that strictureplasty is safe with acceptable long-term outcomes.

One of the largest systematic reviews and meta-analyses of the safety and efficacy of strictureplasty for CD was published by Yamamoto et al. in 2007 (Table 3). A total of 3250 strictureplasties were performed, with a mean number of three at one operation (range, 1–21). A bowel resection for long strictures, perforation, fistula, or abscess was performed in 61% of these patients (668 of 1086). The overall complication rate was 12% (132 of 1127) for jejunoileal stricturoplasty or both. The most common complications were septic complications in 4% (leak, fistula, or abscess in 39 of 1057 patients), of which 60% required reoperation for sepsis. Other complications included hemorrhage 3% (36 of 1057), ileus 3% (34 of 1057), wound infection 2% (19 of 1057), and bowel obstruction 1% (11 of 1057). Risk factors for complications included hypoalbuminemia, preoperative weight loss, emergency operations, and presence of an intra-abdominal abscess with peritoneal contamination, anemia, and older age. The recurrence rate for jejunoileal or ileum strictureplasty or both was 9% (), recurrence requiring reoperation occurred in 30% of patients (312 of 1078). The median

follow-up duration was 107 months. Risk factors for recurrence included younger age, short duration of disease, and short interval since previous resection.

Michelassi and colleagues recently reported 25-year follow-up on side-to-side isoperistaltic strictureplasty in CD in 40 patients with extensive fibrostenosing CD with very impressive results. The authors state, "The majority of patients maintain the original side-to-side isoperistaltic strictureplasty after a median follow-up of 11 years." This was a rarely used option (more than 2000 patients underwent surgery over these 25 years for CD), but it is an important option for patients with difficult extensive disease and the need to preserve bowel length.

A key study may provide insight into new thinking regarding strictureplasty as opposed to resection for CD. In this study, a series of 29 patients with terminal ileal disease abutting the cecum underwent modified side-to-side isoperistaltic strictureplasty to include the ileocecal valve. The median stricture length was 10 cm. Median postoperative follow-up was 21 months and consisted of magnetic resonance imaging, radiologic scoring, and endoscopy. The authors report marked improvement in mucosal and bowel wall thickness in many of the studied patients in the absence of tissue resection. The authors state that, "We speculate that the alteration of fecal stasis may play a key role in postoperative mucosal healing, modifying the microbial-mucosal interaction." This suggests that resolving the stasis of bowel contents may play a role as important as or more important than tissue resection. Although this is speculative, it may be that future surgical interventions may focus more on bowel content flow and less on tissue resection.

SUMMARY

Strictureplasty is an integral part of the surgical management of patients with obstructive jejunoileal CD and ileocolonic recurrence. The primary role of strictureplasty is to preserve small bowel length in a patient population prone to recurrence and multiple surgical interventions over a lifetime. The most commonly performed strictureplasty is the Heineke-Mikulicz technique. The length of the stricture and location dictate the specific technique of strictureplasty to be used. Although preoperative evaluation of patients with CD and consultation with a gastroenterologist experienced in inflammatory bowel disease should be performed in all patients with complications of CD requiring surgery.

MANAGEMENT OF SMALL BOWEL TUMORS

Sandra R. DiBrito, MD, PhD, and Mark D. Duncan, MD, FACS

Small bowel malignancies are rare, difficult to diagnose, and have low treatment guidelines. Because small bowel tumors present with vague and common symptoms, it is imperative that the surgeon keep them on the differential for abdominal pain, obstruction, and gastrointestinal blood. However, the majority of patients referred to surgeons for small bowel tumors have a suspicious mass on imaging. Evidence-based guidelines on management of small bowel malignancy are difficult to find, and given the rarity of these lesions, there is little information in the literature to provide reference for clinical decision making.

PRESENTATION

The typical presenting symptoms of small bowel tumors are vague and highly variable. Many patients present to surgeons as a referral from a primary care provider or a gastroenterologist with a known mass, discovered following workup for gastrointestinal (GI) bleeding or encountered incidentally on imaging. Others will present with colicky pain from obstruction, either partial or complete, and will be found to have a small bowel tumor during surgery. The mass itself can be intraluminal or circumferential, directly responsible for obstruction, or can have surrounding fibrosis that results in stricture and adhesions to the mesentery or retroperitoneum. Small bowel tumors (SBTs) are frequently asymptomatic but can present with bleeding or obstruction.

Nonspecific symptoms such as weight loss and vague abdominal pain are concerning for malignant neoplasms such as adenocarcinoma and lymphoma, particularly in the context of a known small bowel mass; however, these nonspecific symptoms should prompt broad investigations because small bowel tumors are one of the rarer malignancies. Neuroendocrine tumors that are productive of vasoactive amines can present with a wide range of symptoms, from epigastric pain and ulcerations to flushing, sweating, and diarrhea. Most are asymptomatic, however, and are found incidentally on imaging workup for other conditions.

Predisposing Conditions

Familial adenomatous polyposis, hereditary nonpolyposis colon cancer, and Peutz-Jeghers syndrome are genetic cancer syndromes that predispose to small bowel malignancy. Crohn's disease, celiac sprue, and chronic inflammatory conditions involving the small bowel also predispose to small bowel malignancy, and risk increases with increased severity and longer duration of disease. Patients with cystic fibrosis have 19 times higher incidence than the general population, and with an additional two- to five-fold higher risk following lung transplantation. Obesity, tobacco use, and high dietary intake of red meat, smoked foods, alcohol, and refined sugar have all been shown to have an association with small bowel tumors, but the links between these risk factors and tumorigenesis are not clear. In fact, the etiology of small bowel tumors that are not associated with either chronic inflammatory diseases or genetic cancer syndromes is poorly understood.

Examination and Diagnostics for Patients With Small Bowel Tumors

On physical examination, it is only rarely possible to palpate an abdominal mass. Laboratory workup should include the standard complete blood count to look for anemia or elevated white blood cell count in the acute setting if signs of perforation are present. Elevated liver enzymes or amylase suggest possible duodenal mass or obstruction. Carcinoembryonic antigen is often elevated in small bowel adenocarcinoma but is not sensitive or specific. Serum 5-HIAA and chromogranin A should be routinely tested if there is a strong clinical suspicion of neuroendocrine tumor based on symptoms or imaging features.

Imaging

On presentation with obstructive symptoms, a computed tomography (CT) scan with intravenous (IV) contrast allows clinicians to visualize the location of obstruction and possibly even the mass itself (Fig. 1). Masses can be constricting, occasionally demonstrating an "apple core" appearance with a circumferential constriction of the lumen. Some masses are polypoid, projecting intraluminally, and are better visualized with oral contrast. Close evaluation of the contour of the bowel is necessary to find submucosal lesions, and the keen surgeon should also thoroughly evaluate the mesentery for associated enlarged nodes or a mesenteric based mass. Occasionally, enlarged nodes are the only sign of a nearby small tumor. Negative CT scans should not rule out small bowel tumor because they are not particularly sensitive in this condition. However, CT does detect abnormalities in up to 80% of patients who do have a small bowel tumor. CTs are also valuable for staging nodes and metastatic lesions (Table 1). Additional specialized imaging modalities such as octreotide or positron emission tomography/computed tomography scans are helpful in localization of neuroendocrine tumors, but these more costly studies should be reserved for patients in whom a high clinical suspicion is present (Fig. 2).

Endoscopy

Esophagogastroduodenoscopy can detect tumors into the third portion of the duodenum and is an excellent tool to begin the workup for GI blood or other symptoms that are suspicious for GI tumors. Endoscopic ultrasound is a useful adjunct to standard esophagogastroduodenoscopy but, in the discussion of small bowel tumors, is limited to evaluation of duodenal lesions. For more distal evaluations, balloon-assisted deep enteroscopy or push endoscopy techniques can be performed by expert gastroenterologists and allow for visualization of most or even all of the small bowel lumen. This, however, is only rarely used and only available in specialized centers. Video capsule endoscopy also affords the ability to evaluate the

MANAGEMENT OF SMALL BOWEL TUMORS

Sandra R. DiBrito, MD, PhD, and Mark D. Duncan, MD, FACS

Small bowel malignancies are rare, difficult to diagnose, and have low treatment guidelines. Because small bowel tumors present with vague and common symptoms, it is imperative that the surgeon keep them on the differential for abdominal pain, obstruction, and gastrointestinal blood. However, the majority of patients referred to surgeons for small bowel tumors have a suspicious mass on imaging. Evidence-based guidelines on management of small bowel malignancy are difficult to find, and given the rarity of these lesions, there is little information in the literature to provide reference for clinical decision making.

PRESENTATION

The typical presenting symptoms of small bowel tumors are vague and highly variable. Many patients present to surgeons as a referral from a primary care provider or a gastroenterologist with a known mass discovered following workup for gastrointestinal (GI) bleeding or encountered incidentally on imaging. Others will present with colicky pain from obstruction, either partial or complete, and will be found to have a small bowel tumor during surgery. The mass itself can be intraluminal or circumferential, directly responsible for obstruction, or can have surrounding fibrosis that results in stricture and adhesions to the mesentery or retroperitoneum. GI stromal tumors (GISTs) are frequently asymptomatic but can present with bleeding or obstruction.

Paraneoplastic symptoms such as weight loss and vague abdominal pain are concerning for malignant neoplasms such as adenocarcinoma and lymphoma, particularly in the context of a known small bowel mass; however, these nonspecific symptoms should prompt broad investigations because small bowel tumors are one of the rarer malignancies. Neuroendocrine tumors that are productive of vasoactive amines can present with a wide range of symptoms, from epigastric pain and ulcerations to flushing, sweating, and diarrhea. Most are asymptomatic, however, and are found incidentally on imaging workup for other conditions.

Predisposing Conditions

Familial adenomatous polyposis, hereditary nonpolyposis colon cancer, and Peutz–Jeghers syndrome are genetic cancer syndromes that predispose to small bowel malignancy. Crohn's disease, celiac sprue, and chronic inflammatory conditions involving the small bowel also predispose to small bowel malignancy, and risk increases with increased severity and longer duration of disease. Patients with cystic fibrosis have 19 times higher incidence than the general population, and with an additional two- to five-fold higher risk following lung transplantation. Obesity, tobacco use, and high dietary intake of red meat, smoked foods, alcohol, and refined sugar have all been shown to have an association with small bowel tumors, but the links between these risk factors and tumorigenesis are not clear. In fact, the etiology of small bowel tumors that are not associated with either chronic inflammatory diseases or genetic cancer syndromes is poorly understood.

Examination and Diagnostics for Patients With Small Bowel Tumors

On physical examination, it is only rarely possible to palpate an abdominal mass. Laboratory workup should include the standard complete blood count to look for anemia or elevated white blood cell count to the acute setting if signs of perforation are present. Elevated liver enzymes or amylase suggest possible ductal mass or obstruction. Carcinoembryonic antigen is often elevated in small bowel adenocarcinoma but is not sensitive or specific. Serum 5-HIAA and chromogranin A should be routinely tested if there is a strong clinical suspicion of neuroendocrine tumor based on symptoms or imaging features.

Imaging

On presentation with obstructive symptoms, a computed tomography (CT) scan with intravenous (IV) contrast allows clinicians to visualize the location of obstruction and possibly even the mass itself (Fig. 1). Masses can be constricting, occasionally demonstrating an "apple core" appearance with a circumferential constriction of the lumen. Some masses are polypoid, projecting intraluminally, and are better visualized with oral contrast. Close evaluation of the contour of the bowel is necessary to find submucosal lesions, and the keen surgeon should also thoroughly evaluate the mesentery for associated enlarged nodes or a mesenteric based mass. Occasionally, enlarged nodes are the only sign of a nearby small tumor. Negative CT scans should not rule out small bowel tumor because they are not particularly sensitive in this condition. However, CT does detect abnormalities in up to 80% of patients who do have a small bowel tumor. CTs are also valuable for staging nodes and metastatic lesions (Table 1). Additional specialized imaging modalities such as octreotide or positron emission tomography/computed tomography scans are helpful in localization of neuroendocrine tumors, but these more costly studies should be reserved for patients in whom a high clinical suspicion is present (Fig. 2).

Endoscopy

Esophagogastroduodenoscopy can detect tumors into the third portion of the duodenum and is an excellent tool to begin the workup for GI blood or other symptoms that are suspicious for GI tumors. Endoscopic ultrasound is a useful adjunct to standard esophagogastroduodenoscopy but, in the discussion of small bowel tumors, is limited to evaluation of duodenal lesions. For more distal evaluations, balloon-assisted deep enteroscopy or push endoscopy techniques can be performed by expert gastroenterologists and allow for visualization of most or even all of the small bowel lumen. This, however, is only rarely used and only available in specialized centers. Video capsule endoscopy also affords the ability to evaluate the

mucosal surface of the entire small bowel, with an average of 30,000 images captured in the small bowel alone during an examination. With the assistance of neural networks and machine learning, the interpretation of these studies is becoming more sensitive and specific, making it an increasingly helpful tool for the investigation of small bowel tumors. Video capsule endoscopy does not allow for tissue diagnosis and is contraindicated in patients with obstructive symptoms.

MANAGEMENT

Benign

Several types of benign small bowel neoplasms exist, and all are quite rare. Adenomas can be categorized as either villous, tubular, or Brunner's gland associated. As in colorectal cancer, some adenomas have malignant potential. There are no firm guidelines regarding management of these masses, but conventionally, the colorectal cancer pathway is followed with endoscopic resection if possible. Adenomas have increased malignant potential when associated with familial adenomatous polyposis. The number, size, histology, and dysplastic characteristics of the polyps should guide management using the Spigelman classification.

FIG. 1 Adenocarcinoma in the fourth portion of duodenum (arrow).

surgical resection is warranted for large adenomas that are not amenable to endoscopic resection, particularly if biopsy reveals villous features. In addition, patients should be screened for synchronous colorectal lesions with colonoscopy.

Leiomyomas are small tumors that are present in the submucosa of the small bowel. They are routinely small, firm, and well circumscribed. Although they may cause obstruction and require resection for this reason, their presence alone is not an indication for surgery. Differentiating between leiomyosarcoma and leiomyoma can be difficult, and often these lesions are surgically resected to rule out malignant disease.

Lipomas are diagnosed relatively easily on CT because of their characteristic fatty density. Hamartomas associated with Peutz-Jeghers syndrome should be resected only if causing bleeding or obstructive symptoms. In addition to lipomas and hamartomas, fibromyomas and ganglioneuromas do not require resection although biopsy may be necessary for diagnosis confirmation. Hemangiomas can be present along the length of the small bowel. Fortunately, these are easily differentiated on CT with IV contrast or magnetic resonance enterography obviating the need for biopsy.

Malignant

Malignant tumors of the small bowel are rare, with estimates of 10,420 cases in the United States and only 1450 mortalities for 2018. Small bowel cancer comprises 1% to 2% of GI malignancies only. Because of the rarity of these cases and available retrospective data, very few guidelines are available even worldwide for treatment of small bowel malignancy, and those are routinely derived from expert opinion based on multiple management of colon cancer. For this reason, each case should be evaluated on an individual basis and overseen by a multidisciplinary oncology team led by the surgical oncologist.

Neuroendocrine Tumors

Derived from neuroendocrine cells, known as Kulchitsky cells, neuroendocrine tumors are found throughout the crypts of Lieberkühn and are the most common small bowel tumor. As secretory tumors, their presentation can be defined by the hormone or amine output; however, most are found incidentally. Carcinoid tumors that secrete serotonin are the most common neuroendocrine tumor in the small bowel, comprising more than 20% of the malignant lesions in the small bowel. Although carcinoid tumors can occur anywhere in the GI tract, 45% of them occur in the small intestine, and most are found within 60 cm of the ileocecal valve. Between 40% and 80% of GI carcinoids spread to the mesentery with nodal metastasis present on presentation. On CT scan, carcinoid lesions are hypervascular, in contrast to adenocarcinomas, which are only moderately enhancing (Fig. 2). They tend to extend through the serosa and can cause fibrobastosis of the mesentery secondary to a desmoplastic reaction. Frequently, the primary small bowel lesion is not visualized on imaging, and the presenting finding is bulky mesenteric adenopathy

FIG. 2. Gallium positron emission tomography/computed tomography scan demonstrating focal uptake of somatostatin receptor tracer in primary neuroendocrine tumor.

FIG. 3. Small bowel neuroendocrine tumor specifically carcinoid (large *arrow*) and associated lymphadenopathy (*small arrow*).

The regional spread of carcinoid tumors necessitates en bloc resection of the mass and mesentery, including an extensive lymphadenectomy, which is often more amenable to an open exploration (Fig. 4). During the operation, it is important to inspect for multicentric disease and liver metastases. Even if these are present, however, it is still recommended to resect the primary lesion both for local control and longevity. Evidence indicates that 60% of the disease burden should be removed to yield the most durable symptomatic improvement, so any disease that seems resectable should be targeted at the time of surgery. For duodenal carcinoid, endoscopic resection may be possible for small lesions. Anterior wall duodenal lesions may be directly excised with laparoscopic or open surgery. For select posterior lesions, local excision through an anterior duodenotomy to expose the posterior wall is an excellent approach. When both an anterior and posterior duodenotomies are performed, a gastrojejunostomy is recommended to avoid obstruction from narrowing of the duodenum. A Fogarty balloon, introduced through the gallbladder or cystic duct, and passed proximally through the ampulla can provide guidance during resection of tumors in the second portion of the duodenum. A cholecystectomy is then performed. This avoids opening the common bile duct. If the tumor is too close to the ampulla to be safely resected, a pancreaticoduodenectomy may be the only recourse.

Typical small bowel carcinoid resection removes 1 to 2 feet of small bowel, with wide lymphatic mesenteric clearance. The mesenteric involvement of this disease is often underestimated and can be misleading, necessitating more bowel resection than originally anticipated in some cases. It is important that patients are counseled about the risks of extensive resection preoperatively. Cases with extensive involvement of small bowel mesentery require careful deliberation. In some cases, leaving mesenteric disease behind in a disconcerting but necessary consideration to avoid short gut syndrome. . . .e emphasize that although extensive resection should be considered for debulking symptomatic, multifocal, or metastatic disease, the consequences of a near complete enterectomy, if less than 100 cm of small bowel remain, certainly outweigh the benefits of resection for these cases. Similarly, if the disease is extensive but relatively asymptomatic, with heavy mesenteric involvement to the root, the operative suite may best be left out of the treatment plan and systemic medical treatment with octreotide is warranted.

FIG. 4. Carcinoid tumor marked by adjacent tattoo dye and nodal metastases.

Both multiple endocrine neoplasia type 1 and neurofibromatosis predispose patients to small bowel neuroendocrine tumors; however, these occur primarily in the foregut, presenting as gastrinomas or somatostatinomas.

Adenocarcinoma

More than one third of small bowel cancers are adenocarcinoma and occur primarily in the duodenum. Unfortunately, because they are relatively asymptomatic until they are large enough to be obstructive or cause clinically evident bleeding, more than half of these tumors present at advanced stages, one third with nodal spread, and one quarter with distant metastases. Because of this, the 5-year survival following diagnosis is nearly 40% in most cases. Surgical resection is the mainstay of therapy, with a segmental resection and accompanying wide local excision of the mesentery to collect the nodal basin (Fig. 5). For those at the terminal ileum, an ileocolectomy should be performed. For duodenal lesions at the ampulla, a pancreaticoduodenectomy is necessary.

For unresectable primary disease, it is reasonable to perform a palliative surgical bypass of the obstructive lesion. Palliative radiation for unresectable disease is usually not beneficial. Clinical trials are ongoing to improve local and systemic control of unresectable disease, and surgeons are encouraged to help patients seek out these resources if possible.

GIST

Mesenchymal tumors such as GIST are most often found in the stomach (~50%) but also develop in the small bowel, with 25% in the jejunum. Derived from the interstitial cells of Cajal, they comprise approximately 10% of small bowel tumors. About 20% to 30% of GISTs are malignant at presentation, more often malignant when involving the small bowel. On CT scan, they appear as smooth, well-defined masses arising from the small bowel wall, demonstrating exophytic growth patterns and internal heterogeneity. They may have areas of central hemorrhage or necrosis (Fig. 5). GISTs rarely metastasize to nodes or spread outside of the abdominal cavity, but can be aggressive. Metastases to the liver can present with multiple normal bowel nodules. The primary lesions are known for causing ulceration through the mucosa, presenting with bleeding. GIST can be differentiated from other sarcomas of smooth muscle by immunostaining for c-KIT. Activating mutations of the KIT oncogene can be seen in more than 80% of GISTs. CT guided biopsy is usually not necessary as radiographic appearance is distinctive and resection is indicated.

A laparoscopic approach for resection of GIST is often ideal. These tumors are exophytic, making them easier to locate than other small bowel tumors during laparoscopic exploration, and because they do not spread via lymphatics, lymphadenectomy is not required. A short segmental enterectomy with only 2 cm margins is recommended. If the tumor is bulky or if adjacent organ involvement is suspected, preoperative imatinib can aid in shrinking the mass to facilitate resection. Unfortunately, more than 50% of these tumors recur within 5 years. To prolong disease free survival, high risk patients should be treated postoperatively with a minimum of 12 to 24 months of imatinib, and studies are ongoing regarding longer or even indefinite

treatment to prevent recurrence. High-risk features include tumor size >2 cm, high mitotic index, poorly differentiated cell type, presence of metastasis, and positive margin (Table 1).

Sarcoma

Sarcoma, typically leiomyosarcoma, is rare, occurring most often in the ileum. Five-year survival is approximately 50%. Radical surgical excision is recommended if the primary disease is resectable. Similar to adenocarcinoma, if the disease is deemed unresectable, surgical bypass should be considered. Palliative radiation has a greater role in sarcoma management compared with other small bowel tumors.

Lymphoma

The small bowel is the most frequently encountered extranodal site for lymphoma. This tumor is usually non-Hodgkin's type lymphoma and involves the small bowel mesentery more commonly than the luminal surface. It is most common in the ileum, the most lymphoid-rich region of the small bowel. Clinicians should maintain a high suspicion for other sites of involvement because a solitary small intestinal lesion is a rare presentation for lymphoma. Patients with celiac disease have a 20-fold higher risk of GI lymphoma, and patients with chronic immunosuppression including transplant recipients and those with human immunodeficiency virus are also at an increased risk. On CT with IV contrast, the mass often appears well circumscribed and homogeneous (Fig. 7).

A tissue diagnosis is required for lymphoma, and because there are a variety of non-Hodgkin's subtypes, it is imperative that enough tissue is harvested to perform the full battery of cytopathology and flow cytometry. The subtype dictates the tumor behavior, treatment, and prognosis. Most small bowel lymphomas do not require resection, but rather are best treated with multidrug chemotherapy. The 5-year survival is 50%, with poorer prognosis in males and the elderly. Surgery may be necessary for obstruction, or the diagnosis of lymphoma may be made postoperatively after surgical intervention for small bowel obstruction has already taken place. In patients without signs and symptoms of small bowel obstruction, CT-guided or endoscopic biopsy is appropriate to guide therapy. Indeed, the main role of biopsy in small bowel tumors is to distinguish lymphoma because most all other small bowel masses require resection as the primary management.

FIG. 7 Small bowel lymphoma (arrow).

Metastatic Disease

Secondary involvement of the small bowel from other metastatic lesions presents as multifocal advanced cancer and not as an isolated small bowel lesion. Lung, melanoma, breast, colon, and cervical cancer can all spread to the small bowel. Sarcomas and adenocarcinomas can also affect the small bowel, either through direct erosion or carcinomatosis of overlying peritoneum. As an innocent bystander, the small bowel may need to be resected or bypassed, depending on the type and stage of primary tumor.

SUMMARY

Small bowel tumors are rare and present with a constellation of common symptoms. Late diagnosis makes the prognosis of small bowel malignancy particularly poor, and a thorough workup to rule out small bowel tumors should be undertaken in anyone with vague abdominal pain and gastrointestinal symptoms with no other apparent source. Aside from small bowel lymphoma, most other suspicious small bowel masses do not require biopsy and should be resected. Neoadjuvant management of these malignant lesions has room for investigation, and surgeons should feel compelled to lead efforts to discover optimal treatment paradigms and create guidelines.

MANAGEMENT OF DIVERTICULOSIS OF THE SMALL BOWEL

Ryan R. Francescon, MSc, and John V. Fanfair III, MD, FACS

Although diverticulosis of the small bowel remains relatively uncommon, appropriate management is clinically important. The reported prevalence from multiple autopsy series ranges from 0.3% to 1.5%. Diverticulosis of the small bowel has been observed in approximately 2% to 6% of small bowel contrast studies and in 7% of patients undergoing endoscopic retrograde cholangiopancreatography. Most small bowel diverticula are asymptomatic, and it is estimated that less than 4% become overtly symptomatic, with an estimated 10% of patients reporting of chronic nausea, bloating, flatulence and diarrhea.

Small bowel diverticula can be congenital or acquired and can be classified as true diverticula (containing all layers of the intestinal wall) or false diverticula (containing only mucosa, submucosa, and serosa). They can occur in the duodenum, jejunum, and ileum but are most commonly found in the duodenum. Most asymptomatic small bowel diverticula are identified incidentally at colonoscopy or on radiographic study and are usually managed nonoperatively. Advances in endoscopy have also increased the recognition and diagnosis.

A fair amount of literature exists addressing the management of complications from diverticulosis of the small bowel. There have been hundreds of publications, most of which are case reports including review of the literature. Since larger series have attempted to extrapolate the findings to the general population however, their utility remains limited.

DETECTION AND MANAGEMENT OF ASYMPTOMATIC (INCIDENTALLY DISCOVERED) SMALL BOWEL DIVERTICULOSIS

In the current era of radiologic imaging combined with advances in endoscopy, diverticulosis of the small bowel is being diagnosed more frequently. Despite the seeming increase in detection, there has not been a notable increase in symptomatic diverticula. Most truly are discovered incidentally and while still asymptomatic.

Duodenal and periampullary Diverticula

Duodenal diverticula are the most common diverticula of the small bowel, accounting for approximately 82% to 78% of cases. They are usually solitary and asymptomatic. Although they are found in 1% to 6% of all upper gastrointestinal radiologic series, they are discovered even more commonly at autopsy. Fortunately, less than 10% become symptomatic because surgical intervention can carry significant morbidity and mortality.

Duodenal diverticula can develop congenitally or as an acquired entity. In addition to those classically described, pseudodiverticula or windsock diverticula also can occur congenitally in the duodenum as prolapse of mucosa or incompletely divided congenital septa. They typically arise from the second portion of the duodenum and can extend as far as the fourth portion. Frequently, pseudodiverticula are associated with other congenital anomalies: malrotation, omphalocele, annular pancreas, congenital biliary cysts, and various cardiac and urinary congenital abnormalities. Symptoms vary depending on the size and location, especially regarding proximity to the ampulla of Vater.

Asymptomatic diverticula, by definition, are discovered incidentally on radiographic or endoscopic examination and at autopsy for another reason. Because most are asymptomatic, it has become the standard recommendation to not operate or resect any asymptomatic small bowel diverticula, especially because an asymptomatic patient cannot be made better.

There is statistical justification for operating only on symptomatic diverticula of the small bowel, which is infrequent because less than 10% are symptomatic and less than that ever come to operation. Conversely, there is also statistical justification for not operating on asymptomatic diverticula. Zani and colleagues calculated that 250 patients with incidental Meckel's diverticulum would need to undergo intestinal resection to prevent 1 death.

Jejunoileal Diverticula

Diverticula arising in the jejunum and ileum account for 10% to 25% of all small bowel diverticulum; however, about 10% of these are likely to become symptomatic. They are commonly multiple 80% occur in the jejunum, 15% occur in the ileum, and 5% occur in both.

These jejunoileal (false) diverticula are thought to develop as a result of myoneural abnormalities, often dysmotility in the migrating motor complexes, leading to spastic contractions that result in prolonged, increased intraluminal pressures. Over the course of many years, this is thought to lead to the formation of the false diverticula. Enteroclysis is the best radiographic study to evaluate jejunoileal diverticula, often to confirm the diagnosis. CT/magnetic resonance enterography likewise has been used increasingly in diagnosis. The use of capsule endoscopy also has a role in the diagnosis and evaluation of jejunoileal diverticula, especially asymptomatic but not infected.

As with most other diverticula of the small bowel, surgical resection is not warranted in an asymptomatic patient with jejunoileal diverticula or those discovered incidentally. There has been no proven role for prophylactic resection.

Meckel's Diverticula

Meckel's diverticulum is the most common congenital small bowel abnormality and accounts for the remaining 25% of small bowel

SUMMARY

Small bowel tumors are rare and present with a constellation of common symptoms. Late diagnosis makes the prognosis of small bowel malignancy particularly poor, and a thorough workup to rule out small bowel tumors should be undertaken in anyone with vague abdominal pain and gastrointestinal symptoms with no other apparent source. Aside from small bowel lymphoma, most other suspicious small bowel masses do not require biopsy and should be resected. MANAGEMENT OF DIVERTICULOSIS OF THE SMALL BOWEL

Ryan R. Francescutti, MSc, MD, and John W. Harmston, MD, FACS

Although diverticulosis of the small bowel remains relatively uncommon, appropriate management is clinically important. The reported prevalence from multiple autopsy series ranges from 0.3% to 1.5%. Diverticulosis of the small bowel has been observed in approximately 2% to 6% of small bowel contrast studies and in 7% of patients undergoing endoscopic retrograde cholangiopancreatography. Most small bowel diverticula are asymptomatic, and it is estimated that less than 6% become overtly symptomatic, with an estimated 10% of patients reporting of chronic nausea, bloating, flatulence and diarrhea.

Small bowel diverticula can be congenital or acquired and can be classified as true diverticula (containing all layers of the intestinal wall) or false diverticula (containing only mucosa, submucosa, and serosa). They can occur in the duodenum, jejunum, and ileum but are most commonly found in the duodenum. Most asymptomatic small bowel diverticula are identified incidentally at colonoscopy or on radiographic study and are usually managed nonoperatively. Advances in endoscopy have also increased the recognition and diagnosis.

A fair amount of literature exists addressing the management of complications from diverticulosis of the small bowel. There have been hundreds of publications, most of which are case reports including review of the literature. Since larger series have attempted to extrapolate the findings to the general population, however, their utility remains limited.

DETECTION AND MANAGEMENT OF ASYMPTOMATIC (INCIDENTALLY DISCOVERED) SMALL BOWEL DIVERTICULOSIS

In the current era of radiology, imaging combined with advances in endoscopy, diverticulosis of the small bowel is being diagnosed more frequently. Despite the seeming increase in detection, there has not been a notable increase in symptomatic diverticula. Most truly are discovered incidentally and while still asymptomatic.

Duodenal and Intraluminal Diverticula

Duodenal diverticula are the most common diverticula of the small bowel, accounting for approximately 82% to 78% of cases. They are usually solitary and asymptomatic. Although they are found in 1% to 6% of all upper gastrointestinal radiologic series, they are discovered even more commonly at autopsy. Fortunately, less than 10% become symptomatic because surgical intervention can carry significant morbidity and mortality.

Duodenal diverticula can develop congenitally or as an acquired entity. In addition to those classically described, periampullary or midduct diverticula also can occur congenitally in the duodenum as prolapse of mucosa or incompletely divided congenital septa. They typically arise from the second portion of the duodenum and can extend as far as the fourth portion. Frequently, periduodenal diverticula are associated with other congenital anomalies: malrotation, omphalocele, annular pancreas, congenital biliary cysts, and various cardiac and urinary congenital abnormalities. Symptoms vary depending on the size and location, especially regarding proximity to the ampulla of Vater.

Asymptomatic diverticula, by definition, are discovered incidentally on radiographic or endoscopic examination and at autopsy for another reason. Because most are asymptomatic, it has become the standard recommendation to not operate or resect any asymptomatic small bowel diverticula, especially because an asymptomatic patient cannot be made better.

There is statistical justification for operating only on symptomatic diverticula of the small bowel, which is infrequent because less than 10% are symptomatic and less than that ever come to operation. Conversely, there is also statistical justification for not operating on asymptomatic diverticula. Zani and colleagues calculated that 250 patients with incidental Meckel's diverticulum would need to undergo intestinal resection to prevent 1 death.

Jejunoileal Diverticula

Diverticula arising in the jejunum and ileum account for 10% to 25% of all small bowel diverticulum; however, about 10% of these are likely to become symptomatic. They are commonly multiple 80% occur in the jejunum, 15% occur in the ileum, and 5% occur in both.

These jejunoileal (false) diverticula are thought to develop as a result of myoneural abnormalities, often dysmotility in the migrating motor complexes, leading to spastic contractions that result in prolonged, increased intraluminal pressures. Over the course of many years, this is thought to lead to the formation of the false diverticula. Enteroclysis is the best radiographic study to evaluate jejunoileal diverticula, often to confirm the diagnosis. CT/magnetic resonance enterography likewise has been used increasingly in diagnosis. The use of capsule endoscopy also has a role in the diagnosis and evaluation of jejunoileal diverticula, especially asymptomatic but not infected.

As with most other diverticula of the small bowel, surgical resection is not warranted in an asymptomatic patient with jejunoileal diverticula or those discovered incidentally. There has been no proven role for prophylactic resection.

Meckel's Diverticula

Meckel's diverticulum is the most common congenital small bowel abnormality and accounts for the remaining 25% of small bowel

FIG. 1. Common presentation of a Meckel's diverticulum projecting from the antimesenteric border of the ileum. [From Feldman, Sleisenger, and Scharschmidt's Gastrointestinal and Liver Disease, 7th ed. Philadelphia: Saunders, 2002.]

diverticulosis. A Meckel's diverticulum is the remnant of a persistent portion (from failure of obliteration) of the proximal vitelline (omphalomesenteric) duct, which connects the embryonic midgut to the yolk sac. It only occurs on the antimesenteric border of the ileum as a true diverticulum, which contains all layers of the intestinal wall.

Meckel's diverticula are located approximately 2 feet from the ileocecal valve often containing one of two types of heterotopic tissue, most commonly gastric (75%) or pancreatic (15%) (Fig. 1). The "rule of two" follows that Meckel's diverticula occur twice as commonly in males in 2% of the population and become symptomatic in 2% of cases usually within the first 2 years of life, they can extend over 2 inches in length and predominantly cause two types of symptoms: bleeding and obstruction.

The lifetime risk of an asymptomatic Meckel's diverticulum becoming symptomatic is very low. Most Meckel's diverticula become symptomatic within the first 2 years of life and certainly by the age of 10. Based on 19 autopsy studies, in which seven reported postnatal autopsies, Meckel's diverticulum has a prevalence of 1.23%. Mortality from Meckel's diverticulum is low (<0.001%) and is most common in the pediatric population. Incidentally discovered Meckel's diverticula should be left in situ because the risk of postoperative complication from resection outweighs the risk of late complications.

A comprehensive systematic review done by Yaxt and colleagues concluded that there is no compelling evidence in the literature to support prophylactic resection of an incidentally discovered Meckel's diverticulum at operation for an unrelated condition, even in young children. Nonetheless, palpable evidence of ectopic tissue intraoperatively, a prior history of diverticulitis, hemorrhage, or intussusception, or the presence of a nondiverticular band serves as a relative indication. Most experts concur that a symptomatic or incidentally discovered Meckel's diverticulum in a young child should be resected.

MANAGEMENT OF SYMPTOMATIC SMALL BOWEL DIVERTICULA

Duodenal Diverticula

The investigational modalities of choice for duodenal diverticula include esophagogastroduodenoscopy and endoscopic retrograde cholangiopancreatography. These two modalities have become the cornerstone of visualizing duodenal diverticula, especially to clarify the relationship with and proximity to the ampulla of Vater and any contiguous biliary or pancreatic ductal structures. Increasingly, CT and magnetic resonance cholangiography are being used for imaging, often ordered as a follow up study to better characterize findings from standard contrast radiography.

Symptomatic duodenal diverticula are often the most difficult to manage because they usually include or are adjacent to the ampulla of Vater, specifically biliary and pancreatic ductal structures. Endoscopic therapy, including sphincterotomy as well as temporary stent placement, typically is attempted first. Operative management is reserved until after the inability to undergo endoscopic therapy or failure of endoscopic therapy.

Operative treatment of duodenal diverticula can be difficult and can be associated with significant morbidity and mortality, especially in inexperienced hands. Keys to the operative approach include a wide Kocher maneuver, clarification of the anatomy, relationship of the diverticulum to biliary and pancreatic ductal structures, identification of all biliary and pancreatic ductal structures, liberal use of intraoperative ductal stents, transverse or oblique closure of the duodenum, and sometimes a T-tube patch, including cholecystectomy with any operation for duodenal diverticula. The diverticulum usually is resected, often with a stapler after extensive mobilization, or it can just be inverted.

Jejunoileal Diverticula

Symptomatic jejunoileal diverticulitis is diagnosed most often using CT/magnetic resonance enterography. After enterography, unrelated, symptomatic jejunoileal diverticula also may be evaluated by push enteroscopy, double balloon endoscopy, and capsule endoscopy. Jejunoileal diverticula can present as diverticulitis, refractory inflammation, obstruction, perforation, and hemorrhage. Complicated jejunoileal diverticula often require surgical management, although jejunoileal diverticulitis usually can be managed nonoperatively, at least initially.

Most recommendations support segmental resection of jejunoileal diverticula, when necessary, especially to prevent narrowing of the small bowel. The real possibility of postoperative complications (reason to not operate when asymptomatic) is the usual reason offered for including incidental appendectomy at the time of operation.

Meckel's Diverticulum

Meckel's diverticula can become symptomatic in many ways. Most commonly, acid produced by ectopic gastric mucosa causes ulceration along the mesenteric border of the ileum, of those with hemorrhage, 90% contain gastric mucosa. Meckel's diverticulum can be a cause of chronic and acute gastrointestinal hemorrhage in the broader pediatric population but also occurs in adults.

Diagnostic modalities usually include a form of angiography or radioisotope scintigraphy (Fig. 2). Angiography can be useful during active hemorrhage, where it shows bleeding into the diverticulum or distal small bowel. Angiography is even more useful when it demonstrates a persistent right vitelline artery arising from the superior mesenteric artery or an enlarged, long, nonbranching, embryonic ileal artery leading to the diverticulum. The most useful arteriographic finding is a nonbranching end artery in the right lower abdomen containing a cluster of small, irregular arteries at its distal distribution. These often contain irregular arteries in the wall of the diverticulum and vitelline artery remnants as well as increased parenchymal blush from the ectopic gastric mucosa lining the diverticulum.

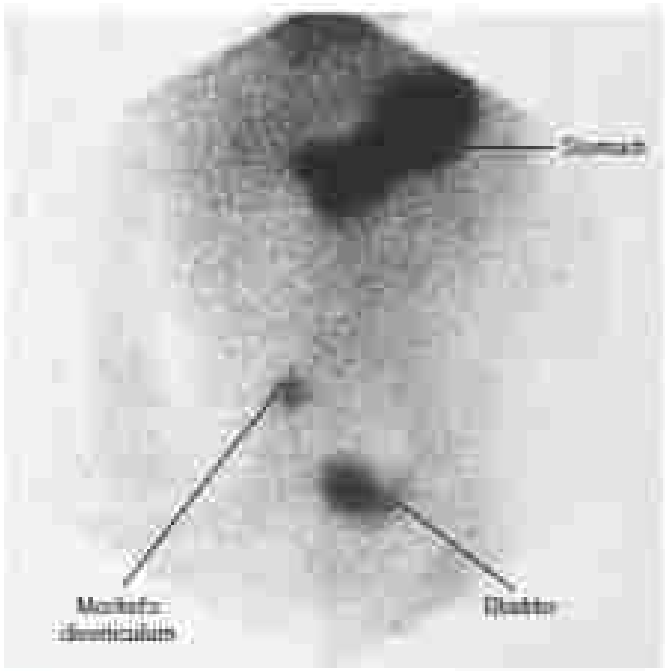

FIG. 2. Technetium 99m pertechnetate scintigram from a child with a Meckel's diverticulum clearly differentiated from the stomach and bladder. (From McKenzie S.J. In: JM, Wolf BG, et al., eds. Textbook of Surgery. 15th ed. Philadelphia: Elsevier; 2001.)

Meckel's scintigraphy uses technetium 99m pertechnetate, which is concentrated and then secreted by mucous-producing cells (gastric mucosa). It is important to remember that a Meckel's scan identifies ectopic gastric mucosa, not the hemorrhage. To obtain a quality study, it is often necessary to obtain oblique, lateral, or posterior films to distinguish a diverticulum from other activity. The activity in a Meckel's diverticulum should occur at about the same time as activity in the stomach. Depending on the center and radiologist, the sensitivity of a Meckel's scan is reportedly as high as 75% to 85% and supposedly can be increased by pretreatment with pentagastrin or glucagon.

In adults, Meckel's diverticula commonly are seen as small bowel obstruction (42%). After adequate resuscitation, obstruction is managed operatively as quickly as possible usually by wedge excision and primary closure or amputation with a surgical stapler.

Diverticulitis (25%) within a Meckel's diverticulum is often indistinguishable from acute appendicitis and is managed by segmental resection and primary anastomosis. Hemorrhage (20%) and ulceration are managed by segmental resection and primary anastomosis. At operation for hemorrhage, segmental resection is recommended because the ulcer is typically on the mesenteric border of the ileum opposite the antimesenteric border location of the Meckel's diverticulum and occasionally distal to it. Despite improved diagnostic modalities, most bleeding Meckel's diverticula are diagnosed at celiotomy.

Appendectomy should be considered at any operation for a symptomatic Meckel's diverticulum to prevent any future diagnostic dilemmas. Some texts also describe the need to search for an asymptomatic Meckel's diverticulum during appendectomy and or any acute abdomen exploratory laparotomy and if identified diverticulectomy should be considered.

Management of Motility Disorders of the Stomach and Small Bowel

Robert Sitrin, MD, PhD, and Pankaj Jay Pasricha, MBBS, MD

Entry of solids and liquids into the stomach normally results in gastrointestinal relaxation to allow the initial storage of food for proteins and fat digestion. Receptive relaxation, thought to be vagally mediated, will occur within the first 20 seconds, followed by adaptive relaxation within the first 15 minutes. Fundal tone then increases because of hormone response to intraluminal amino acids, which facilitates emptying of chyme into the distal stomach. Antral contraction occurs against a partially closed pylorus at a rate of 3 cycles/min, grinding contents to allow for expulsion. It has long been thought that damage or dysfunction of the vagus nerve mediates gastric dysmotility, whether from surgical intervention (upended or inadvertent) or chronic illness. Evidence has accumulated that damage to the interstitial cells of Cajal (pacemaker cells) in the gastric wall may also be important in diabetic and idiopathic gastroparesis, related to or independent of vagal dysfunction. The complex interplay between dimensualities in antral contractility, pyloric relaxation (which modulate emptying), and fundic accommodation, which mediate symptoms in these patients, likely explains the difficulties in improving symptoms in patients with gastroparesis, whether a pharmacologic or surgical approach is used.

Disorders of gastric motility are typically divided into disorders of delayed emptying (gastroparesis) and rapid emptying (dumping); however, in reality this distinction is not that clear cut in the clinic as there may be considerable overlap in symptomatology. This review will discuss postsurgical effects on gastric motility.

■ DELAYED GASTRIC EMPTYING (GASTROPARESIS)

Gastroparesis is a disorder characterized by symptoms of nausea, vomiting, early satiety, postprandial fullness, and abdominal pain. Gastroparesis is most often idiopathic; in one third of the patients, the etiology is suspected to be secondary to diabetes (either type 1 or type 2). Other causes (such as scleroderma, Parkinson's, or surgical injury) are important to recognize but relatively uncommon.

Regardless of the etiology, the pathogenesis of gastroparesis has not been established. In diabetics and postsurgical cases, vagal neuropathy or injury may lead to disruption of processes that are at least partially dependent on a healthy vagus such as gastric accommodation, antral motility, and pyloric relaxation. Impairment of all three

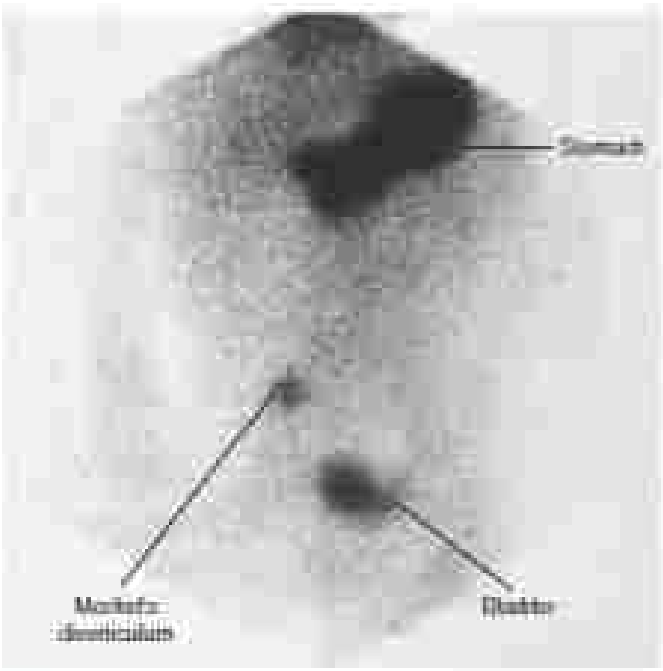

FIG. 2 Technetium 99m pertechnetate scintigram from a child with a Meckel's diverticulum clearly differentiated from the stomach and bladder. (From McKenzie S, Lowe JM. Small intestine. In Grosfeld JL, et al, editors. Textbook of Surgery. 16th ed. Philadelphia: Elsevier; 2015.)

Meckel's scintigraphy uses technetium 99m pertechnetate, which is concentrated and then secreted by mucous-producing cells (gastric mucosa). It is important to remember that a Meckel's scan identifies ectopic gastric mucosa, not the hemorrhage. To obtain a quality study, it is often necessary to obtain oblique, lateral, or posterior films to distinguish a diverticulum from other activity. The activity in a Meckel's diverticulum should occur at about the same time as activity in the stomach. Depending on the center and radiologist, the sensitivity of a Meckel's scan is reportedly as high as 75% to 85% and supposedly can be increased by pretreatment with pentagastrin or glucagon.

In adults, Meckel's diverticula commonly are seen as small bowel obstruction (42%). After adequate resuscitation, obstruction is managed operatively as quickly as possible usually by wedge excision and primary closure or amputation with a surgical stapler.

Diverticulitis (25%) within a Meckel's diverticulum is often indistinguishable from acute appendicitis and is managed by segmental resection and primary anastomosis. Hemorrhage (20%) and ulceration are managed by segmental resection and primary anastomosis. At operation for hemorrhage, segmental resection is recommended because the ulcer is typically on the mesenteric border of the ileum opposite the antimesenteric border location of the Meckel's diverticulum and occasionally distal to it. Despite improved diagnostic modalities, most bleeding Meckel's diverticula are diagnosed at celiotomy.

Appendectomy should be considered at any operation for a symptomatic Meckel's diverticulum to prevent any future diagnostic dilemmas. Some texts also describe the need to search for an asymptomatic Meckel's diverticulum during appendectomy and or any acute abdomen exploratory laparotomy and if identified diverticulectomy should be considered.

Management of Motility Disorders of the Stomach and Small Bowel

Robert Bulkley, MD, PhD, and Pankaj Jay Pasricha, MBBS, MD

Entry of solids and liquids into the stomach normally results in gastrointestinal relaxation to allow the initial storage of food for proteins and fat digestion. Receptive relaxation, thought to be vagally mediated, will occur within the first 20 seconds, followed by adaptive relaxation within the first 15 minutes. Fundal tone then increases because of hormone response to intraluminal amino acids, which facilitates emptying of chyme into the distal stomach. Antral contraction occurs against a partially closed pylorus at a rate of 3 cycles/min, grinding contents to allow for expulsion. It has long been thought that damage or dysfunction of the vagus nerve mediates gastric dysmotility, whether from surgical intervention (vagotomy or inadvertent) or chronic illness. Evidence has accumulated that damage to the interstitial cells of Cajal (pacemaker cells) in the gastric wall may also be important in diabetic and idiopathic gastroparesis, related to or independent of vagal dysfunction. The complex interplay between dysmotilities in antral contractility, pyloric relaxation (which modulate emptying), and fundic accommodation, which mediate symptoms in these patients, likely explains the difficulties in improving symptoms in patients with gastroparesis, whether a pharmacologic or surgical approach is used.

Disorders of gastric motility are typically divided into disorders of delayed emptying (gastroparesis) and rapid emptying (dumping); however, in reality this distinction is not that clear cut in the clinic as there may be considerable overlap in symptomatology. This review will discuss postsurgical effects on gastric motility.

■ DELAYED GASTRIC EMPTYING (GASTROPARESIS)

Gastroparesis is a disorder characterized by symptoms of nausea, vomiting, early satiety, postprandial fullness, and abdominal pain. Gastroparesis is most often idiopathic; in one third of the patients, the etiology is suspected to be secondary to diabetes (either type 1 or type 2). Other causes (such as scleroderma, Parkinson's, or surgical injury) are important to recognize but relatively uncommon.

Regardless of the etiology, the pathogenesis of gastroparesis has not been established. In diabetics and postsurgical cases, vagal neuropathy or injury may lead to disruption of processes that are at least partially dependent on a healthy vagus such as gastric accommodation, antral motility, and pyloric relaxation. Impairment of all three

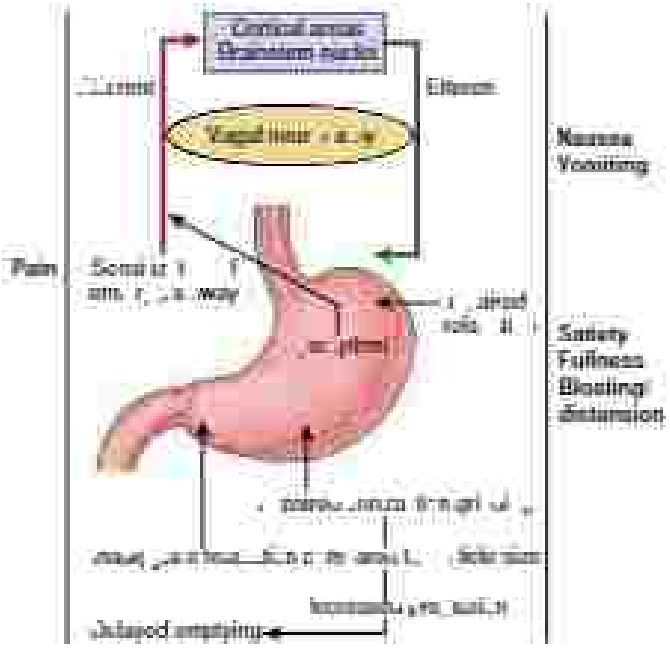

FIG. 1 Proposed pathophysiologic basis of symptoms experienced by patients with gastroparesis. *(From Soffer EE, Parkman HP. Investigational drug therapies for the treatment of gastroparesis. Expert Opin Investig Drugs. 2013;22:1111–1122.)*

of these processes has been reported to a lesser or greater extent in patients. In both idiopathic and diabetic gastroparesis there is a loss of gastric interstitial cells of Cajal associated with evidence of alternative macrophage activation. Interstitial cells of Cajal loss in turn correlates inversely with gastric emptying time in these patients, implying a possible etiologic link.

Although gastroparesis implies a delay in gastric emptying by definition, it has become clear that there is poor correlation between the severity of delay and symptoms in these patients. A significant number of patients have normal emptying although their symptoms are indistinguishable from those in patients with overt delay; this syndrome is likely part of the spectrum of gastroparesis and has been termed chronic unexplained nausea and vomiting or gastroparesis-like syndrome. In these patients, other mechanisms (e.g., impaired gastric accommodation, sensitization of vagal afferent pathways) may account for the symptomatology (Fig. 1).

Most patients who present with symptoms of delayed gastric emptying postoperatively will complain of early satiety and frequently with nausea exacerbated after meals. They may vomit undigested food many hours after eating, often the next day. There may be accompanying abdominal pain. Liquids are typically better tolerated than solid foods, but not always. Inpatient oral intake may lead to dehydration, weight loss and nutritional compromise. Some patients have frequent emergency room visits for these symptoms.

History taking should include prior GI tract surgery (especially foregut), presence of diabetes or thyroid disease (especially if poorly controlled), presence of connective tissue disorders such as scleroderma, and history of chronic constipation. Medication history should include use of anticholinergics or opiates. Symptoms of intense nausea and vomiting occurring in a periodic fashion that lasts a few days at a time with the patient being well in the interval is suggestive of cyclic vomiting syndrome. In such patients, a history of relief with hot showers or baths is highly suggestive for cannabinoid induced hyperemesis, which is associated with chronic marijuana use. On the other hand, the absence of nausea in a patient along with "vomiting" that occurs within a few minutes should raise suspicion for rumination disorder. On physical examination, most patients either have a normal weight or, somewhat counterintuitively, are overweight. Patients with poorly controlled type 1 diabetes are the most likely to be underweight and overtly malnourished. Abdominal examination often reveals tenderness in the epigastric region on deep palpation. More superficial tenderness should elicit consideration of chronic abdominal wall pain that can occur secondarily, especially around laparoscopic scars (a history of cholecystectomy for "gallbladder dyskinesia" is common in these patients). In our opinion, looking for a succussion splash, as has been advocated historically, is not only seldom fruitful, but often results in worsening of nausea and pain. We do not recommend it. If it has not already at the time of presentation, mechanical obstruction of the stomach (and occasionally more distally) must be ruled out principally by endoscopy. We often use computed tomography or magnetic resonance enterography to obtain both cross-sectional imaging and evaluate bowel patency. Occasionally, these tests will lead to a radiologic suggestion of superior mesenteric artery syndrome, particularly in patients who report recent loss of significant amounts of weight. This can lead to a clinical dilemma, in our experience, although decompression surgery is often attempted in these patients, it seldom leads to reversal of their symptomatology and should be approached with caution. The current gold standard for the diagnosis of gastroparesis is the 4 hour gastric emptying scintigraphic using a solid egg based meal study, now carried out by most nuclear medicine departments in the United States. Patients should be instructed to abstain from opioids for several days before the study. In addition, diabetic patients should have a finger stick glucose level at acute hyperglycemia (>250 to 300 mg/dL) by itself can delay gastric emptying (in addition to causing nausea).

MEDICAL APPROACHES

Patients are started on a low fat, low fiber diet, and encouraged to eat more frequent small meals (up to six) daily instead of a single daily meal. A small controlled trial of a "microparticle" diet has been shown to improve symptoms in patients. Patients with more severe gastroparesis may be recommended a "step" approach, starting with liquids, and graduating to more solid meals. Common deficiencies (iron, B12, vitamin D) should be looked for and corrected.

In people with diabetes, tight glucose control is the key for both long-term improvement as well as symptomatic amelioration resulting from frequent hyperglycemic excursions. In the past, physicians have shied away from aggressive measures to control diabetes in this population from concerns about the unpredictable timing of meal-related glucose surges because of the delay in gastric emptying. A recent study from the Gastroparesis Clinical Research Consortium suggests, however, that the use of insulin pumps in patients with type 1 diabetes leads to fewer hypoglycemic (as well as hyperglycemic) events, reduction in HbA$_{1c}$, and significant improvement in symptoms related to gastroparesis.

The traditional approach for treating gastroparesis is to improve gastric emptying by so-called prokinetic agents (Table 1), but it is no longer clear that delayed gastric emptying is solely responsible for the pathogenesis of symptoms and there is poor correlation between improvement in emptying and clinical relief, leading to the search for alternative approaches. In this country, metoclopramide is the only prokinetic approved for gastroparesis. It is a dopamine 2 (D_2) receptor antagonist that provides a potent central antinausea effect that probably contributes more to its efficacy than the peripheral prokinetic effect on gastric emptying. As to be expected with any D_2 receptor antagonist that penetrates the brain, its use is associated with higher risk of extrapyramidal effects, both acute (spasmodic dystonia) and chronic (tardive dyskinesia), especially in the elderly. The latter risk has led to the US Food and Drug Administration (FDA) issuing a black box warning and led to a decline in its use. Domperidone is a closely related D_2 receptor antagonist but does not cross the blood-brain barrier and is widely used in the rest of the world. Although never formally approved in this country, it was recommended frequently by US physicians (with patients either filling their prescriptions at

TABLE 1 Medication for GI Motility Disorders

Drug	Indication	Mechanism	Dose	Side Effects
Metoclopramide	Gastroparesis (FDA approved for this indication)	Central/peripheral dopamine receptor antagonist, 5HT3 receptor antagonist, 5HT4 receptor agonist (prokinetic and antiemetic)	5–10 mg 3 times daily	Up to 30% CNS parkinsonism, tardive dyskinesia (FDA black box warning)
Domperidone	Gastroparesis (not available in the United States except under FDA IND)	Peripheral dopamine receptor antagonist (prokinetic and antiemetic)	10–20 mg 4 times daily	Can cause QTc prolongation, with risk of arrhythmia, hyperprolactinemia
Erythromycin	Gastroparesis (off-label)	Motilin receptor agonist (prokinetic)	50–250 mg up to 4 times daily	May worsen nausea, vomiting, abdominal pain; tachyphylaxis with long-term use requires drug holidays; can cause QTc prolongation with risk of arrhythmia
Mirtazapine	Gastroparesis (off-label)	Alpha adrenergic, 5HT2, 5HT3, and H1 receptor antagonist (prokinetic, antiemetic)	15–30 mg every day at bedtime	Somnolence, increased appetite, and weight gain
Prucalopride	Constipation, gastroparesis, POI, CIPO (off-label)	Highly selective 5HT4 receptor agonist (prokinetic, serotonergic)	1–2 mg daily	Headache, nausea, abdominal pain, diarrhea
Aprepitant	Chemotherapy-induced and postoperative nausea and vomiting (FDA approved), gastroparesis (off-label)	NK-1 receptor antagonist (antiemetic)	125 mg/day	Lightheadedness, nausea
Ibuprofen	Nausea (off-label)	5HT3 receptor agonist, dopamine receptor antagonist (improves gastric fundal compliance)	10–20 mg 2 or 3 times daily (maximum, 40 mg/day)	Dizziness, nausea, headache
Pyridostigmine	Constipation, CIPO, POI (off-label)	AChE inhibitor	30 mg/day to 60 mg 3 times daily	Nausea, vomiting, diarrhea
Octreotide	Symptomatic rapid gastric emptying (off-label)	Somatostatin agonist (inhibits GI motility and secretion)	50–100 μg subcutaneously before meals (up to 3 times daily); can convert to depot intramuscular once dose stability is achieved	Diarrhea
Olanzapine	Nausea (off-label)	5HT2A and dopamine receptor antagonist	5–20 mg daily	Weight gain, somnolence, hyperprolactinemia
Alvimopan	Prevention of POI	Peripheral mu-opioid receptor antagonist	6–12 mg 0.5–5 hours before surgery, then 6–12 mg by mouth every 12 hours from 1 to 7 days postoperatively (not >15 doses)	Nausea, vomiting, abdominal distension

AChE, acetylcholinesterase; CIPO, chronic idiopathic intestinal pseudo-obstruction; CNS, central nervous system; FDA, US Food and Drug Administration; GI, gastrointestinal; IND, investigational new drug; PO, postoperative ileus.

compounding dispensaries or in other countries). Recently, however, substantial concerns have been raised about the cardiovascular proarrhythmic risk from domperidone leading to warnings in Europe. This has led to stricter regulation of domperidone dispensation by the HPA in this country.

Other classes of prokinetic agents include motilin agonists (erythromycin) and 5HT4 receptor agonists (prucalopride). Erythromycin is useful for improving gastric emptying in the short term (e.g., in hospitalized patients) but has never been rigorously evaluated for symptomatic relief with long-term use, which is limited by tachyphylaxis, advocating some practitioners to prescribe "drug holidays" to allow for recovery from the same. Its prokinetic effect is limited to the upper gastrointestinal (GI) tract. Prucalopride, a 5HT4R agonist is in the same class as tegaserod and is a more general prokinetic effect. There is little to no published evidence on its utility in gastroparesis, however; many patients also have slow transit constipation and may benefit from relief of colonic distention with perhaps secondary effects on symptoms such as nausea, bloating, and fullness.

Other pharmacologic treatment is clearly directed at ameliorating symptoms, particularly nausea. Classical antinauseants such as the 5-HT3 receptor antagonists are generally considered first line therapy in this regard, typically beginning with ondansetron (which is also available in an orally disintegrating tablet form). Alternatives include granisetron, which is available as a subcutaneous delivery patch. The patient response is variable, ranging from significant improvement to no relief; with higher doses, constipation can be a problem. Other nonspecific antinauseants such as promethazine or prochlorperazine should be recommended as rescue medications but many patients may have to use these on a daily basis. Vestibular antinauseants such as dimenhydrinate or scopolamine (in transdermal patch form) may be beneficial in the occasional patient. A more general approach to nausea has been in the form of neuromodulators (e.g., tricyclic antidepressants such as nortriptyline). Although most of them have prominent anticholinergic activity, these drugs generally do not affect motility when used in low doses (e.g., less than 50 mg nortriptyline). Anecdotal reports have suggested significant relief, however, a relatively large randomized controlled study showed no improvement in nausea. A more promising agent in this regard is mirtazapine, which is increasingly being used to treat nausea (it has potent 5HT3 receptor antagonism), improve appetite, and to a lesser extent modulate pain. Buspirone is an anxiolytic that is an agonist of the 5HT1A receptor, which may also be responsible for its ability to improve gastric accommodation. It can therefore be particularly useful in patients with prominent early satiety.

SURGICAL APPROACHES

Nutritional interventions are often delayed unnecessarily in patients who are unable to maintain weight. At the first visit, therefore, it is important to devote time to both a nutritional assessment and a plan to deliver adequate calories and other nutrients. In patients who are stable in weight, diet can also be used judiciously to minimize symptoms (see the previous sections). In patients on a trajectory that is leading to more than 10% weight loss, early intervention should be planned in the form of intestinal feeding tubes inserted either directly via surgical or radiologic jejunostomy or indirectly via a gastric port (gastrojejunostomy). Gastric ports are used by some patients to vent the stomach between meals; this may provide some symptomatic relief, although the utility of this approach has not been tested rigorously. In general, these feeds are well tolerated although in some patients with significant small bowel dysmotility there may be a limiting rate of infusion. If successful, jejunostomy tube placement can maintain nutrition without the substantial risks of line sepsis seen in long-term home total parenteral nutrition (TPN). These tubes may be uncomfortable and localized infection may occur.

Despite these measures, TPN may be required in some patients who have severe weight loss and intractable vomiting. This should be seen as a temporizing measure to provide gut rest for 2 to 3 months while replenishing nutritional needs and avoiding further exacerbation of symptoms. Longer term TPN is fraught with risk for infections and thromboembolism and has been associated with increased risk of death in these patients.

Gastric electrical stimulation is a technique in which electrodes are implanted onto the gastric antral serosa using open or laparoscopic techniques. The Enteria device is FDA approved under a Humanitarian Device Exemption for use in gastroparesis, which means that its efficacy is unproven. Randomized crossover trials have shown modest or no symptom benefit with the device when on versus off, although prospective open label trials have suggested benefit, particularly in diabetic patients. The putative mechanism of action is thought to be modulation of vagal signaling as in its current form the device does not improve gastric emptying. The role of this treatment in gastroparesis therefore remains unclear.

Other approaches have targeted the pyloric sphincter, based on the rationale that its dysfunction could result in gastric outlet obstruction. Although the prevalence and contribution of this pathophysiologic mechanism has never been established with any confidence, there have nevertheless been many therapies directed at it. Early studies of intrapyloric botulinum toxin injection showed symptom improvement in gastroparesis but were not confirmed in randomized controlled trials. Laparoscopic pyloroplasty and more recently, endoscopic pyloromyotomy (gastric per oral endoscopic myotomy) have been evaluated in treatment of drug refractory gastroparesis of surgical and nonsurgical origin. Retrospective studies suggest symptom and gastric emptying improvement up to 3 to 6 months of follow up, as have some prospective studies. However, lack of prospective randomized sham controlled data with validated outcomes, and short follow up would not support its general use at this time.

Near total or completion gastrectomy has been proposed as possible treatment for refractory patients. Retrospective data spanning 20 years from the Mayo Clinic on patients with prior partial gastrectomy and truncal vagotomy indicates that only one half of patients could sustain themselves with oral nutrition, and another study of patients with post Nissen gastroparesis showed no benefit in symptom control or nutritional status with near total gastrectomy.

RAPID GASTRIC EMPTYING (DUMPING SYNDROME)

Disorders of rapid gastric emptying (dumping syndrome) are characterized by fast passage of liquid or hyperosmolar chyme into the duodenum. Dumping has been most often seen after surgery and is increasingly recognized due to the popularity of bariatric procedures although it can also be seen after a variety of others such as classical vagotomy and pyloroplasty. Neuroendocrinologic and esophagectomy. Currently the most common cause of this syndrome are Roux-en-Y gastric bypass or sleeve gastrectomy, which are associated with nearly a 40% incidence of symptoms putatively ascribed to dumping as a result of impaired gastric storage and/or rapid and uncontrolled entry of nutrients into the small intestine. In some patients, these symptoms resolve over time, but may persist for years in a significant minority. Idiopathic dumping syndrome also probably exists but may not be suspected in the absence of a culpable surgical cause without performing more sophisticated tests.

Theories on the genesis of symptoms resulting from rapid gastric emptying are generally in keeping with our knowledge of the postprandial physiologic response. Hyperosmolar chyme or liquid rapidly enters the duodenum. This leads to rapid shifting of fluid into the lumen, and release of gut peptide hormones with vasoactive and gut motor effects. These are thought to mediate the symptoms of early dumping, which typically begin 30 minutes after ingestion. Symptoms are proportional to the osmolarity of the bolus. These symptoms include early satiety, nausea, abdominal pain, and vasomotor

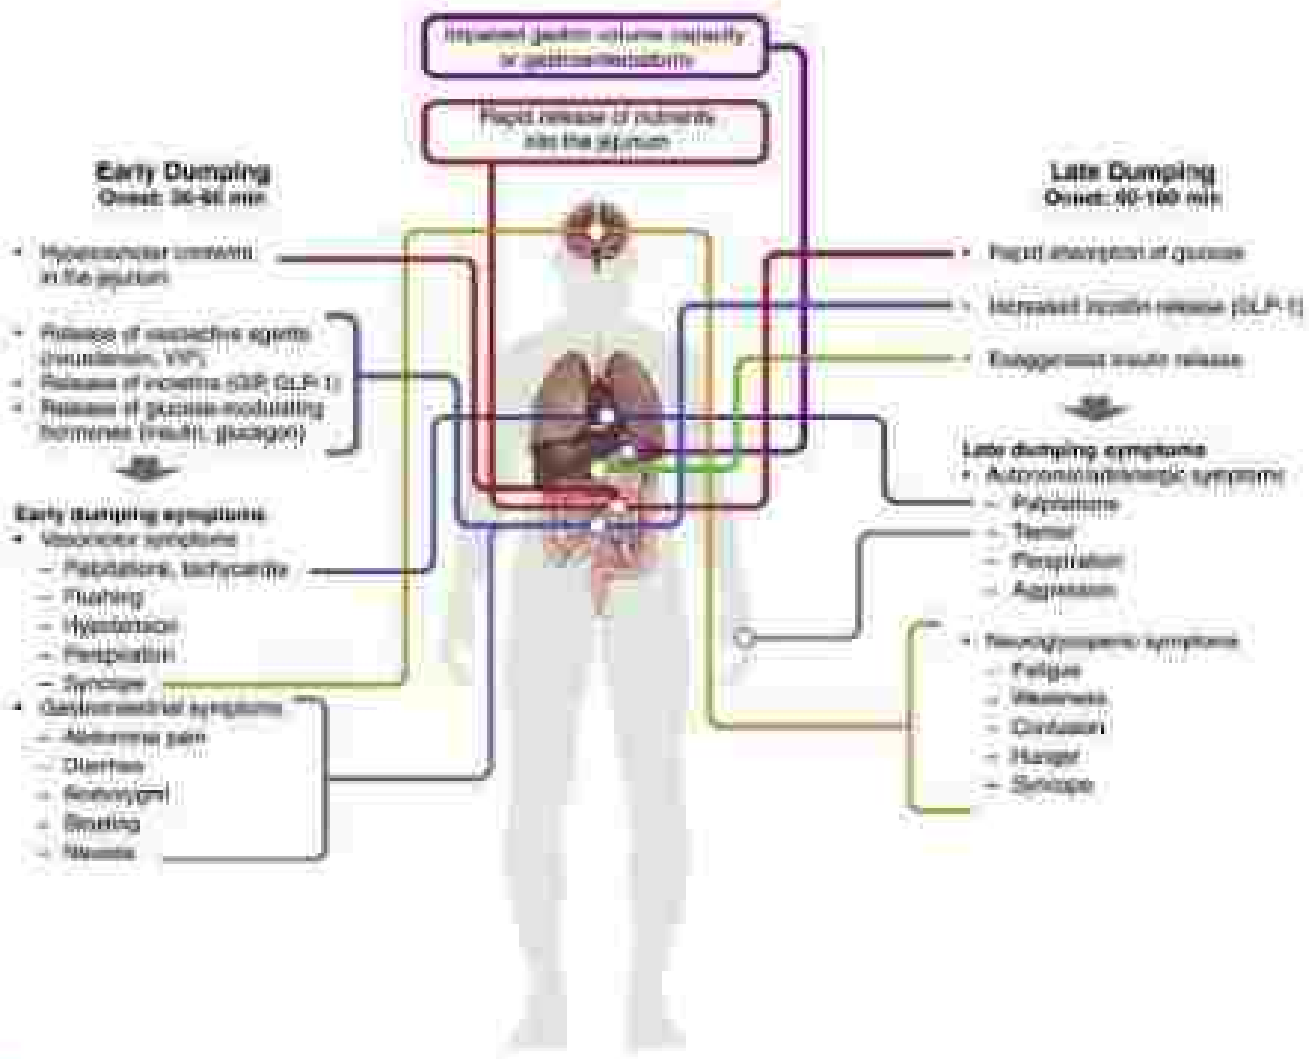

FIG. 2 Pathophysiology of dumping syndrome. *GIP*, gastric inhibitory polypeptide; *GLP-1*, glucagon-like peptide-1; *VIP*, vasoactive intestinal peptide. (From Kim M, Kim H, Kwon H, et al. Dumping syndrome after esophagogastric surgery: pathophysiology, diagnosis, and management. *Korean J Intern Med*. 2017;32(4):609–617.)

symptoms (tachycardia/palpitations, lightheadedness, diaphoresis, and tremor). Paradoxically, many of these symptoms can be seen in patients with gastroparesis, indicating their nonspecific nature. Symptoms may last for an hour and be incapacitating. Early dumping symptoms are often but are always accompanied by late symptoms as well, typically 2 hours or more after a meal. In about one-quarter of patients, late dumping manifests itself in isolation and can make the diagnosis more difficult to make. Late dumping is thought to be from hypoglycemia in response to the excessive rate of carbohydrate absorption leading in turn to exaggerated release of incretin peptides (GLP1 and GIP) and an "overswing" insulin response. This leads to hypoglycemia and associated autonomic responses. These concepts are illustrated in Fig. 2.

DIAGNOSIS

The diagnosis of dumping syndrome begins with maintaining a high index of suspicion in the right clinical setting, typically with a history of upper GI surgery. Various clinical scoring systems have been suggested as aids to this regard, but their utility in the clinical setting is not clear and lack rigorous validation. Simple measures such as asking the patient to monitor their blood sugar levels at the time of symptoms are complicated by the fact that finger stick capillary blood methods are not considered accurate in the hypoglycemic range. Nevertheless, if obtained, a plasma glucose level of less than 72 to 40 mg/dL is considered consistent with post-gastric bypass hypoglycemia. The role of continuous ambulatory glucose monitoring in this setting is unclear, even if it were practical.

For these reasons, a provocative test for hypoglycemia in a monitored setting is considered the gold standard, even though not endorsed by most endocrine societies because of problems with specificity. This is either a classical oral glucose tolerance test or a mixed meal test, done in a carefully monitored setting. A positive oral glucose tolerance test for early dumping in this setting consists of increase in hematocrit of more than 3% or increase in heart rate greater than 10 per minute after 30 minutes. Late dumping is diagnosed if hypoglycemia develops between 1 and 3 hours after ingestion.

Finally, others have advocated studying gastric emptying by scintigraphy, with 1 hour emptying of more than 60% of the meal indicating rapid emptying. If this criterion is met, it is supportive of the diagnosis in the right clinical context. On the other hand, many symptoms of early dumping occur within minutes of ingestion and standard nuclear medicine tests do not provide information during this time period, so a negative test does not necessarily rule out the diagnosis.

TREATMENT

The first step in treatment is diet modification. Simple sugars and dairy products are avoided, as are large carbohydrate loads. Complex carbohydrates, proteins, fat, and fiber are encouraged as they

will slow gut transit time. Water intake should be plentiful to avoid dehydration but should not be taken one half hour before or after meals. Patients have also been advised to not eat while upright, but an alternative is to be supine for 30 minutes after meals, which is thought to slow gastric emptying and increase venous return.

Next line therapy usually consists of over the counter measures to reduce gastric emptying. This can be achieved by substances such as guar gum, pectin, and glucomannan, several studies attest to the efficacy of these agents in this setting when administered at doses of at least 15 g with meals. Patients may not always tolerate these supplements because of gas and bloating or find them unpalatable. Further, the concomitant restriction on fluid intake with a meal may theoretically increase the risk of obstruction from these highly viscous compounds.

When these measures are not sufficient, drug therapy may be prescribed. Acarbose is an alpha glycosidase hydrolase inhibitor that impairs the breakdown of luminal carbohydrates, thus limiting the glucose surge that triggers late dumping syndrome. Although several studies suggest its utility in this setting, unabsorbed carbohydrate loads in the colon may exacerbate other symptoms such as flatulence and diarrhea. Pharmacologic therapy for early (and late, if present) dumping consists of somatostatin analogs such as octreotide (available in short- and long-acting forms), and the long-acting drugs lanreotide and pasireotide. These drugs work by slowing gastric emptying, inhibiting CCK-1 and other hormones and preventing postprandial vasodilation. Symptom control in up to 80% of patients has been demonstrated in controlled studies. If a trial of subcutaneous dosing 30 minutes before or after meals is successful, a longer acting depot preparation can be substituted with equivalent efficacy. Steatorrhea is the most significant side effect, although usually mild. Other side effects include an increased risk for gallstone formation, diarrhea, nausea, and local pain (at injection sites).

Other drugs that have been tried on an anecdotal basis or in small numbers include diazoxide or nifedipine (both of which are thought to act by decreasing calcium-activated insulin release from pancreatic beta cells). Continuous enteral feeding by a gastric or jejunal route has been used in some patients as an alternative to pharmacologic therapy with the rationale that avoiding fluctuations in glycemic levels after a steady state has been achieved will prevent the endocrine and autonomic reflexes that contribute to the pathogenesis of symptoms. Finally, refractory patients have been offered surgery usually in the form of reversal of the bypass or other interventions; in some cases, pancreatectomy has been performed when persistent beta cell hyperplasia or nesidioblastosis is suspected. Although uncontrolled reports suggest that this may be effective, given the drastic nature of the surgery, it should only be considered after a thorough diagnostic evaluation and exhaustive trial of other measures.

SMALL BOWEL MOTILITY DISORDERS

Small bowel motility disorders are not commonly seen but can be divided into reversible disorders such as adynamic ileus, and very progressive disorders such as familial chronic intestinal pseudo-obstruction and acquired scleroderma. Less common disorders such as bypass enteropathy after bariatric surgery, small bowel intussusception, and dysmotility in intestinal ataxia will not be discussed.

ADYNAMIC ILEUS

Adynamic ileus is actually a generalized gut motility disorder involving the entire GI tract including the small bowel. It is most commonly seen in the presence of a systemic inflammatory disorder (i.e., sepsis), retroperitoneal hematoma or other trauma, or after abdominal surgery (postoperative ileus [POI]). The pathophysiologic basis of intestinal dysfunction in POI is complex with many factors (intestinal inflammation, autonomic imbalance, perioperative opioid use, electrolyte and fluid imbalance, and perhaps activation of defensive intrinsic enteric nervous system programs). Further, the contribution of colonic, small intestinal and gastric dysfunction may vary in individual patients.

Patients with adynamic ileus will present with vomiting, abdominal distension, and obstipation, with physical examination findings of ringing bowel sounds. Abdominal radiographs will usually reveal distension of the small bowel and/or colon. Prevention of ileus in the postoperative setting is a major emphasis for patients undergoing abdominal or related surgery. The risk is higher for open rather than laparoscopic approaches and can be further attenuated by judicious intraoperative use of opioids, limiting intestinal trauma and using epidural rather than general anesthesia. Electrolyte and electrolyte homeostasis are important to maintain. Early feeding and ambulation are encouraged, and many programs suggest coffee and chewing gum as adjuncts to promote early recovery. Pain control with nonsteroidal anti-inflammatory drugs (and selective COX2 inhibitors such as celecoxib) may not only provide effective opioid sparing analgesia but may also improve motility probably by reducing neural inflammation. However, the use of classical nonselective anti-inflammatory drugs must be balanced against the risk for mucosal injury and kidney dysfunction in this setting. Systemic lidocaine infusions after surgery may also help prevent the development of POI while reducing pain. Alvimopan (a peripheral mu opioid receptor antagonist) has been shown to shorten recovery time after gut surgery and has been approved for the prevention of POI in patients who have been treated with narcotic analgesics; however, its use is heavily restricted because of the risk for cardiovascular ischemia. Methylnaltrexone, the other peripherally acting mu opioid receptor antagonist, has not been shown to be of benefit for POI.

If ileus has set in, treatment is usually conservative, with continuing attention to the factors just outlined. Although the use of routine nasogastric or nasoduodenal tubes is discouraged for prophylaxis, decompression with these tubes becomes important in established cases for relieving discomfort and vomiting. The role of pharmacological agents remains unclear. Although erythromycin may help improve gastric motility in patients in whom this is a predominant factor, metoclopramide is not considered helpful in this setting. Other prokinetics such as prucalopride have the potential to improve POI but have not been rigorously tested for this indication. Further, the lack of intravenous formulations may further limit their efficacy in these patients. Acetylcholinesterase inhibitors such as neostigmine or pyridostigmine may be tried in refractory cases, particularly if colonic ileus dominates. Gastroparesis control studies have also been reported to be helpful in some patients.

CHRONIC IDIOPATHIC INTESTINAL PSEUDO-OBSTRUCTION AND ASSOCIATED SMALL INTESTINAL BACTERIAL OVERGROWTH

This relatively rare disorder is often first suspected in a patient who has presented with recurrent small intestinal obstruction and typically undergone one or more exploratory surgeries with no mechanical etiology found. In some cases, there is a strong family or genetic history. Familial visceral myopathy is primarily a smooth muscle dysfunction in which gut contraction amplitude and coordination of contraction are reduced. Eventually it affects all gut and genitourinary smooth muscle but may start in the esophagus, duodenum, colon, or urinary tract. Familial visceral neuropathies are also described with both autonomic and enteric neural dysfunction contributing to abnormal gut contractility and transit. Other genetic causes include mitochondrial neurogastrointestinal encephalopathy disease, a multisystem disorder with prominent GI dysfunction and associated neurologic phenotype (ptosis/ophthalmoplegia, peripheral neuropathy, leukoencephalopathy) affects teens and young adults and is caused by a mutation in the gene encoding for thymidine phosphorylase. Non-hereditary causes of chronic idiopathic intestinal pseudoobstruction (CIIPO) include scleroderma, paraneoplastic syndromes (e.g., small cell lung cancer associated with circulating antibodies against the

neuronal (hu antigen). In some patients, no obvious cause is apparent and "neuromuscular dysmotility" is ascribed as a nonspecific descriptor. The lack of specialized centers for interpretation of subtle changes in the enteric nervous system/visceral muscle remains a problem in these cases, even if bowel segments are available for review.

Patients may present with symptoms in late childhood/teenage years with vague chronic GI symptoms, or in early adulthood after years of more specific intermittent symptoms including dysphagia, bloating, abdominal pain, or constipation. In severe, usually genetic cases, megaesophagus or megaduodenum may be seen on contrast studies. Abdominal radiographs can indicate significant dilation in the entire small bowel down to the colon, sometimes with gastric dilation as well. Computed tomography or magnetic resonance enterography may be useful radiologic techniques to document the extent and severity of the bowel dysfunction. While gut scintigraphy and wireless motility capsules are useful to measure small bowel transit, but the former is not generally available and the latter is contraindicated if there is suspicion of mechanical obstruction (risk of impassage of capsule). Antroduodenal manometry has been used to identify classic low amplitude contractions described in visceral myopathy as well as abnormalities of the migrating myoelectric complex thought to be from neuropathy, but these findings correlate poorly with histology. The most sensitive diagnostic method is diagnostic laparoscopy (rather than laparotomy) to rule out mechanical obstruction and to obtain full thickness small bowel biopsies, which should be examined by an expert GI pathologist to rule out visceral neuropathy. Often such expertise is not available on site and slides need to be sent to specialized centers. It is important to ask for an opinion on the presence of intramural inflammation (eosinophils, lymphocytes, and other immune cells) as these patients may respond to a trial of immunomodulator therapy.

Treatment is supportive. There are some data supporting the use of prokinetic agents, a placebo controlled randomized controlled trial indicates that pyridostigmine reduces symptoms and the need for rescue analgesics in adults with CIPO. These patients often have small intestinal bacterial overgrowth and empirical treatment with drugs such as rifaximin or other antibiotics may be useful. In some practices, lactulose based breath testing is recommended before initiation of these drugs, but the sensitivity and specificity of this test is poor and a negative result does not rule out small intestinal bacterial overgrowth. Because of the chronic nature of the disorder, patients with CIPO who respond to antibiotics may have to be treated multiple times per year. This can be either done based on symptom exacerbation or occasionally prophylactically (e.g., metronidazole for 2 to 3 weeks every month). Octreotide injections are often used in these patients because this drug can reduce small bowel contractions and may improve symptoms and the frequency of small intestinal bacterial overgrowth recurrence. This drug is expensive, however, and not always covered by medical insurance carriers. Pyridostigmine has also been used in CIPO in children and adults with reported benefit but may not be as effective as octreotide. Tunneling or gastrostomy can help decompress patients in later stages of the disorder, but fistulas form through these tubes must be replaced intermittently. Many patients with severe disease will eventually require chronic TPN support. The role of small bowel transplantation continues to evolve and there are few centers which offer this. Nevertheless, outcomes continue to improve and it is important to offer this as a potential option in this unfortunate group of patients.

Management of Intestinal Failure

Jason S. Hawkinworth, MD, and Thomas M. Fish ian, MD

The field of intestinal failure (IF) has witnessed transformative advancements since the advent of parenteral nutrition (PN) more than 40 years ago. Once a uniformly lethal condition, IF now has an excellent prognosis, with a 90% long term survival rate. In the last decade alone, medical and surgical advances, including implementation of multidisciplinary care teams, standardization and rejuvenation of intestinal lengthening procedures, improved central line care, utilization of novel glucagon like peptide 2 (GLP-2) analogs, and lipid sparing PN formulations have revolutionized the care of the patient with IF. For patients with IF and complications of PN, intestine transplant offers an excellent option, with continually improving outcomes. In this chapter, the etiology and epidemiology, medical and surgical management, and transplantation for IF are reviewed.

Definitions and Etiology

Intestinal Failure

The function of the intestine includes digestion and absorption of nutrients and the maintenance of a barrier against the external environment. IF is defined as a critical reduction of functional gut mass below the minimum amount necessary for adequate digestion and absorption to satisfy body nutrient and fluid requirements. A practical approach to define the degree of IF includes the amount of PN required for maintenance of nutritional status in adults and of growth in children. This also provides a way to track progress following any medical or surgical intervention in a patient with IF.

neuronal dysfunction). In some patients, no obvious cause is apparent and "neuromuscular dysmotility" is ascribed as a nonspecific descriptor. The lack of specialized centers for interpretation of subtle changes in the enteric nervous system/visceral muscle remains a problem in these cases, even if bowel segments are available for review.

Patients may present with symptoms in late childhood/teenage years with vague chronic GI symptoms, or in early adulthood after years of more specific intermittent symptoms including dysphagia, bloating, abdominal pain, or constipation. In severe, usually genetic cases, megaesophagus or megaduodenum may be seen on contrast studies. Abdominal radiographs can indicate significant dilation in the entire small bowel down to the colon, sometimes with gastric dilation as well. Computed tomography or magnetic resonance enterography may be useful radiologic techniques to document the extent and severity of the bowel dysfunction. While gut scintigraphy and wireless motility capsules are useful to measure small bowel transit, but the former is not generally available and the latter is contraindicated if there is suspicion of mechanical obstruction (risk of impaction of capsule). Antroduodenal manometry has been used to identify classic low amplitude contractions described in visceral myopathy as well as abnormalities of the migrating myoelectric complex thought to be from neuropathy, but these findings correlate poorly with histology. The most sensitive diagnostic method is diagnostic laparoscopy (rather than laparotomy) to rule out mechanical obstruction and to obtain full thickness small bowel biopsies, which should be examined by an expert GI pathologist to rule out visceral neuropathy. Often such expertise is not available on site and slides need to be sent to specialized centers. It is important to ask for an opinion on the presence of intramural inflammation (eosinophils, lymphocytes, and other immune cells) as these patients may respond to a trial of immunomodulator therapy.

Treatment is supportive. There are some data supporting the use of prokinetic agents; a placebo-controlled randomized controlled trial indicates that pyridostigmine reduces symptoms and the need for rescue analgesics in adults with CIPO. These patients often have small intestinal bacterial overgrowth and empirical treatment with drugs such as rifaximin or other antibiotics may be useful. In some practices, lactulose hand breath testing is recommended before initiation of these drugs, but the sensitivity and specificity of this test is poor and a negative result does not rule out small intestinal bacterial overgrowth. Because of the chronic nature of the disorder, patients with CIPO who respond to antibiotics may have to be treated multiple times per year. This can be either done based on symptom exacerbation or occasionally prophylactically (e.g., metronidazole for 2 to 3 weeks every month). Octreotide injections are often used in these patients because this drug can reduce small bowel contractions and may improve symptoms and the frequency of small intestinal bacterial overgrowth recurrence. This drug is expensive, however, and not always covered by medical insurance carriers. Pyridostigmine has also been used in CIPO in children and adults with reported benefit but may not be as effective as octreotide. Tpnmimicry or gastrostomy can help decompress patients in later stages of the disorder, but fistulas (through these tubes must be replaced intravenously. Many patients with severe disease will eventually require chronic TPN support. The role of small bowel transplantation continues to evolve and there are few centers which offer this. Nevertheless, outcomes continue to improve and it is important to offer this as a potential option in this unfortunate group of patients.

Management of Intestinal Failure

Jason S. Hawkesworth, MD, and Thomas M. Fishbein, MD

The field of intestinal failure (IF) has witnessed transformative advancements since the advent of parenteral nutrition (PN) more than 40 years ago. Once a uniformly lethal condition, IF now has an excellent prognosis, with a 90% long-term survival rate. In the last decade alone, medical and surgical advances, including implementation of multidisciplinary care teams, standardization and rationalization of intestinal lengthening procedures, improved central line care, utilization of novel glucagon-like peptide 2 (GLP-2) analogs, and lipid-sparing PN formulations have revolutionized the care of the patient with IF. For patients with IF and complications of PN, intestinal transplant offers an excellent option, with continually improving outcomes. In this chapter, the etiology and epidemiology, medical and surgical management, and transplantation for IF are reviewed.

■ DEFINITIONS AND ETIOLOGY

Intestinal Failure

The function of the intestine includes digestion and absorption of nutrients and the maintenance of a barrier against the external environment. IF is defined as a critical reduction of functional gut mass below the minimum amount necessary for adequate digestion and absorption to satisfy body nutrient and fluid requirements. A practical approach to define the degree of IF includes the amount of PN required for maintenance of nutritional status in adults and of growth in children. This also provides a way to track progress following any medical or surgical intervention in a patient with IF.

TABLE 1 Pediatric and Adult Intestinal Failure Etiologies

Adult	Pediatric
Mesenteric ischemia	Congenital short bowel
Crohn's disease	Congenital enteral disease
Radiation enteritis	Chronic intestinal pseudo-obstruction
Chronic intestinal pseudo-obstruction	Volvulus
Surgical complications	Necrotizing enterocolitis
Familial polyposis	Hirschsprung's disease
Cancer	Crohn's disease

Etiology

The etiology of IF can be anatomic or functional and varies by pediatric or adult demographics. The most common anatomical etiology of IF is short gut syndrome (SGS), which is generally characterized by a state of malabsorption following extensive loss of small intestine. The clinical consequences of SGS depend on the length and site of the resected small intestine, the state of the intestinal remnant, and the age of the patient. These factors influence the capacity of the remnant intestine to function as well as the potential for adaptation. Functional etiologies of IF involve conditions that impair the normal absorption of nutrition.

In children, the etiology of IF is commonly congenital and, whether related to SGS or functional disorders, often requires protracted or indefinite PN support. SGS is the cause of permanent IF in 50% of pediatric cases and is often secondary to congenital anomalies of the digestive tract, such as intestinal atresia and gastroschisis. In patients born with a normal gastrointestinal tract, the most frequent cause of SGS is necrotizing enterocolitis, especially in premature infants. Midgut volvulus from malrotation is another cause of SGS when it results in ischemia and necrosis with subsequent extensive intestinal resection.

Functional disorders of the intestine include neuromuscular motility disorders and a variety of enteropathic diseases. Hirschsprung's disease is a common cause of functional IF and is due to congenital intestinal aganglionosis. Hirschsprung's disease commonly affects the rectum and sigmoid, but when the aganglionosis involves a significant portion of the small intestine it can result in IF. Chronic intestinal pseudo-obstruction is a heterogeneous group of enteric nerve and muscle diseases characterized by intestinal obstruction in the absence of a lumen occluding lesion. Severe variants of chronic intestinal pseudo-obstruction often result in IF and require lifelong medical care. Congenital diseases of enterocyte development such as microvillus atrophy, autoimmune enteropathy, and intestinal epithelial dysplasia or "tufting enteropathy" cause IF.

In adults, SGS represents more than 80% of IF cases, and includes ischemia, Crohn's disease, desmoid tumors, Gardner's syndrome, and familial polyposis, trauma, volvulus, and rare causes such as radiation enteritis and postbariatric surgery. IF secondary to Crohn's disease is a unique entity because it may be related to extensive primary disease and/or multiple resections. Notably, the use of available immunosuppressive and biological antiinflammatory therapies as well as use of less invasive surgeries such as strictureplasty has reduced the incidence of IF in Crohn's disease. SGS related to mesenteric thrombosis is commonly associated with hypercoagulable states, which may have implications for anticoagulation management, particularly in the setting of intestinal transplant (Table 1).

INTESTINAL ADAPTATION

Small intestine that remains following a massive gut loss demonstrates enhanced absorptive function through numerous mechanisms collectively described as adaptation. Adaptation may be sufficient to permit restoration of nutritional autonomy even in cases in which the magnitude of intestine loss is extensive. In the absence of complete adaptation, patients remain committed to varying amounts of supplemental PN indefinitely. The probability of weaning patients off PN becomes less than 10% if weaning is not obtained during the first 4 years of PN in children and 2 years in adults.

The small intestine epithelium is perpetually proliferating and differentiating and is largely responsible for adaptation. The intestinal epithelium can morphologically and functionally adapt to the loss of functional surface area through crypt cell hyperplasia, villus lengthening, and increased absorptive function. Although adaptation has been demonstrated in numerous animal models, evidence for adaptation in humans includes improved fluid and electrolyte absorption over time following massive intestinal resection.

Several factors predict long-term PN, including a remnant jejunoileal length less than 50 to 100 cm in older children and adults and less than 20 to 40 cm in small children. Enterocolonic continuity and the ileocecal valve are also important determinants of successful adaptation. Site of resection is predictive of IF prognosis because jejunal resection is better tolerated than ileal resection; the ileum has an increased capacity to adapt and is also the site of bile acid and vitamin B12 absorption and synthesis of gastrointestinal hormones such as enteroglucagon. In the setting of SGS, the colon becomes important by absorbing sodium, water, some amino acids, and short-chain fatty acids.

CLINICAL ASSESSMENT

The clinical assessment of a patient with IF includes history and physical examination, imaging and endoscopy studies to determine the anatomy and length of intestine, assessment for liver dysfunction, and nutritional assessment. Critical components of the initial history include the etiology of IF, the anatomy and length of intestine, number of central lines and any central line complications including infections and thrombosis, and a detailed nutritional assessment. Physical examination should emphasize hydration and nutritional status, type and site of central line, and any signs of vascular thrombosis, chronic liver disease, or cardiovascular disease.

In some cases, it can be difficult to determine the anatomy and length of intestine. It is critical to review all prior surgical documentation, which should annotate the specific anatomic findings, including small and large intestine length and appearance. Intestinal length and quality should be verified by a combination of imaging with upper gastrointestinal series, barium enema, and upper and lower endoscopy. Endoscopy can also be used to obtain tissue biopsies and intestinal effluent sampling.

Nutritional assessment begins with patient weight, percentage of parenteral and enteral intake, and bowel function questions including diarrhea, nausea, vomiting, and bloating. A dietician evaluation is critical in this process. Physical examination should include accurate height and weight with calculation of body mass index. Signs of inadequate nutrition on PN include poor dentition, loss of subcutaneous fat, and temporal muscle wasting. Laboratory evaluation includes serum electrolytes, albumin level, prothrombin time, vitamin B12, and fat-soluble vitamins.

Evaluation of the small bowel absorptive capacity can be performed with functional assays such as the D-Xylose test. Citrulline has been identified as a biological marker of good functional mass and can be correlated to remnant small bowel length and absorptive capacity. Citrulline is a nonessential amino acid that is primarily produced by enterocytes and is not incorporated into peptides or proteins. A postabsorptive plasma level of citrulline lower than 20 μmol/L is associated with permanent IF when measured beyond a 2-year period of adaptation following extensive small bowel resection.

MEDICAL MANAGEMENT

Enteral Nutrition

Despite the loss of significant intestinal length or function, it is possible to maintain nutrition by enteral route in patients with IF. Enteral

TABLE 2 Parenteral Nutrition–Related Organ Dysfunction

Organ System	Complications
Liver	Steatosis, cholestasis, fibrosis, cirrhosis, portal hypertension
Gallbladder	Sludge, cholelithiasis, acalculous disease
Kidney	Chronic dehydration, renal insufficiency, hypernatremia, nephrolithiasis
Intestine	Bacterial overgrowth, increased permeability, bacterial translocation
Bone	Osteomalacia, osteopenia, osteoporosis
Immune	Immunosuppression
Neurologic	Memory disturbance

nutrition (EN) is vital for normal intestinal growth and function and adaptation is optimized with the provision of EN. EN promotes adaptation through intestinal epithelial contact with nutrients, promotion of mucosal hyperplasia, pancreaticobiliary secretion, and trophic hormone stimulation. Observational studies have correlated early EN with PN weaning in pediatric patients. The recommended formulations of EN vary depending on the length and site of remaining intestine.

Parenteral Nutrition

PN is the cornerstone of medical management of IF. Parenteral solutions have improved with increased understanding of energy, fluid, and micronutrient requirements. Careful prescribing and monitoring of PN patients can reduce complications. Although PN is an effective therapy, it is associated with significant morbidity. PN complications include central venous catheter–related, metabolic, and organ dysfunction.

Central venous complications include infection, occlusion, mechanical problems, and central vein thrombosis. Up to 15% of patients will experience a central venous catheter complication and PN is a risk factor. Improvements in catheter design and aseptic placement techniques have reduced septic complications.

Metabolic complications include derangements in hydration, electrolytes, and macro- and micronutrients. Fluid and electrolyte disturbances may be exacerbated in the setting of a high output ileal, jejunostomy, enterocutaneous fistula, or a patient with compensatory hyperphagia. An acute setting initiation of PN in a severely malnourished patient may result in rapid, intracellular shifts of magnesium, potassium, and phosphate leading to severe hypophosphatemia and hypokalemia, known as *refeeding syndrome*. Commercially available lipid, multivitamin, and trace element preparations provide the 35 essential nutrients (electrolytes, minerals, vitamins, and trace elements) and have reduced the potential for micronutrient deficiencies.

PN can result in the dysfunction of a variety of organs (Table 2). Liver disease represents one of the most important and lethal PN complications and is known as intestine failure–associated liver disease (IFALD). The pathophysiology of IFALD is poorly understood but appears to be multifactorial and related to a systemic inflammatory response associated with an influx of cytokines and bacterial toxins to the liver, inducing inflammation and collagen synthesis. Progression of IFALD to chronic and advanced disease, including fibrosis, cirrhosis, portal hypertension, and ultimately hepatocellular failure, occurs more commonly in young children than adults. The only proven treatment for IFALD is PN reduction with increased enteral feeding that is made possible by adaptation of the remnant bowel or by intestine replacement with a transplant.

Small Intestine Bacterial Overgrowth

Healthy enteric flora is critical to the normal function of the intestinal mucosal barrier and immunity. Anatomic and functional abnormalities intrinsic to patients with IF can predispose to small intestine bacterial overgrowth (SIBO). SIBO increases the risk of intestinal bacterial translocation, compromises the absorptive capacity in IF and may prevent PN weaning, and can exacerbate the hepatotoxicity related to PN. Treatment of SIBO includes reversing any predisposing anatomic conditions, and pharmacologic promotility treatment of functional disorders. Cyclical antibiotic therapy can be used but may increase the risk of multidrug resistant bacteria.

Recent Medical Advances in IF

Recent medical advances, including implementation of multidisciplinary care teams, utilization of novel GLP-2 analogs, and lipid-sparing PN formulations have transformed care of the patient with IF. Recent single-center reports have all confirmed a decrease in mortality with IF survival rates as high as 90% in some series. Successful liver sparing PN practices combined with the adoption of comprehensive, multidisciplinary approaches to IF management may be decreasing the incidence of end-stage liver disease in IF. These data represent a cumulative effect of multiple improvements in the management of IF and is a paradigm shift in the field.

Multidisciplinary coordination and individualization of care for the IF patient has been shown to decrease mortality from IFALD and sepsis, as well as improve enteral autonomy and even transplant outcomes. The comprehensive team should include a physician leader with expertise in gastrointestinal disease, a surgeon with gastrointestinal and transplant expertise, nurse coordinator, nutritionist, and social worker to optimize the patient outcome.

One of the most important recent advancements in the management of IFALD is the development of liver sparing lipid emulsions. Specifically, increasing evidence supports the substitution of soy oil–based intravenous lipid emulsion high in omega-6 polyunsaturated fatty acids with preparations derived from fish oil rich in omega-3 fatty acids. The underlying mechanisms of omega-6 fatty acid–induced liver injury are related to oxidative stress and inflammatory mediators and is an area of intense investigation. Multiple studies using various formulations of fish oil lipid emulsions have consistently demonstrated resolution of cholestasis in patients with IFALD.

GLP-2 is an amino acid intestinotrophic factor that has been shown to increase crypt villous length and epithelia proliferation in animal studies. Recent clinical trials have demonstrated improvements in intestinal absorption and nutritional status following treatment with GLP-2 analogs, thus is an extremely promising area of medical advancement in the treatment of IF.

SURGICAL MANAGEMENT

The role of surgical management in IF is to optimize use of the gastrointestinal tract. Because EN has been demonstrated to enhance intestinal adaptation, surgical interventions to facilitate EN are paramount to the successful management of IF. In PN dependent patients, surgical recruitment of any bypassed or unused remnant intestine can be performed by closing enterocutaneous fistulas or surgical enterotomy.

Some patients develop bowel dilation and dysmotility during the adaptation process, which can lead to decreased absorptive capacity and risk of bacterial overgrowth. In these cases, surgical lengthening and tailoring procedures can taper the dilated intestine and increase the total small intestinal length.

Bianchi was the first to describe an intestinal lengthening procedure by creating a tunnel in the vascular plane between the mesenteric vessels and then longitudinally stapling the intestine. The Bianchi lengthening procedure was demonstrated to be superior over

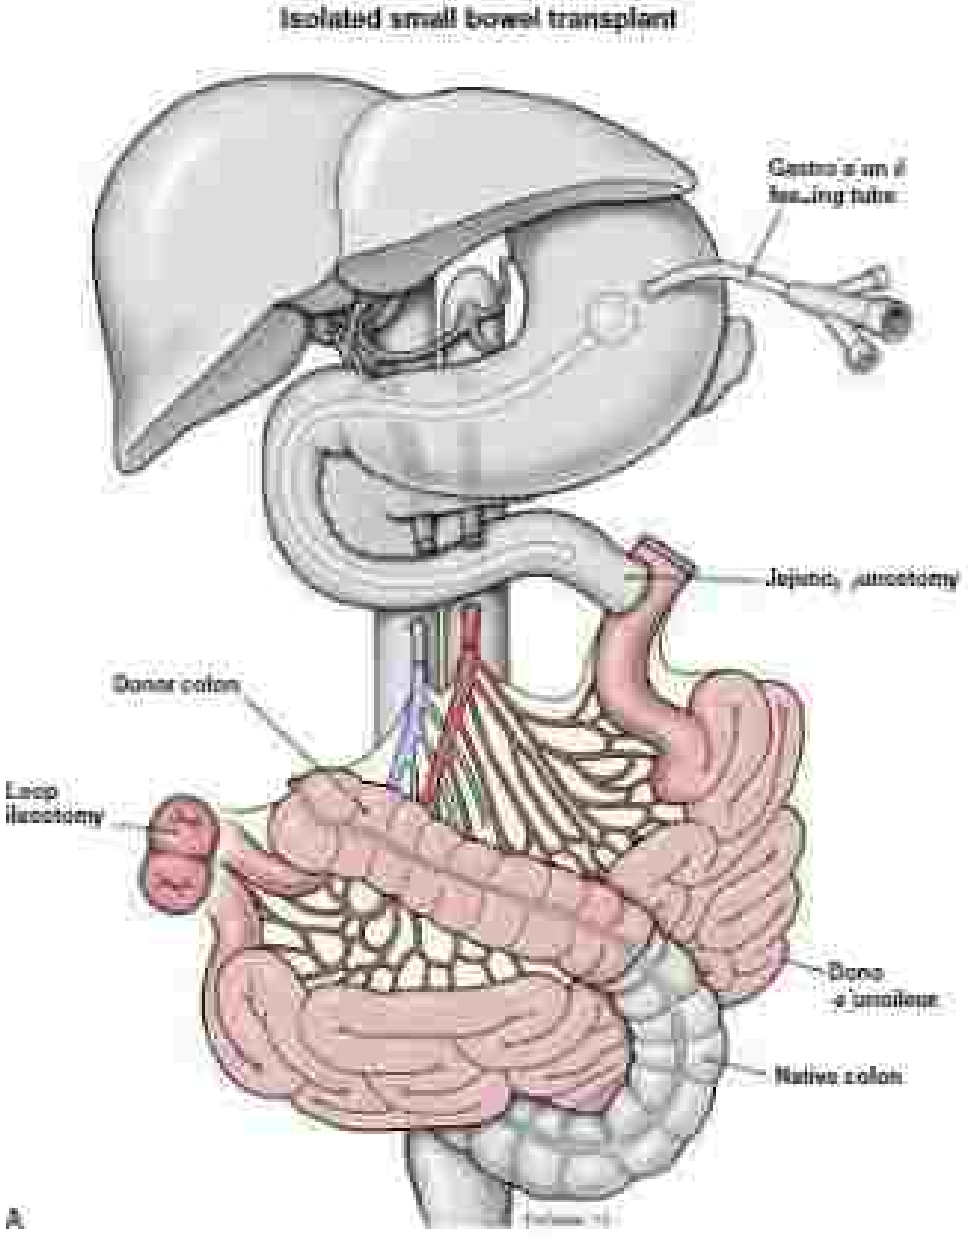

FIG. 1 Visceral transplantation for IFALD graft variations with graft to native ileum in gray (A) Isolated intestine graft (jejuno-ileum with native colon) variation.

simple adaptation in an experimental model. Clinical experience, mostly in children, demonstrated clinical improvement in the majority of patients, with 84% of survivors achieving independence from PN. The complexity of this procedure and associated complications has prevented its widespread application.

The predominant lengthening surgery currently is the serial transverse enteroplasty (STEP) procedure. STEP lengthening is performed by firing linear staplers alternately from the mesenteric and antimesenteric edge of the dilated small intestine. The clinical experience with the STEP procedure is growing and current data suggest that weaning from total PN is achieved in at least 50% of patients. The STEP procedure appears to be safer than the Bianchi lengthening procedure, with fewer reported complications.

Patient selection is critical to ensuring a successful surgical intervention in the setting of IF. Particular attention must be made to the patient's liver function because cirrhosis may be a contraindication and has considered for transplantation.

INTESTINE TRANSPLANTATION

As intestinal transplantation continues to improve, this therapy offers the hope of enteral independence and improved survival for patients with advanced IF. When patients with IF experience complications on PN that threaten survival, intestine transplantation is indicated. These complications include recurrent life-threatening central line associated sepsis, extensive central vein thrombosis that precludes confident preservation of PN catheter access, progressive IFALD, and repeated episodes of severe dehydration and associated electrolyte disorders that are refractory to standard management.

The term intestinal transplant comprises not only isolated intestinal transplant, but also combined liver-intestinal and multivisceral transplants (Fig. 1). The defining component of these variations is the small intestine (i.e., jejunum-ileum). When only the jejunum and ileum are transplanted, this is conventionally known as an isolated

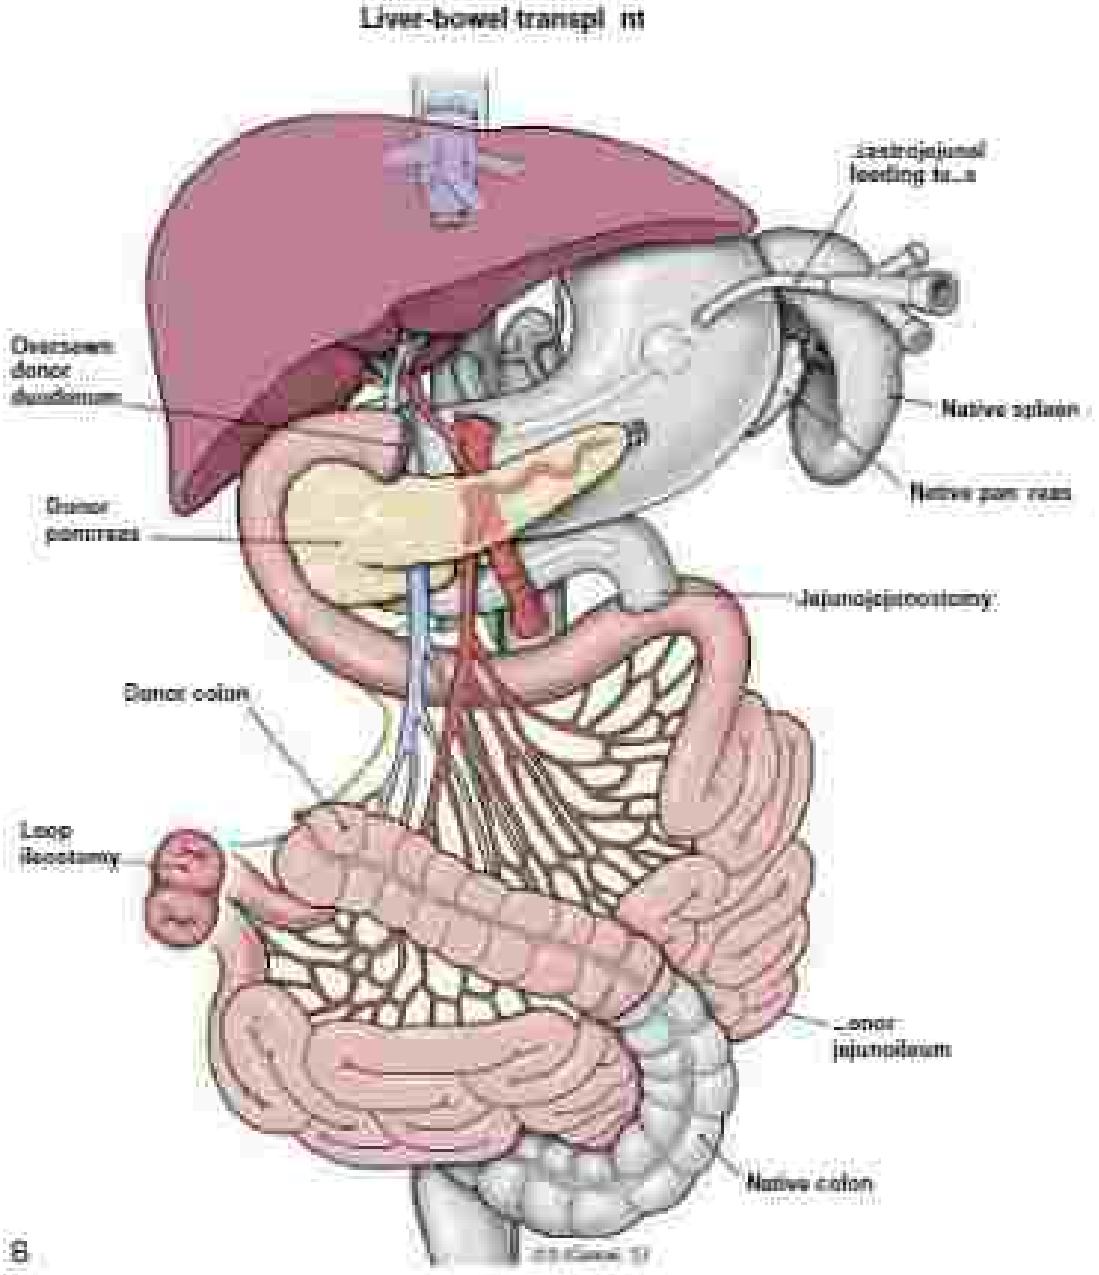

FIG. I, cont'd (B) Composite liver-intestine graft (en bloc liver, duodenum, pancreas, jejunum with colon) with native hepatic preservation, including native pancreaticoduodenectomy.

intestinal transplant. In the setting of advanced liver disease, combined liver and intestine are generally transplanted en bloc with the pancreas. The native hepatic is preserved in children whenever possible, and venous drainage with a portocaval shunt is required. Multivisceral transplantation that incorporates the stomach and entire duodenum may be appropriate in patients with extensive foregut tumor, trauma, and pseudo-obstruction. A segment of colon including ileocecal valve may be included with any of these variants, particularly in patients with little or no native colon remaining after resection or in patients with Hirschsprung's disease. The type of operation selected for an individual patient thus depends on the etiology of IF, state of existing abdominal and vascular anatomy, and severity of IFALD.

Short-term outcomes after intestinal transplant are excellent because of progressive surgical advances, improved detection and control of acute cellular rejection, and a decrease in lethal infections. According to the International Intestinal Transplant Registry, favorable prognostic variables include patients who have been admitted directly from home to undergo transplantation, younger patients, a first transplant, and those who receive antibody induction therapy or maintenance steroids. In contrast, long-term survival rates after intestine transplant remain modest, equaling only about 50% after 5 years for all types of intestinal transplants. For recipients of a liver-inclusive graft, graft survival beyond the first post-transplant year closely exceeds that of the isolated intestinal transplant because of relative immunologic tolerance provided by the liver. Immunologic risk factors for graft loss include not only transplantation without liver, but also defective innate immunity in the recipient because of nucleotide binding oligomerization domain containing protein 2 mutations similar to those in patients with severe forms of Crohn's disease. Recently, the role of donor specific antibody (DSA) has emerged as an important risk factor for rejection and malabsorption

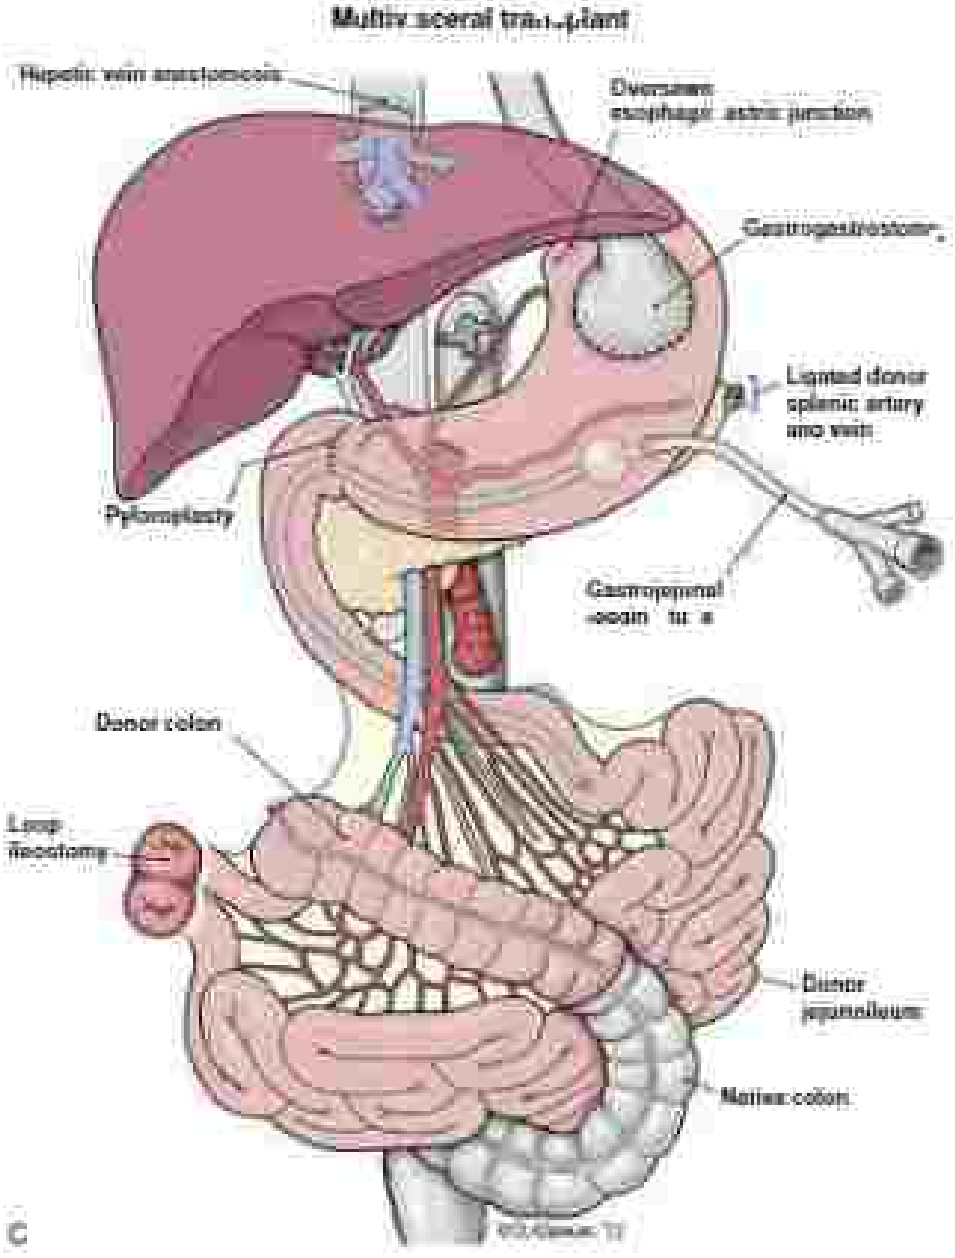

FIG. 1, (cont'd) (C) Multivisceral graft (stomach, duodenum, pancreas, jejuno-ileum with colon). (From Hoekstra H, Monkhorst TS, Fidelman Kempen-Voogd N, et al. Intestinal function as monitor in concert with other organs. In: Stein AP, Wiesner L, eds. Solid Organ Transplantation in Infants and Children. Springer; 2011.)

of preformed DSA with a virtual cross-match strategy with long-term management of de novo DSA may improve outcomes following intestine transplantation, particularly in the sensitized liver exclusive recipient.

CONCLUSIONS

IF is a rare, although devastating, condition that has profound implications for the quality of life and mortality for those affected. However, in the modern era, no patient with massive intestinal loss should be approached with the historically fatalistic approach. Cumulative improvements in the medical and surgical management of IF have resulted in long-term survival in more than 90% of patients. As transplant outcomes continue to improve, intestine transplantation may become the definitive treatment option for the IF patient.

Management of Enterocutaneous Fistulas

Josef E. Fischer, MD

Gastrointestinal cutaneous fistulas are among the most catastrophic outcomes of gastrointestinal surgery. Complications of gastrointestinal surgery include anastomotic leaks, abscesses after drainage, leaving residual purulence, and abscesses after operation.

Although I do not have much data on the point to follow, I believe that the training of gastrointestinal surgeons has become less rigorous, less indispensable, and associated with fewer difficult cases. With the emphasis on work hours, there are fewer cases with less independence and greater faculty supervision. The emphasis on laparoscopy may result in a greater leak rate than following open cases by the comparatively inexperienced surgeon. As new gastrointestinal surgeons sign contracts, they often have comparatively rigid and attractive work hours, which should not be denigrated because these hours allow the surgeons more time to spend with their families. There is more emphasis on overnight and having a senior surgeon in the operating room, especially in difficult cases.

In a complicated situation such as a patient with a gastrointestinal cutaneous fistula, it is probably easier to divide the history into current periods and the attempts to have the patient recover. The phases of treatment outlined in Box 1 are somewhat different and more detailed than the five steps that I have written about in the past (stabilization, investigation, decision, definitive therapy, and healing). To a certain extent, this updated schedule is the result of good and bad experiences. What I have learned is that there is little room for error. Meticulous care and meticulous operation will result in lower mortality. A review of the past 50 gastrointestinal cutaneous fistulas I have performed shows that there has been no patient mortality. I believe that this is largely the result of waiting 5–6 months after the discovery of the fistula for reoperation. At this point, the adhesions have softened and are often filmy, resulting in fewer enterotomies and an easier operation.

STABILIZATION AND RECOGNITION

The most important aspect of initial treatment for the patient suspected of a gastrointestinal cutaneous fistula is the restoration of blood volume. In the past 20 years, there has been some movement away from colloid and blood; however, in the case of the gastrointestinal cutaneous fistula, crystalloid alone is inadequate. Albumin, occasionally plasma, or occasionally fresh frozen plasma for clotting factors, and blood, especially fresh whole blood when the surgeon suspects that the patient has a clotting abnormality, are the best option. I am aware that the blood banks typically dispense the oldest blood to the patient. Although small numbers of blood banks say that old blood is just as good to administer as fresh blood, there is evidence to the contrary, especially in patients who are critically ill. The surgeon in charge should insist on the freshest blood available and, when necessary, components such as platelets, fresh frozen plasma, and other components of blood, which will be essential.

DRAINAGE OF OBVIOUS ABSCESSES

Unfortunately, patients discovered to have a gastrointestinal cutaneous fistula often have an accompanying abscess. This often is associated with a high fever. The fever is associated with catabolism and an increase in the loss of protein. If the abscess is recognized, it should be delineated as best as possible. This can be done with various radiologic procedures. If the patient is sick and cannot be separated, it is essential to take the patient to the operating room. Drainage of an abscess is not something to be undertaken lightly or at the end of the schedule. If one is in a small facility, the patient must be transferred to an appropriate tertiary facility. The surgeon should have ample help, including another surgeon of known skill and, if possible, experience with drainage of abscesses. Whenever possible, the surgeon should convince the operating room staff that this procedure must be scheduled in the morning so that an ample number of surgeons is available to assist if necessary.

INVESTIGATION AND DEFINITION OF THE ANATOMIC SITUATION

The definition of the anatomic situation is not an emergency. It is much more important to get the patient's fluid situation and his or her infection under control and stabilize nutrition so that anabolism proceeds. If not, catabolism will proceed. These patients can lose up to 500 g of protein daily, so it is absolutely essential that peritonitis be drained and the patient's temperature return to normal so that catabolism decreases. A computed tomography scan may not be necessary, unless an abscess is suspected, and drainage is urgent. If there is an obvious abscess, this should be drained with a catheter if possible. If the surgeon cannot drain it, once the patient is stabilized, drainage should proceed in the operating room with adequate help, adequate culture, crystalloid, and blood, and the sepsis is eradicated as best as possible.

NUTRITIONAL ASSESSMENT AND BEGINNING NUTRITIONAL REPLENISHMENT

Nutritional support cannot be delayed because patients lose protein daily. It is highly unlikely that the patient can begin enteral nutrition quickly when major nutritional support is required. Thus, one starts the patient with total parenteral nutrition. An experienced surgeon should place a subclavian line under good conditions with adequate help and under strict aspsis. Nutritional support should begin immediately and the blood sugar should be checked so that life-threatening hyperglycemia does not occur. After the anatomic situation is stabilized and abscesses are drained so that sepsis is eliminated, decision making can begin. Supplying the patient with enteral nutrition as meeting the entire needs of the patient may not be possible, but there is reasonable evidence that the combination of enteral and parenteral nutrition may result in better anabolism. In some patients, enteral nutrition may not be possible.

SPONTANEOUS CLOSURE

Spontaneous closure occurs in approximately 30% to 35% of patients. In a few patients with specific types of fistulas, the percentage may be higher. The anatomy will usually predict which fistulas will close. Sepsis prevents closure. The fistula may open and close depending on the anatomy, sepsis, and cleaning up the abdominal wall. A cleaner, healthier abdominal wall around the fistula may aid spontaneous closure.

Aids to Closure

Keep the edges of the fistula clean, especially from gastrointestinal contents. Stenge (Fig. 1) may help in using a soft latex tube, usually of urologic design and various sizes. An extra hole with a No. 14 whistle tip catheter in gentle suction within a 22 or 24 yellow latex stump will help aspirate gastrointestinal contents from around the

BOX 1 Phases of Care of Patients With Gastrointestinal Fistulas

I. Resuscitation: first 24 hours
  A. Stabilization
    1. Restoration of blood volume
      a. Minimize crystalloid
      b. Albumin
        Plasma: especially fresh frozen, for clotting factors
      c. Fresh blood: avoid the "old blood"
        A practice of many blood banks
      d. Platelets when necessary
II. Recognition and drainage of obvious abscesses 24–48 hours
  A. High fever
  B. An accelerated rate of catabolism: up to 500 g of protein daily
  C. Radiologic investigation
    1. The most experienced surgeon and collaborating radiologist
    2. Transfer when necessary to a tertiary facility
    3. Drainage in the operating room: cases should be done in the morning with adequate assistance
    4. When possible use a soft latex catheter (see Fig. 1)
III. Nutritional assessment and beginning nutritional supply: resuscitation 24–48 hours
  A. Minimize delays
    1. Patients may lose 500 g of protein daily
    2. Enteral nutrition cannot make up all needs quickly
  B. Start parenteral nutrition
    1. A central line should be placed by an experienced surgeon
  C. Repeated measuring of blood sugar to avoid significant hyperglycemia
  D. After stabilization
    1. A combination of central and parenteral nutrition is probably best 48–72 hours
  E. How much nutrition
    1. 80–120 g of protein daily @ 5% hours
    2. Calories: 2200–3600 (depending on fever, sepsis)
    3. 30% fat
    4. Adequate
      a. Trace metals
      b. Vitamins
      c. Essential fatty acids
IV. Spontaneous closure up to 28 days
  A. Occurs in 30%–35% of patients
    1. The anatomy usually predicts which fistulas will close
    2. Sepsis prevents closure
    3. Some fistulas may open and close
    4. Healthier nonseptic abdominal wall more likely to close
  B. Aids to closure
    1. Keep edges protected and clean
    2. Sumps with gentle suction
      a. Keep moist and pat away from edges
V. Operation
  A. If no closure has occurred by 28 days, operation
    1. 60 days for infected hernia
    2. 120–150 days for clean hernia
  B. The incision
    1. The incision must be closed: if not, fistula will reopen
    2. Go to areas that are easier
    3. The operation should begin early
    4. Keep skin edges clean with antiseptic soaked blue towels or plastic drapes
VI. Lysis of adhesions
  A. Scissor dissection is safer
  B. Free everything up before attacking the fistula
  C. You will probably have to resect 18 inches of small bowel in removing the fistula
VII. The anastomosis
  A. Two layers of interrupted permanent suture
VIII. Postoperative care 150–270 days
  A. Do not be in a rush to feed the patient
  B. When feeding, maintain calories and protein until bowel function is normal
  C. Make certain calorie and protein intakes are adequate before stopping total parenteral nutrition
IX. Maintain nutrition and start rehabilitation 6 months
  A. Patients have lost protein, muscle, and neurologic function
  B. Patients may take up to 1.5 years before regaining total neural function
  C. Warn patients, tell them the length of time it will take
  D. Tell patients not to quit their jobs

fistula. The protection may be with powders such as karaya powder or more recently with some of the better plastic material, which is adherent to the edge of the fistula and protects the skin (Fig. 2).

Suction is broken by urologic type soft sumps, keeping the irritating material away from the edges of the sump (see Fig. 2). Notice that the area is large and sumps themselves may be multiple, making certain that bowel or other noxious material does not irritate the skin and prevent healing.

OPERATION

Operation will be required in between 50% and 65% of patients. This should only be attempted after an adequate trial of soft sumps, antibiotics, nutrition, and keeping the patient's abdomen clean. My rule is to allow the patient to be treated with sumps and wound protection that keeps the wound clean for 60 days without sepsis. When the absence of sepsis, suction, and other protection of the wound have been successful for 60 days and show no sign of closing, the surgeon prepares for operating.

The incision is an extremely important part of the operative procedure (Fig. 3). If you cannot close the incision after a resection, it is likely that an open-ended closure of the fistula will fail. The incision should be made in a clean area so that it is likely to allow the lysis of adhesions away from the fistula and, if possible, to avoid making further enterotomies. The surgeon should start in clean soft abdomen. My practice is to allow 5.5 to 6 months to elapse so that the adhesions within the abdomen become firm, and entering the abdomen and freeing up the bowel avoids enterotomies. The surgeon must start far away from the fistula and must not force the lysis of adhesions. If you are not making progress in one area, put some soft laparotomy packs soaked in antibiotic solution (Kantrex is my favorite) and go elsewhere. Start early in the morning and do not put any other procedures on the operative schedule. The worst thing you can do is hurry the procedure because you undoubtedly will make unintended enterotomies. These procedures will take between 6 and 8 hours, so be prepared, you may want some nourishment and hydration in the middle of the case.

After you have made the incision and sterilized the skin and the fascia and have some freedom, my practice is to take blue towels, soaking the edges in Kantrex and sew them in place; that way, you will not contaminate the edges with stool or septic material, and the case will remain clean until you get to the fistula (Fig. 4).

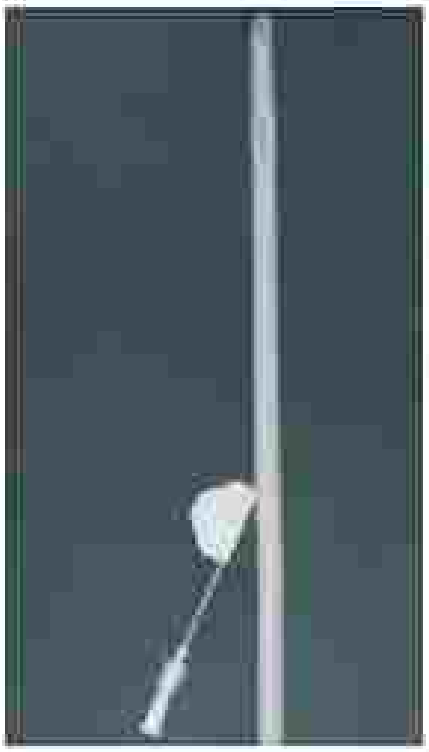

FIG. 1 Sump system for management of fistulae. (From Hocker JR, et al. In: Yeo CJ, ed. Yeo's Atlas of Surgical Anatomy. Philadelphia: Elsevier, Mosby, 2017.)

LYSIS OF ADHESIONS

You should go from where the incision was made to freeing up everything else. Achieve dissection is safer. Once everything else is free, you must attack the fistula. It is usually not possible to free up the skin around the fistula and mobilize the fistula without enterotomies. As much as 10 inches of small bowel, which is dissected in and around the fistula, will likely be sacrificed. If you begin making enterotomies, take a break and sit down; you will have to resect shorter lengths of bowel with enterotomies and will have less chance of short bowel syndrome (Figs. 5 and 6).

The anastomosis should be a two layer interrupted anastomosis carried out with permanent suture. Do not use an absorbable suture. Do not test the anastomosis for a period by giving oral intake. If you give oral intake too early, the anastomosis may disrupt and there may be a leak.

POSTOPERATIVE CARE

The patient should be ambulated, and the wound should be managed with healthy dressings.

Do not be in a rush to feed the patient, especially solid food. You may continue with enteral nutritional support but certainly do not let total parenteral nutrition decrease to a point at which the patient is not getting adequate protein and calories. Wait until the patient is having regulated bowel movements (preferably soft).

If the area in which you will be working and the anastomosis had infected contents, do not rush to stop the antibiotics.

If the area in which you were working had drainage, maintain the suction until the drainage dries for a time.

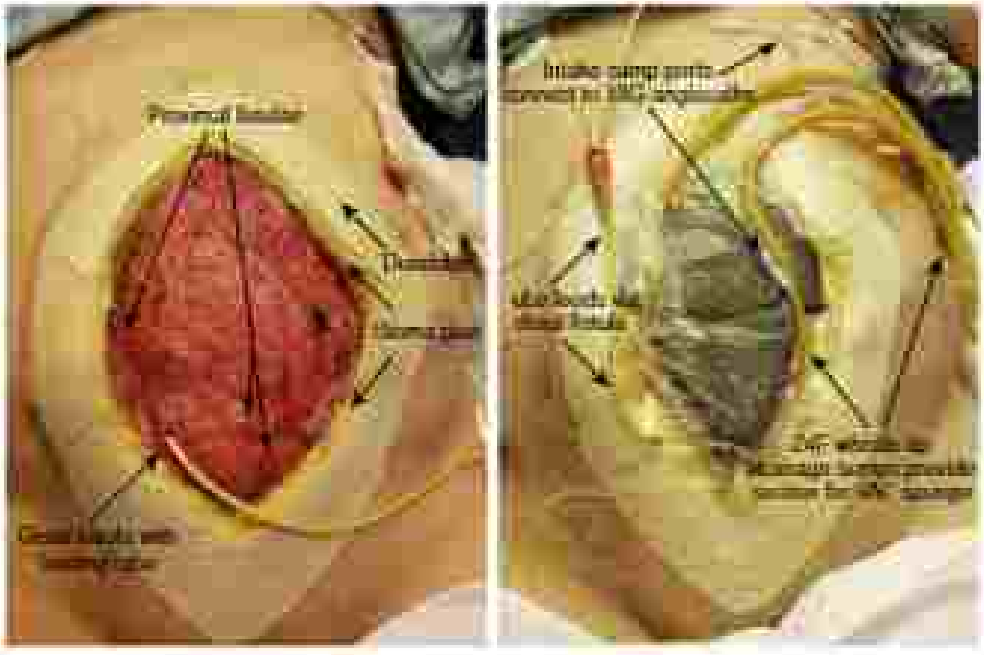

FIG. 2 Vacuum-assisted closure dressing in situ. (From Hocker JR, et al. In: Yeo CJ, ed. Yeo's Atlas of Surgical Anatomy. Philadelphia: Elsevier, Mosby, 2017.)

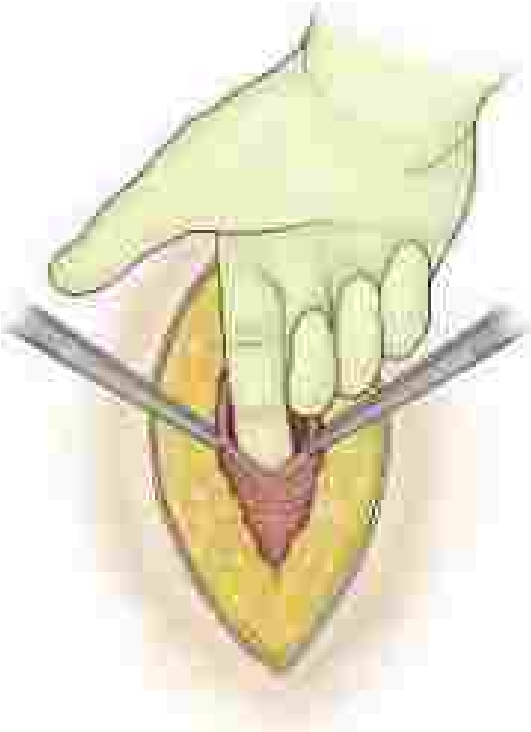

FIG. 3 Once the surgeon has made the skin incision and clears the subcutaneous tissue from the fascia, he or she lifts the fascia with a pair of Allis clamps so that one can see and then uses either a finger to separate the bowel from the underside of the fascia, without making an enterotomy. (From Mulholland MW, Lillemoe KD, Doherty GM, et al, eds. Greenfield's Surgery: Scientific Principles & Practice. Philadelphia: Lippincott Williams & Wilkins; 2017.)

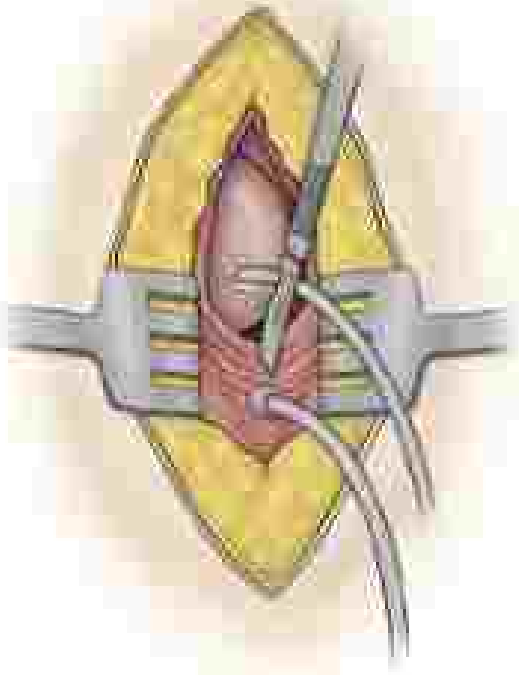

FIG. 5 Further dissection of the abdomen: the bowel and fistula are cleared down to the bottom of the wound. The fistula can be excised without fear of enterotomy. The goal is to resect the area with the fistula and the only adherent area is rarely larger than 12 inches of bowel. Entero-enteric anastomoses are made only to 12 inches of bowel or less. (From Mulholland MW, Lillemoe KD, Doherty GM, et al, eds. Greenfield's Surgery: Scientific Principles & Practice. Philadelphia: Lippincott Williams & Wilkins; 2017.)

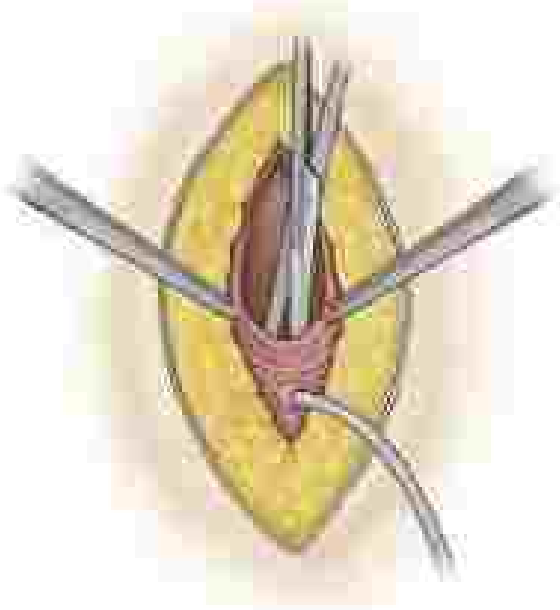

FIG. 4 Both the skin incision and the fascia incision are lengthened carefully as the undersides of the fascia is separated from the bowel and one can see clearly. The fascia may be divided with Metzenbaum scissors or a No. 15 blade scalpel.

MAINTAIN NUTRITION AND START REHABILITATION

Remember that most of these patients have lost body mass. Allow nutrition to proceed before putting them through a vigorous aspect of rehabilitation. Make certain that bowel movements are regular and above all do not use a cathartic in the presence of a fistula anastomosis.

Allow 4 to 6 months of rehabilitation before patients should think about returning to work. They have lost much protein, they will have also lost some of their neurologic function, and they will complain that they cannot think clearly. Resumption of function is important but if done too early, the patient will get depressed.

RESUMPTION OF FUNCTION

Most of these patients have lost body mass and neurologic function. If they return to work too early, particularly if they have a position of responsibility, they will find that they cannot think clearly and make mistakes. They will then retire prematurely. My experience is it will take up to 18 months for the nervous system to recover. I insist that patients wait 18 months before going back to work and make certain that they do not attempt to run their business early but only as a loyal work associate. Once they return slowly to the job, they will find that they can think as clearly as in the past. That will avoid depression that will occur by returning to work too early.

A fistula is a devastating event for a patient. Muscle protein and neurologic function are likely to deteriorate. Do not let patients return to work too soon. They should return slowly over months. That will keep them, their families, and their jobs intact.

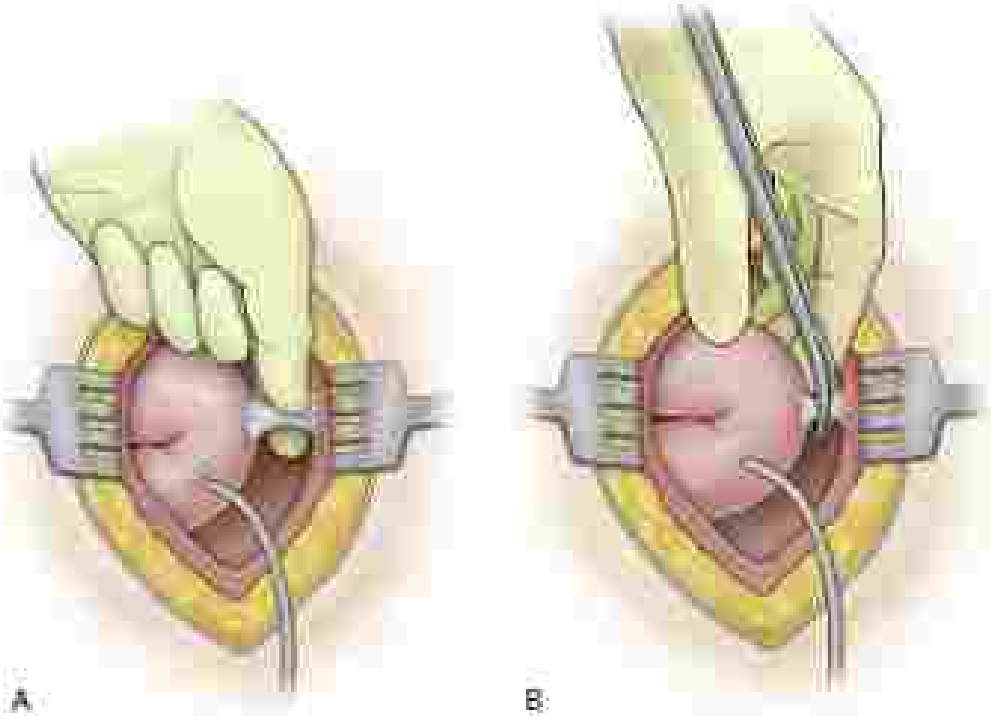

FIG. 6 Adhesions can sometimes be dealt with by compressing the adhesions from a broad base to a narrow base. When the adhesion is narrowing and is easily visible, the narrowed adhesion can be sharply divided. (From Fischer JE, et al. eds. Fischer's Mastery of Surgery. 6th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins, 2012.)

Preoperative Bowel Preparation: Is It Necessary?

Travis P. Webb, DO, MHPE

Elective colorectal resection is usually performed with mechanical bowel preparation (MBP) and antibiotic prophylaxis. Surgical site infection rates for patients undergoing colorectal surgery range from 5% to 30%, depending on the patient population and the definition of infection used. Although the use of MBP and antibiotics has become standard practice, there is controversy regarding the benefit of MBP. Some surgeons believe that MBP is necessary to decrease the risk of anastomotic leak and surgical site infection, whereas others believe that MBP is unnecessary and may actually increase the risk of complications. Recent studies have shown that MBP is not associated with a decrease in anastomotic leak or surgical site infection. Furthermore, MBP may be associated with dehydration, electrolyte abnormalities, and increased length of stay. Despite this evidence, MBP is still commonly used in practice. Surgeons who perform colorectal surgery should be aware of the evidence regarding MBP and should be able to counsel patients on the risks and benefits of MBP.

Historical Background

Surgical site infection is a common complication after colorectal surgery. Historically, the rate of surgical site infection was 50% to 80%. Surgeons began to recognize that the presence of bowel contents was associated with an increased risk of infection. Early attempts to reduce the risk of infection included diverting stool proximal to the anastomosis and performing a staged procedure. Over time, surgeons began to perform primary anastomoses with MBP and antibiotics, thereby reducing the risk of infectious complications. During the 1970s and 1980s, when mortality after colon resection was 10% and SSI was as high as 80% to 90%, studies began to describe multiple strategies of mechanical and antibiotic preparation that led to improved outcomes. By the 1990s, the oft-cited Condon nonrandomized mechanical bowel preparation strategy was widely adopted. It was believed that mechanical cleaning facilitated the action of nonabsorbable oral antibiotics. As bowel preparation moved to the outpatient setting in recent decades, however, the oral antibiotic component was often omitted because it was considered unnecessary if intravenous antibiotics were administered at the time of incision. Recent data now argue that this omission was ill advised.

Mechanical Bowel Preparation

Oral mechanical bowel preparation comes in several forms. Polyethylene glycol (PEG) solutions typically are given in large (4 L) or reduced volumes (2 L) when bisacodyl is added. PEG solutions are osmotically balanced and provide colonic cleansing through washout, whereas the addition of bisacodyl stimulates colonic peristalsis. Hyperosmotic preparations with insoluble salts containing phosphates or magnesium achieve cleansing by drawing water into the bowel lumen. The risk of electrolyte imbalances is therefore higher with hyperosmotic preparations and should be used with caution in at-risk patients. Multiday regimens using nasogastric tubes for whole gut irrigation are largely of historic interest and no longer widely used. See Table 1 for additional details on available mechanical preparations and their use.

Data for Mechanical Preparation

Between the 1970s and 2011, many observational and randomized studies failed to show a difference in key outcomes between MBP and no preparation. Surgeons have been questioning the value of MBP almost since its inception. Indeed, there is substantial, level 1 evidence from large randomized trials clearly indicating that MBP alone offers no advantage over no bowel preparation in elective colorectal surgery. The Cochrane *The Value of Stoma in Reversal* first addressed this topic in 2003 and has since published three updates (2006, 2009, and 2011). The most recent update includes data from 26 published articles, encompassing 7,665 patients. Examining a series of outcomes, including wound infection, anastomotic leak, peritonitis, reoperation and mortality, the authors conclude that mechanical bowel preparation (and rectal enema) may be omitted safely without any statistically significant difference in postoperative complications.

One often cited weakness of prior studies (and their subsequent meta-analyses) is the heterogeneity of mechanical preps and, fundamentally, the inclusion of a range of different operations. In 2014 the Agency for Healthcare Research and Quality conducted a clinical effectiveness review to expand upon the Cochrane reviews. The authors aimed to examine additional factors such as anatomic location of surgery, operative approach, and even a range of mechanical preparations

TABLE 1 Mechanical Bowel Preparations

Preparation Type	Product Example	Volume	Administration	Notes on Use
PEG (electrolyte lavage)	CoLyte[a] GoLYTELY	3.8 L 4000 mL	…on solid food for at least 2 hours before ingestion of the solution; 240 mL (8 oz) every 10 minutes until rectal output is clear or 4 L are consumed	…Divided dose regimens (1 L the night before procedure, 1 L morning of procedure) may improve patient tolerance. PEG is considered safer than osmotic laxatives/NaP for patients with electrolyte/fluid imbalances, renal or liver insufficiency, CHF, or renal or liver failure.
Sulfate-free PEG (improved smaller tasty, more palatable for patients)	NuLYTELY …ntLyte[a]	4000 mL 4000 mL	No solid food for at least 2 hours before taking the solution; 240 mL (8 oz) every 10 minutes until rectal output is clear or 4 L are consumed	Similar efficacy to PEG
Low-volume PEG and bisacodyl tablets (decrease volume related discomfort [e.g., bloating, cramping])	…ulyte and bisacodyl tablet bowel prep MiraLAX	2000 mL 255 g in 2000 mL	Only clear liquids on the day of the preparation. Two sets of bisacodyl delayed-release tablets (5 mg) at noon. Wait for bowel movement or maximum of 4 hours; 240 mL (8 oz) low-volume PEG (i.e., HalfLytely) or 240 mL (8 oz) of clear liquid containing one capful of MiraLAX or other PEG; 8 oz every 10 minutes until 2 L are consumed.	Equally effective as 4 L solutions; additional studies needed to guide safety
Aqueous NaP with…tions	Fleet	90 mL with 48 oz additional liquid	Only clear liquids can be consumed on the day of preparation. Two doses of 30–45 mL (2–3 tbsp) of oral solution are given at least 10–12 hours apart. Each dose is taken with at least 8 oz of liquid followed by an additional minimum of at least 16 oz of liquid. The second dose must be taken at least 3 hours before the procedure.	May cause significant…ical shifts. Not for use in pediatric or elderly patients or those with bowel obstruction, gut dysmotility, other structural intestinal disorders, renal or liver failure, or congestive heart failure. NaP may cause ulceration or mucosal abnormalities; do not use in patients with inflammatory bowel disease. Patients with compromised renal function or those taking…CE inhibitors or ARBs are at risk for phosphate nephropathy. In 2006, the FDA issued an alert regarding the risk for acute phosphate nephropathy, a type of acute renal failure, with use of oral sodium phosphate solutions or tablets.
Oral sodium phosphate (tablet)	…trasol (discontinued)	32–40 tablets with 64 oz clear liquid	Dosage is 32–40 tablets: 20 tablets on the evening before the procedure and 12–20 tablets the day of the procedure (3–5 hours before). The 20 tablets are taken as 4 tablets every 15 minutes with 8 oz of clear liquid. Bisacodyl is prescribed by some physicians as an adjunct.	Early tablet components included higher concentration of microcrystalline cellulose per tablet, which left residue obscuring the mucosal surface. Later tablet composition decreased microcrystalline cellulose concentration. Overall, tablet NaP is not associated with significantly improved patient tolerance when compared with aqueous NaP.
Adjuncts to mechanical preparation	Agent	…Tablets/Dose	Mechanism	…se

TABLE 1 Mechanical Bowel Preparations—cont'd

Preparation Type	Product Example	Volume	Administration	Notes on Use
Enemas	Tap water Soap suds Fleet enema Fleet bisacodyl enema Fleet mineral oil	500–1000 mL 500–1000 mL 4.5 mL 10 mg (1.25 oz; 37 mL) 60 mL	Distention and lavage of rectum and distal colon	Routine addition of enemas to oral preparations does not improve the quality of bowel cleansing, but does increase patient discomfort. Use enemas in patients presenting for endoscopy with poor distal colon preparation and in patients with distal functional distal colon (e.g., Hirschsprung).
Bisacodyl	Bisacodyl	5-mg tablet	Poorly absorbed diphenylmethane that stimulates colonic peristalsis; used as adjunct for NaP or PEG preparations	Can been found to decrease the volume of PEG preparation required
Saline laxatives	Magnesium citrate (liquid) Picolax (sodium picosulfate/ magnesium citrate)	7.9–300 mL	Hyperosmotic saline laxatives that increase motility by increased intraluminal volume	Addition of magnesium citrate to PEG allows for lower volume preparations. Use with extreme caution in patients with renal insufficiency or renal failure because of exclusive renal excretion of magnesium.
Senna	Senna Senokot Senna Syrup (8 mg/5 mL)		Anthraquinone derivatives (glycosides and sennosides) are activated by colonic bacteria and directly increase the rate of colonic motility with a subsequent increase in colonic transit and reduced water and electrolyte secretion.	Senna with PEG may improve the quality of preparation and reduce volume required.
Simethicone	Gas-X Mylicon Mylanta Generic formula (some 180 mg)		Antifoaming agent used to prevent foam formation after PEG preparation. Mechanism of action is unclear.	May improve lumen visualization and patient tolerance of bowel prep.
Metoclopramide	Reglan Generic formula (some also available)	5 mg	Dopamine antagonist gastric prokinetic, increasing the amplitude of gastric contraction, with increased peristalsis in duodenum and jejunum but without change in colonic motility	May reduce nausea. Slowing does not improve colonic cleansing
Carbohydrate electrolyte solutions	Cleprado ClearPEG Generic formula (some	20 oz.	Used with PEG and/or NaP solutions to improve flavor and prevent NaP/ related fluid and electrolyte shifts	Carbohydrate based solutions more palatable for patients; however, associated with a theoretical risk of colonic gas-induced explosion if these carbohydrates are metabolized by colonic bacteria into explosive gases.

[illegible]

[illegible]

used, despite a broad array of sixty studies (including 44 randomized controlled trials, 10 nonrandomized comparative studies, and 6 single group cohorts), the authors concluded that the evidence base is weak. They could not identify evidence of any benefit of mechanical bowel preparation, however, they could not exclude modest effects (30%–50%) in either direction for overall mortality, anastomotic leak, wound infection, or peritonitis. In the end, it was concluded that the heterogeneity of study methods, small sample sizes, and inadequate reporting prohibited meaningful comparisons of MBP strategies. In examining anatomic location of surgery, only one outcome, anastomotic leak, had sufficient data for analysis, and the results showed no difference between MBP and no MBP in either colon or rectal location. More recent meta analyses, including one in 2018, have further verified that MBP alone has no significant effect on patient outcomes.

Because of the lack of benefit, patient complaints of prep-related discomfort, and physician concerns regarding electrolyte imbalances, dehydration, mucosal injury, and other adverse events, MBP has been abandoned in many areas of the world. Certainly, complications do arise for the routine use of MBP, but adverse events from bowel preparations are poorly reported in the literature. Based on the current available evidence, MBP alone generally is not recommended for routine elective colon operations.

DATA ON ORAL ANTIBIOTIC PREPARATION

Few data exist regarding OA given without MBP, but, a recent 2017 study using data from the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP) attempted to determine whether OA alone is beneficial. This study matched 14,61 (OA) with 9800 (MBP) and 8819 (MBP+OA) patients to determine whether OA alone reduced patient morbidity. They concluded that OA alone compared with MBP significantly reduced SSI, anastomotic leakage, postoperative ileus, and major morbidity after colorectal surgery. They suggest that the addition of MBP may not be necessary. Because this is a retrospective study of a national database, randomized controlled trials are warranted to further clarify this issue.

Several oral antibiotic regimens have been described over the past century. Refer to Table 2 for common examples of oral antibiotic prophylaxis.

MECHANICAL AND ORAL ANTIBIOTIC PREPARATION

Evidence is now strong that, when compared with no bowel preparation, MBP+OA is beneficial in patient outcomes. A 2014 Cochrane Review on antimicrobial prophylaxis for colorectal surgery showed that combined oral and intravenous prophylaxis reduced the risk of SSI by 44% when compared with intravenous antibiotic administration alone (relative risk, 0.56; 95% confidence interval, 0.43 to 0.74). The data, derived from 14 studies including 2465 participants, were deemed high quality, such that further research is very unlikely to change our confidence in the estimate of effect.

Recent publications from statewide and nationwide data registries support this conclusion; combined preoperative oral antibiotic and mechanical bowel preparation is associated with reductions in SSIs, anastomotic leakage, ileus, and health services utilization outcomes such as length of stay and readmission. This includes several studies using data from NSQIP, which have identified decreased infectious complications associated with combined oral antibiotic and mechanical bowel prep. The most recent analysis using data from 2012 and 2015 includes 27,864 patients and revealed lower rates of SSI, organ space infection, wound dehiscence, and anastomotic leakage without increased risk of *Clostridioides difficile* infection. An analysis of Veterans Affairs data came to similar conclusions, with lower readmission rates for infectious complication and shorter length of stay seen among the patients receiving oral antibiotic bowel preparation when compared with mechanical only or no preparation groups. Studies from the Michigan Surgical Quality Collaborative also have identified a decreased rate of abdominal abscess (1.4% vs 2.1%) or SSI (5.0% vs 6.2%) between propensity matched pairs receiving mechanical bowel preparation and oral antibiotics compared with those with neither mechanical nor oral antibiotic preparation. The Michigan data also have been used to evaluate preoperative *C. difficile* colitis, revealing lower rates (0.2% vs 1.9%) among the oral antibiotic group.

Given the evidence from current literature, guidelines for the surgical management of elective colorectal illnesses have been updated by many societies. In 2016, and 2017, the American Society of Colon and Rectal Surgeons, Society of American Gastrointestinal and Endoscopic Surgeons, Surgical Infection Society, and American College of Surgeons recommended that all patients undergoing elective colorectal surgery should receive an MBP+OA.

TABLE 2 Oral Antibiotic Regimens

Oral Antibiotic Prophylactic Regimen*	Use in Prior Literature
Neomycin + erythromycin	Coppa, 1988; Kaiser, 1985; Khubchandani, 1980; Lau, 1988; Nichols, 1973; Stellato, 1989
Metronidazole + neomycin	Gastinne, 2005; Hamel, 1986; Lewis, 2003; Nelis, 1990 (includ. oral bacitracin); Reynolds, 1980
Metronidazole + kanamycin	Lazorthes, 1982; Matthiessen, 1983; Takesue, 2006
Tinidazole + neomycin	Persson, 1987
Kanamycin + erythromycin	Ishida, 2001; Kobayashi, 2007

*Modified from Pollock CE, Mills KT, Kelly JH, Caplinger C. Combination of oral non-absorbable and intravenous antibiotics versus intravenous antibiotics alone in the prevention of surgical site infection after colorectal surgery: a meta-analysis of randomized controlled trials. Int J Colorectal Dis. 2011;26(6):705–718. †Each of these oral antibiotics was combined with a range of intravenous antibiotics in the studies listed.

CONCLUSIONS

Recent literature indicates that MBP+OA reduces complications for patients undergoing colorectal procedures. Although mechanical bowel preparation alone does not appear to provide a benefit, oral antibiotics without mechanical bowel preparation is rarely used and has not been adequately studied. The effects of oral antibiotic prophylaxis without first cleaning the colon are not conclusive and should be a focus for future research. Additional areas for further research include the use of bowel preparation in laparoscopic or minimally invasive approaches and in rectal surgery.

Management of Diverticular Disease of the Colon

Ira L. Leeds, MD, MBA, S.M, and Sandy N. Fa g, M

Colonic diverticula are common among the general population, and pathologic states associated with diverticula may be increasing. These protrusions of colonic mucosa between fibers of the muscularis propria, more appropriately termed pseudodiverticulum, are thought to be a precondition for diverticulitis and diverticular bleeding. Diverticular disease routinely ranks in the top 10 listed diagnoses for ambulatory care in the United States and is the most commonly reported gastrointestinal diagnosis for inpatient hospitalization.

The natural history of colonic diverticula and their resulting disease states is poorly understood. The quantity of diverticula is positively correlated with age: diverticula are present in 65% of the Western population by 85 years and less than 5% of the population younger than age 40 years. Their occurrence is thought to be associated with degradative changes to the integrity of the colon. Age-related collagen structural changes and increased intraluminal pressure often associated with constipation are thought to aggravate existing colonic wall vulnerabilities at the site of the penetrating branches of the vasa recta through the muscularis propria. The effect of increased intraluminal pressure as a contributing factor is supported by studies demonstrating a role of the environment in pathogenesis. Western populations eating similar diets have a much more substantial burden of diverticula in the sigmoid colon, whereas Asian countries demonstrate diverticula predominantly in the right colon. Evidence also exists for an important genetic risk contribution with sibling cohorts and twin studies demonstrating relative risks ratios three times greater than the general population.

The presence of colonic diverticula, or diverticulosis, is necessary but not sufficient to cause diverticular disease. The most recent evidence suggests that only 4% of patients with diverticulosis ever develop symptoms of diverticulitis. This is markedly lower than previously thought, and diverticular bleeding is thought to be similarly rare. For this reason, the only recommendation we give patients with asymptomatic diverticulosis is to increase fiber and fluid intake.

Ongoing debate exists as to why and how otherwise benign diverticula occasionally progress to disease. Manifestations of diverticular disease appear to be specific to their anatomic configuration. Diverticulitis is more commonly associated with sigmoid colon diverticula. Although diverticulitis has typically been conceptualized as an infectious process caused by bacterial overgrowth with or without obstruction akin to appendicitis, similarities between diverticulitis and inflammatory bowel disease have led some to suggest an autoimmune etiology.

Diverticular bleeding typically occurs from right colon diverticula. Right sided diverticula tend to be larger and may be due to the thinner colonic wall at this location. The penetrating arterial branches of the vasa recta end up draped over the herniating colonic mucosa. Recurrent inflammation of the vessels leads to eccentric intimal thickening that may increase the propensity for spontaneous hemorrhage.

This chapter describes the approach to management of diverticulitis and diverticular bleeding.

DIVERTICULITIS

Presentation and Diagnosis

Acute diverticulitis classically presents as left lower quadrant pain, fever, and leukocytosis. Symptoms of more complicated disease such as feculoma, pneumaturia, stool passed via the vagina, and progressively worsening constipation are suggestive of fistula (see The Management of Rectovaginal Fistula) or stricture formation. Numerous other diagnoses can mimic symptoms of diverticulitis, and the initial workup of suspected diverticulitis focuses on ruling out similarly presenting conditions, including appendicitis, inflammatory bowel disease, ischemic bowel, neoplasia, and gynecologic conditions. A urinalysis is helpful to evaluate for a urinary tract infection or nephrolithiasis. Although with some specificity limitations and contraindications in select patients, computed tomography (CT) of the abdomen and pelvis with intravenous and oral contrast is the best initial modality for diagnosing and staging suspected diverticulitis, addressing alternative diagnoses, and identifying diverticulitis associated complications. Magnetic resonance imaging is an alternative diagnostic imaging modality. CT magnetic resonance colonography is used infrequently and primarily in chronic diverticulitis to further evaluate stricture complications.

Staging is a critical component of the diagnostic workup because it is highly predictive of the success of the different management strategies described in this chapter. Staging definitions are myriad, and different systems often have categories of disease severity that overlap. We exclusively use the modified Hinchey classification system based on the original 1978 staging and updated to reflect diagnostic sophistication afforded by modern CT imaging (Table 1; Fig. 1). To accommodate other common classification schemes, we use modified Hinchey stage 0/Ia and "symptomatic, uncomplicated diverticulitis" interchangeably. Importantly, physical examination should be correlated with CT imaging findings as only patients, by definition, at least Hinchey III, may have limited findings on imaging. Our initial approach to management of acute diverticulitis is shown in Fig. 2.

Management of Symptomatic, Uncomplicated Diverticulitis (Modified Hinchey Stage 0 or Ia)

Treating patients with symptomatic, uncomplicated diverticulitis is one of the most rapidly evolving areas of colorectal surgery, with limited consensus among current evidence, expert consensus, and surgical practice. Supported for many years by professional guidelines and as demonstrated in the multicenter Spanish Hospitalization or Ambulatory Treatment of Acute Diverticulitis trial in 2014, most patients with uncomplicated disease have been treated with a single intravenous dose of antibiotics, 10 days of outpatient antibiotics, and close follow up if clinically appropriate.

The Swedish Antibiotic Therapy or Acute Uncomplicated Colonic Diverticulitis trial has challenged this paradigm by demonstrating that inpatient admission for intravenous fluid resuscitation with or without antibiotics was not associated with any difference in future diverticulitis complications, faster hospital discharge, or recurrence. Adoption of an antibiotic-free treatment strategy more broadly is not yet recommended because of the inpatient monitoring of antibiotic-free patients performed in these studies versus the outpatient follow up typically used with antibiotics in most other settings.

In our practice, patients with uncomplicated diverticulitis who are hemodynamically stable, medically uncomplicated, and are able to hydrate well are treated with oral antibiotics and outpatient follow up. If any of the criteria are not met, we recommend hospital admission for at least 2 days to start antibiotics, fluid resuscitate, and maintain a diet under supervision. Oral antibiotics should have excellent gram negative and anaerobic coverage with favorable positioning with reference to an institution's local antibiogram. Resolution of symptoms guides diet advancement. Current evidence suggests nonoperative management success in more than 90% of appropriately selected individuals. If still symptomatic 5 to 7 days after initiating treatment or if the patient's clinical status worsens, a CT scan of the

TABLE 1 Modified Hinchey Classification for Acute [illegible] ertic litis

Stage	Definition	Associated CT findings
0	Mild clinical diverticulitis (uncomplicated diverticulitis*)	Diverticula, with or without associated colonic wall thickening
Ia	Confined pericolic inflammation, phlegmon	Colonic wall thickening with pericolic soft tissue changes
Ib	Pericolic or mesenteric abscess	Stage Ia findings plus local abscess
II	Pelvic, distant intraabdominal, or retroperitoneal abscess	Stage Ia findings plus anatomically distinct, distant abscess
III	Generalized purulent peritonitis	Ileus; with fluid not confined to an abscess cavity; peritoneal wall thickening
IV	Generalized fecal peritonitis	Impossible to distinguish from stage III findings

abscesses and pelvis is repeated to assess for new complications of diverticulitis with the present expectation that a subclinical complication, such as an abscess, has now declared itself.

Management of Diverticulitis Complicated by Diverticular Abscess (Hinchey Stage Ia or Ib)

Abscesses occur in approximately 1 of 5 cases of acute diverticulitis. For small abscesses (<4 cm in largest dimension), a step-up approach to management that has been supported in a number of small studies. In general, small abscesses are not amenable to percutaneous drainage and are treated with intravenous antibiotics. The published literature consistently finds that more than 75% of patients with a small abscess can be managed successfully with this approach and avoid an emergent operation. If patients with small abscesses do not improve on intravenous antibiotics, repeat imaging to obtained 5 days after antibiotic therapy to evaluate for progression to a larger abscess that may then be amenable to percutaneous drainage. Patients with larger abscesses are managed with percutaneous drainage.

Once the patient clinically improves with intravenous antibiotic therapy and/or drain placement, fits or low diet is advanced. If clinical examination improves, leukocytosis resolves, drain output is less than 30 mL/day, then a repeat CT scan is obtained to determine resolution of the abscess and subsequent drain removal.

If the patient progressively worsens on conservative management with intravenous antibiotics and/or percutaneous drainage, then surgical management with abscess drainage, colectomy, and/or diversion may be required.

Management of Free Perforation (Hinchey Stage III or IV)

Diffuse peritonitis or systemic inflammatory response syndrome in the context of diverticulitis on imaging is consistent with perforation. Patients with evidence of freely perforated diverticulitis require emergent surgery without delay. Reasonable adjuncts that should be included if they do not delay surgical intervention are fluid resuscitation and antibiotic administration. These patients are extremely sick, mortality rates for fecal peritonitis even with appropriate surgery can be as high as 30%.

The management of perforated diverticulitis should be driven by clinical examination, laboratory results, and imaging findings. Although select cases of pericolic/mesenteric can be managed non-operatively, multiquadrant peritonitis or hemodynamic instability are hard indications for surgical intervention.

Three common strategies exist for emergent surgery in perforated diverticulitis: two stage colectomy, one stage colectomy, and laparoscopic lavage without resection. The historical standard of care has been two stage colectomy with an emergent Hartmann's procedure (sigmoidectomy, closure of the rectal stump, proximal end colostomy) followed by elective colostomy takedown 3 to 6 months later. A promising modification of this traditional approach has been the use of primary anastomosis and diverting ileostomy. Two multicenter, randomized controlled trials in Switzerland and France (Primary vs. Secondary Anastomosis for Hinchey Stage III–IV Diverticulitis: a Prospective Randomized Trial) have compared a traditional Hartmann's procedure to primary anastomosis with diverting ileostomy. Overall morbidity and mortality between the two approaches was similar, but

the primary anastomosis groups had markedly better rates of stoma reversal (80% vs. 57%, $p<0.001$). When a patient is hemodynamically stable enough to support a longer operation and local inflammation allows it, we prefer to perform a primary anastomosis with diverting ileostomy.

One-stage colectomy or primary anastomosis without diversion, has been proposed and used as a management strategy for acute diverticulitis that does not require any additional operations. This approach is attractive because it avoids the need for stoma reversal and the resulting morbidity associated with a second operation. Importantly, more than half of patients undergoing Hartmann's procedure never return to the operating room for colostomy reversal. No randomized trials have addressed this approach, and the existing evidence cannot rule out a selection bias demonstrating that patients receiving a primary anastomosis without diversion are not less sick at the time of decision making. Thus, the one-stage colectomy is reserved for a select group of patients who are hemodynamically stable, nutritionally replete, and undergo colectomy under optimal conditions of minimal stool spillage.

Laparoscopic lavage, laparoscopic irrigation and drain placement without resection, has been an alternative approach widely used since the 1990s. This approach was predicated on concerns that emergent surgery itself was equally as injurious to the patient as the underlying life-threatening perforation. Laparoscopic lavage was proposed as an option to obtain source control while limiting tissue manipulation of a hostile abdomen. In the past few years, several multicenter, randomized controlled trials have reported results that have seriously questioned the role of laparoscopic lavage as a reasonable management option. A meta-analysis recently reexamined the question pending results of a number of studies including three major trials (Swedish-Norwegian Scandinavian Diverticulitis Trial, the Swedish-Danish Treatment of Acute Diverticulitis Laparoscopic Lavage vs. Resection trial, and the Belgian Italian Dutch Ladies (LOLA trial). Results of these trials consistently demonstrated no composite benefit to laparoscopic lavage over immediate resection and a 3-times increased risk of further need for an invasive procedure. Given these results, we do not advocate for the routine inclusion of laparoscopic lavage as a therapy consideration. Two rare exceptions to this rule are (1) patients with equivocal imaging for free perforation who are found to have no diffuse peritonitis and a contained abscess on diagnostic laparoscopy and (2) patients who are laparoscopically explored and have extraluminal inflammation so severe as to prohibit a safe Hartmann's procedure.

Postdiverticulitis Colonoscopy Evaluation

Historically, a colonoscopy 6 weeks after nonoperative management for acute diverticulitis has been recommended because of an episode's association with colorectal cancer and premalignant advanced adenomas (3 cases per 1000 follow-up patients in observational studies). This practice is currently supported by limited prospective evidence of benefit for colorectal cancer. Our current practice is to obtain a colonoscopy 6 weeks after the first episode of acute diverticulitis or in patients for whom a recent colonoscopy has not been performed. Although CT colonography is an acceptable alternative, CT imaging obtained as part of the original episode of diverticulitis has been shown to be inadequate to rule out a neoplastic etiology.

Postdiverticulitis Elective Surgery

The management of diverticulosis following an episode of diverticulitis has changed markedly over the decades. An important distinction in current practice is that uncomplicated diverticulitis (Hinchey stage I or II) should be managed differently from higher stage disease.

Historically, initially uncomplicated diverticulitis was thought to be progressive relapsing, with each additional episode being worse than the one before. The concern was that patients would eventually develop a complication from diverticulitis, such as a free perforation. This premise has been disproven, with current evidence supporting that there is no difference in mortality or colostomy incidence whether a patient with uncomplicated diverticulitis has elective resection of the diseased colon segment after the first versus after the fourth episode. Thus, patients are counseled that if they were likely to have complicated disease, they are statistically most likely to have the complication with their first episode. Current recommendations leave the choice of resection versus expectant management up to inpatient patient considerations, including the patient's existing lifestyle, tolerance for the unpredictability of a future flare, comorbidities (e.g., an immunosuppressed transplant patient) that may increase the risk of even an elective surgical intervention, and risk of occult neoplasia. Age is not an independent risk factor for future disease; it has been shown that younger individuals have similar severity to older patients but carry a longer cumulative risk of recurrence because of longer life expectancy.

Management following nonoperative uncomplicated diverticulitis is less ambiguous. Although high-quality evidence is not available, retrospective series report recurrence rates following a complicated episode of up to 40%. A resection will likely reduce this recurrence risk, but the benefit of elective resection versus "watch and wait" with urgent resection has not been proven. For those with abscesses requiring percutaneous drainage, fistula, or symptomatic stricture, we recommend elective resection. For those with small abscesses that resolve with antibiotics alone, we encourage a shared decision-making approach with the patient. Furthermore, intramural extraluminal gas seen on initial CT imaging or associated phlegmon is not considered complicated disease and these findings are managed conservatively with antibiotics as uncomplicated diverticulitis.

Certain late complications of diverticulitis warrant further diagnostic assessment, if suspected. Fecaliths or pneumaturia warrant a CT cystogram (± cystoscopy) to evaluate for a colovesical fistula. A patient endorsing stool or air coming from her vagina should have a comprehensive gynecologic pelvic examination and CT with rectal contrast to assess the location of a likely rectovaginal fistula. Obstructive symptoms and imaging consistent with a colonic stricture should be further evaluated with colonoscopy because the operative approach should adapt to a limited resection for a benign stricture versus a wider oncologic resection for neoplasia.

Special Populations in Diverticulitis Management

The surgeon should recognize that diverticulitis in immunocompromised patients manifests as a unique disease process. Immunosuppressed transplant recipients, those on chronic steroids, and HIV-positive patients may present with delayed diagnosis and an impaired immune system to address the eventual infectious source that promulgates complicated diverticulitis. Mortality rates in these populations can be as high as 40%. These patients should be treated more aggressively and may do better with early surgical intervention for source control. A number of other patient populations are also at higher risk of recurrence and complications from diverticulitis. In addition to the immunocompromised, patients with late-stage kidney disease and collagen vascular disease are more susceptible to complications such as perforation and may benefit from more aggressive early intervention.

Surgical Technique and Considerations

There surgical approaches exist for colorectal surgery: robotic, laparoscopic, and open surgery (Fig. 3). Data from the prospective, multicenter, randomized control Sigma trial showed that laparoscopic sigmoid resection and electively for diverticular disease offered advantages over open sigmoid resection. The laparoscopic approach was associated with short-term benefits of a 31.4% reduction in major complications, less pain, and shorter length of hospital stay. Total postoperative long-term morbidity showed a 27% reduction in major morbidity for patients undergoing laparoscopic surgery for diverticular disease. Longer operative times were seen with laparoscopy. Given these benefits, we prefer a laparoscopic approach if a patient's abdominal surgical history and comorbidities are suited to it.

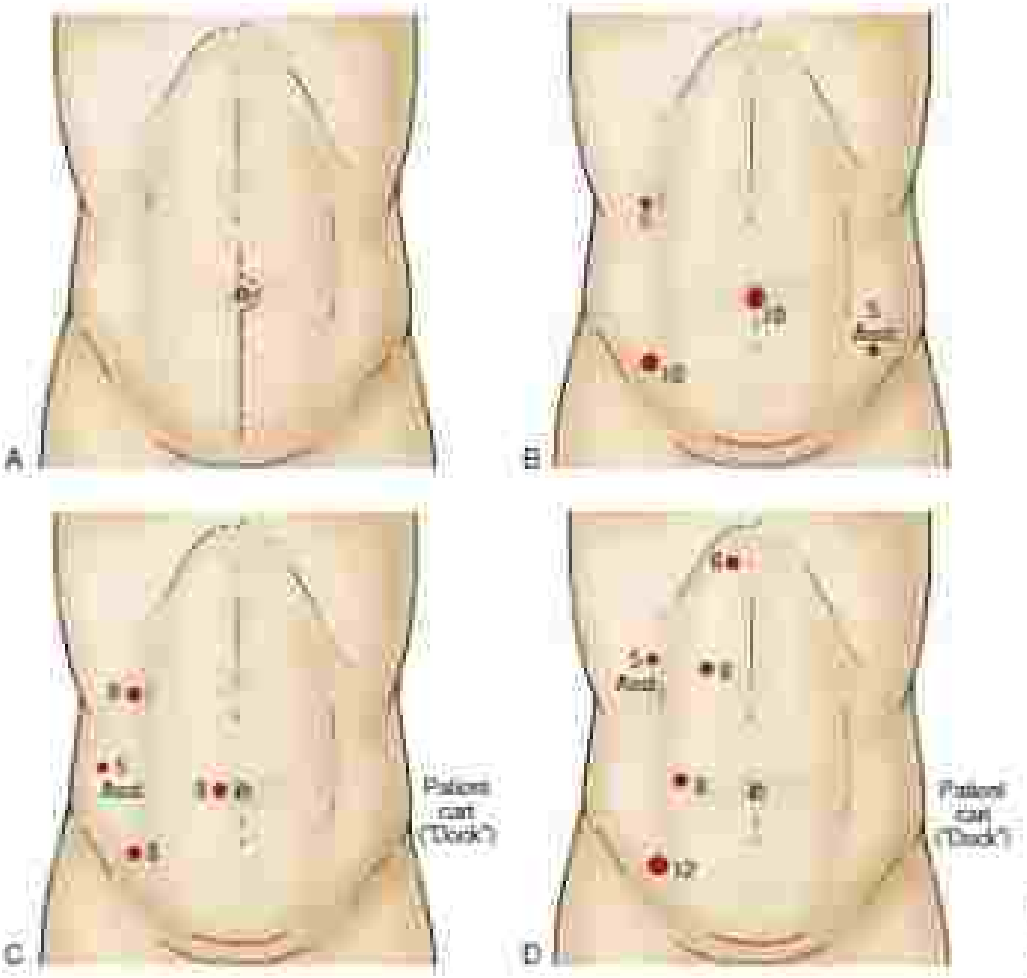

FIG. 3 (A) Open incision. (B) Laparoscopic or robotic. (C) Si Robotic incision. (D) Xi Robotic incision.

Laparoscopic access to the abdomen includes a periumbilical camera port while triangulating the right upper and right lower quadrant ports. The right lower quadrant port is usually a larger sized port to accommodate an endoscopic gastrointestinal stapler. A left, lower quadrant, 5-mm port may be placed to help retract the sigmoid colon during resection.

Currently, two robotic platforms exist and both are manufactured by Intuitive Surgical da Vinci Surgical Systems. Port placement for the Si robot is similar to that described previously for laparoscopy, however, the robotic camera port is placed just to the right of the umbilicus. For the multiquadrant da Vinci Xi, four 8-mm robotic ports are placed in a diagonal line, each a handbreadth apart, spanning from the right side of subxiphoid to two fingerbreadths medial to the right anterior superior iliac spine.

Regardless of surgical approach, the key steps of the operation remain the same. Because of surrounding inflammation, there is a high likelihood of the left ureter being adherent to surrounding structures. It is strongly recommended that the patient undergo cystoscopy and placement of ureteral stents to facilitate identification of the ureter. Although studies show that ureteral stent placement does not decrease the rate of ureteral injury during surgery, the stents may help identify a ureteral injury and facilitate concurrent repair as needed during the initial operation.

The next step is ligation of the inferior mesenteric artery (IMA). From a minimally invasive approach, the most optimal way to isolate the IMA is via a medial to lateral approach. The peritoneum overlying the sacral promontory is incised going up to the base of the inferior mesenteric artery. A medial to lateral dissection aids in identifying the left ureter retroperitoneal and allows it to be isolated from harm. The inferior mesenteric artery is then taken at a high ligation if there is suspicion for malignancy, but may be taken distally if there is no evidence of malignancy. The sigmoid colon is then fully mobilized by incising the white line of Toldt after IMA ligation. If the operation is performed in open fashion, then often a lateral to medial approach is used to identify the left ureter by mobilizing the sigmoid colon via incising the white line of Toldt. The IMA is identified by palpation of the mesentery.

Once the resection target is fully mobilized, the splenic flexure is then mobilized by continuing mobilization of the descending colon as well as taking down the omentum and gastrocolic ligament. The proximal margin of resection is located at the rectosigmoid junction, which helps reduce the risk of recurrence by leaving behind high-risk diverticula located on the sigmoid colon. Landmarks to identify the transition from sigmoid to rectum include the sacral promontory, the peritoneal reflection, confluence of the taenia coli, and distance from the anal verge (12–15 cm). The best indicator is to follow the taenia coli, which are three linear muscles running longitudinally along the colon until they splay or coalesce at the proximal rectum. A stapler is fired to transect the bowel at the proximal rectum after clearing the posterior mesentery to ensure that the entire sigmoid colon is removed.

If an anastomosis is indicated, an end-to-end anastomosis stapler is used. If local diversion is indicated, a colostomy is created when there is no anastomosis or a diverting loop ileostomy is created to protect a colorectal primary anastomosis.

In the case that there is a difficult dissection, such as a phlegmon or colovesical fistula, an open approach may be required to delineate the colon from the ureter or to perform finger fracture to delineate the ureter or colovesical fistula. In general, no pelvic drain is required if the distal dissection remains above the anterior peritoneal reflection. In the case of a colovesical fistula, a drain is placed at the bladder repair to evaluate for a urine leak postoperatively.

DIVERTICULAR BLEEDING

Although diverticular bleeding is traditionally considered self-limiting, the risk of near-term recurrent bleeding without a hemostatic intervention is more than 50%. Risk factors independently associated with diverticular bleeding in those with colonic diverticula include long-term use of nonsteroidal antiinflammatory drugs, antiplatelet agents, and anticoagulants.

The most critical feature of managing a consult for diverticular bleeding is discriminating other etiologies of bleeding per rectum. Colonic diverticula are common, and gastrointestinal bleeding can arise from numerous other etiologies. Approximately 15% of patients with hematochezia ultimately have an upper gastrointestinal source. Among patients who ultimately have a lower gastrointestinal source of bleeding, diverticula are the cause in only one-third of lower gastrointestinal bleeding cases. See Lower Gastrointestinal Bleeding in this text for a comprehensive review of the diagnostic workup.

Initial Management Approach

Our abbreviated approach to the nonsurgical management of diverticular bleeding includes the following. On initial presentation, intravenous access is established, serial hemoglobins are obtained, patients are placed on bowel rest, and the transfusion threshold is set to a hemoglobin goal of 7 to 8 g/dL. There is institutional variation in the bleeding localization study of choice. Initial diagnostic studies used to localize gastrointestinal bleeding include colonoscopy, CT angiography, and nuclear medicine–tagged red blood cell scan (scintigraphy). A colonoscopy is performed to visualize the source of bleeding and perform therapeutic hemostatic measures, such as epinephrine injection, bipolar cautery, endoclipping, and band ligation. Although we prefer this approach for its ability to directly evaluate bleeding and any potential therapy applied, the visualization associated with an emergent colonoscopy in an unprepped colon can be prohibitively difficult, resulting in an endoscopic procedure that may be nondiagnostic and nontherapeutic.

There are number of other modalities that should be used as needed. A technetium-labeled red blood cell scan has the advantage of detecting bleeding rates as low as 0.1 mL/min; however, a tagged red blood cell scan's sensitivity is undermined by its inaccuracy to localize lesions. False localization rates up to 25% with this diagnostic modality have been previously reported. CT angiography of the abdomen and pelvis has localization sensitivity down to bleeding rates of 0.5 mL/min and can provide immediate evidence of whether a formal angiographic procedure is likely to be successful. When bleeding is localized by CT angiography or nuclear medicine–tagged red blood cell scan, catheter-directed angiography may be used for selective angioembolization versus vasopressin infusion. The greatest limitation of angiography is that it is limited to identifying active bleeding only with a rate of at least 0.5 mL/min. In addition, localizing bleeding with another method before conventional angiography may better limit the contrast load administered with more selective arterial branch angiography.

Surgical Considerations for Diverticular Bleeding

The algorithm (Fig. 4) typically addresses more than 80% of diverticular bleeds. For patients who acutely fail this approach and continue to bleed, emergent surgical resection is warranted. Indications

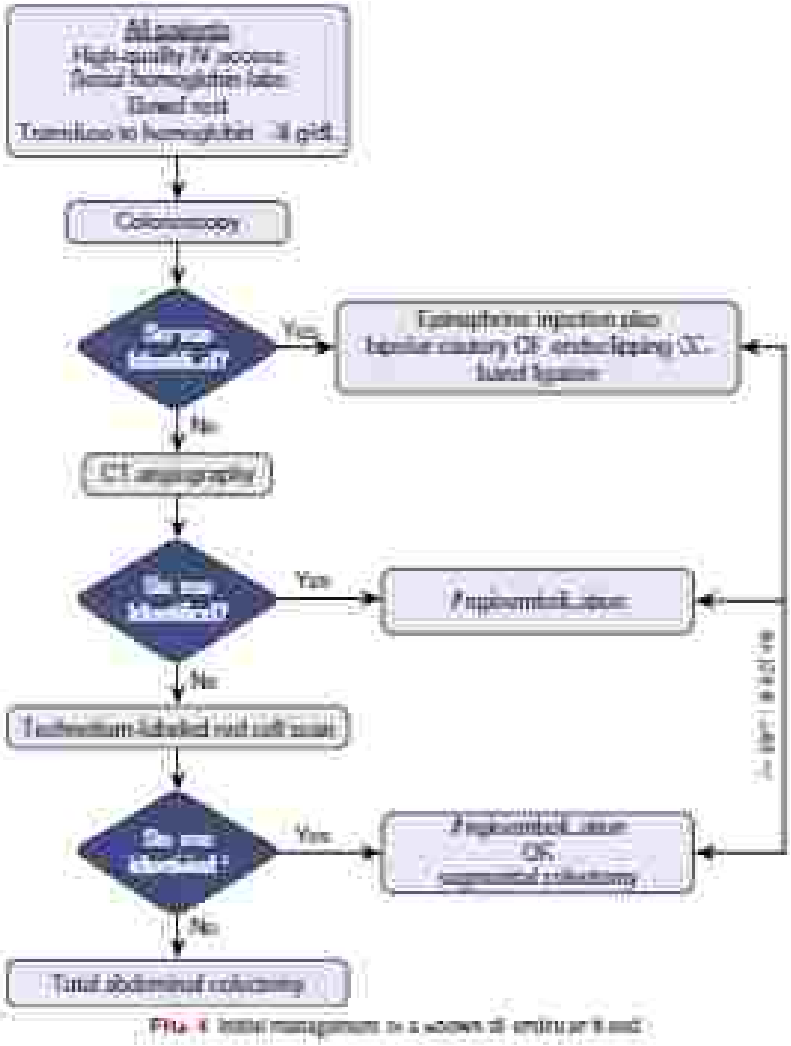

FIG. 4 Initial management in a patient with acute lower GI bleed.

for emergency surgery include requiring more than 4 to 6 units of blood within 24 hours, continuous bleeding for more than 72 hours, or rebleeding on the same admission. For patients operated on specifically for ongoing high-volume transfusion needs, local diversion to the form of an ileostomy is recommended because of the increased risk of anastomotic leak associated with the increasing number of blood transfusions.

The more difficult decision is how to best manage patients who have a life-threatening bleed that is fully addressed through endoscopic therapy or angioembolization alone. Although surgical resection of the offending lesion remains the definitive option for management and prevention of recurrent bleeding, specific indications for transitioning from a "watch and re-treat" paradigm to a surgical approach continue to be debated.

Patients who will ultimately require a life-saving surgical resection for recurrent diverticular bleeding would likely do better with an elective colectomy following a prior episode because mortality rates for emergent colectomy for bleeding are more than 25%. In contrast, rates of lifetime rebleeding for all diverticular bleeding presentations are 17% to 25%, suggesting that most patients do not ever require reintervention. Prophylactic surgical resection between bleeding episodes may be appropriate for the carefully selected patients that may be at high risk for rebleeding (i.e., long-term need for anticoagulation or antiplatelet therapy, social/rebleeding events) and benefit the most from undergoing surgery electively rather than emergently. If an operation is appropriate, careful consideration must be taken before performing a segmental resection given the high risk of rebleeding compared with those undergoing total abdominal colectomy (18% vs 4%). For those patients requiring surgical therapy without confident localization, we do not recommend a segmental resection.

Surgical Technique

If the patient is hemodynamically stable, we prefer to perform the operation via a minimally invasive approach. For patients actively being transfused and who are hemodynamically unstable, an open approach is recommended because of the additional time associated with minimally invasive operations. For those patients in whom the sigmoid colon is localized as the source of bleeding, please refer to the previous discussion of a sigmoid resection for diverticulitis.

In the case of total abdominal colectomy, the surgical technique for diverticular bleeding proceeds from the discussion above for distal colon resection for diverticulitis. After mobilization of the splenic flexure, the omentum and gastrocolic ligament are taken down further to the hepatic flexure. The hepatic flexure is mobilized and the right colon is mobilized by incising the white line of Toldt. The small bowel is mobilized from the right lateral abdominal wall. The proximal point of transection is beyond the ligament of Treves at the terminal ileum. The mesentery for the entire colon is then taken down with suture or a vessel sealing device. An ileorectal anastomosis is considered in the elective setting; however, if the patient has required multiple blood transfusions and/or is hemodynamically unstable, then he or she requires an ileostomy.

Conclusion

The most common disease manifestations of diverticulosis are diverticulitis and diverticular bleeding. Uncomplicated acute diverticulitis can be managed with antibiotics and outpatient follow-up alone or with patients or inpatient supervision with or without antibiotics. Complicated diverticulitis is best managed with a step-up approach under inpatient supervision with clinical condition of the patient determining when more invasive measures are appropriate. Emergency surgery for diverticulitis is required in cases of peritonitis. Elective surgery is indicated for complicated diverticulitis, but should be considered on an individualized basis for cases of uncomplicated disease.

Diverticular bleeding can almost always be managed with endoscopic and angioembolic techniques. In rare cases of ongoing bleeding, emergency resection is warranted. Elective resection should be approached on an individualized basis because of the moderate risk of rebleeding. If pursued, diverticular bleeding must be definitively localized for segment resection, or a total abdominal colectomy is warranted.

Management of Chronic Ulcerative Colitis

Yasmin Rojas-Khalil, MD, and S-ran Galandiuk, MD

The management of chronic ulcerative colitis has changed significantly over the last 15 to 20 years. It has become a disease treated less commonly by surgeons because of the advent of stronger antiinflammatory medications. Beginning with the use of infliximab (Remicade), which was approved for use in ulcerative colitis in 2005, followed by adalimumab (Humira, 2012) and golimumab (Simponi, 2013), fewer patients with this disorder are requiring surgical management.

Ulcerative colitis patients seen in consultation for surgery largely fall into three main groups: (1) those who have severe disease and are not responding to medications, whether it be in the hospital or as an outpatient; (2) those who have significant side effects of medications used to treat their colitis; and (3) patients who require surgery due to the presence of colonic neoplasia (dysplasia or colorectal cancer). Most patients with chronic ulcerative colitis have a disease course characterized by exacerbations and remissions. Exacerbations can be caused by viral or bacterial infections (for example, "*Clostridium difficile* colitis") or by environmental factors, such as smoking cessation,

for emergency surgery include requiring more than 4 to 6 units of blood within 24 hours, continuous bleeding for more than 72 hours, or rebleeding on the same admission. For patients operated on specifically for ongoing high-volume transfusion needs, local diversion to the form of an ileostomy is recommended because of the increased risk of anastomotic leak associated with the increasing number of blood transfusions.

The more difficult decision is how to best manage patients who have a life-threatening bleed that is fully addressed through endoscopic therapy or angioembolization alone. Although surgical resection of the offending lesion remains the definitive option for management and prevention of recurrent bleeding, specific indications for transitioning from a "watch and re-treat" paradigm to a surgical approach continue to be debated.

Patients who will ultimately require a life-saving surgical resection for recurrent diverticular bleeding would likely do better with an elective colectomy following a prior episode because mortality rates for emergent colectomy for bleeding are more than 25%. In contrast, rates of lifetime rebleeding for all diverticular bleeding presentations are 17% to 25%, suggesting that most patients do not ever require reintervention. Prophylactic surgical resection between bleeding episodes may be appropriate for the carefully selected patients that may be at high risk for rebleeding (i.e., long-term need for anticoagulation or antiplatelet therapy, serial rebleeding events) and benefit the most from undergoing surgery electively rather than emergently. If an operation is appropriate, careful consideration must be taken before performing a segmental resection given the high risk of rebleeding compared with those undergoing total abdominal colectomy (18% vs 4%). For those patients requiring surgical therapy without confident localization, we do not recommend a segmental resection.

Surgical Technique

If the patient is hemodynamically stable, we prefer to perform the operation via a minimally invasive approach. For patients actively being transfused and who are hemodynamically unstable, an open approach is recommended because of the additional time associated with minimally invasive operations. For those patients in whom the sigmoid colon is localized as the source of bleeding, please refer to the previous discussion of a sigmoid resection for diverticulitis.

In the case of total abdominal colectomy, the surgical technique for diverticular bleeding proceeds from the discussion above for distal colon resection for diverticulitis. After mobilization of the splenic flexure, the omentum and gastrocolic ligament are taken down further to the hepatic flexure. The hepatic flexure is mobilized and the right colon is mobilized by incising the white line of Toldt. The small bowel is mobilized from the right lateral abdominal wall. The proximal point of transection is beyond the ligament of Treves at the terminal ileum. The mesentery for the entire colon is then taken down with suture or a vessel sealing device. An ileorectal anastomosis is considered in the elective setting; however, if the patient has required multiple blood transfusions and/or is hemodynamically unstable, then he or she requires an ileostomy.

Conclusion

The most common disease manifestations of diverticulosis are diverticulitis and diverticular bleeding. Uncomplicated acute diverticulitis can be managed with antibiotics and outpatient follow-up alone or with patients on inpatient supervision with or without antibiotics. Complicated diverticulitis is best managed with a step-up approach under inpatient supervision with clinical condition of the patient determining when more invasive measures are appropriate. Emergency surgery for diverticulitis is required in cases of peritonitis. Elective surgery is indicated for complicated diverticulitis, but should be considered on an individualized basis for cases of uncomplicated disease.

Diverticular bleeding can almost always be managed with endoscopic and angioembolic techniques. In rare cases of ongoing bleeding, emergency resection is warranted. Elective resection should be approached on an individualized basis because of the moderate risk of rebleeding. If pursued, diverticular bleeding must be definitively localized for segment resection, or a total abdominal colectomy is warranted.

Management of Chronic Ulcerative Colitis

Yasmin Rojas-Khalil, MD, and Susan Galandiuk, MD

The management of chronic ulcerative colitis has changed significantly over the last 15 to 20 years. It has become a disease treated less commonly by surgeons because of the advent of stronger antiinflammatory medications. Beginning with the use of infliximab (Remicade), which was approved for use in ulcerative colitis in 2005, followed by adalimumab (Humira, 2012) and golimumab (Simponi, 2013), fewer patients with this disorder are requiring surgical management.

Ulcerative colitis patients seen in consultation for surgery largely fall into three main groups: (1) those who have severe disease and are not responding to medications, whether it be in the hospital or as an outpatient; (2) those who have significant side effects of medications used to treat their colitis; and (3) patients who require surgery due to the presence of colonic neoplasia (dysplasia or colorectal cancer). Most patients with chronic ulcerative colitis have a disease course characterized by exacerbations and remissions. Exacerbations can be caused by viral or bacterial infections (for example, *Clostridium difficile* colitis) or by environmental factors, such as smoking cessation,

TABLE 1 Montreal Classification for Ulcerative Colitis (UC)

Extent		Location
E1	Ulcerative proctitis	Rectum
E2	Left-sided UC (distal UC)	Distal to splenic flexure
E3	Extensive UC (pancolitis)	Extends proximal to splenic flexure
Severity		**Definition**
S0	Clinical remission	Asymptomatic
S1	Mild UC	<4 stools/day (with or without blood), absence of systemic illness, normal inflammatory markers (ESR)
S2	Moderate UC	>4 stools per day, minimal signs of toxicity
S3	Severe UC	>6 bloody stools daily, pulse rate >90 beats/min, temperature >37.8°C, hemoglobin <10.5 g/100 mL, and ESR >30 mm/h

Modified from Satsangi J, Silverberg MS, Vermeire S, et al. The Montreal classification of inflammatory bowel disease: controversies, consensus, and implications. Gut. 2006;55:749–753.
ESR, erythrocyte sedimentation rate; UC, ulcerative colitis.

Smoking has opposite effects on the different types of inflammatory bowel disease. Cigarette smoking has a protective effect on ulcerative colitis, whereas it is known to exacerbate symptoms of Crohn's disease. In some patients, the use of nonsteroidal anti-inflammatory medications can also exacerbate colitis, as can severe emotional, work related, or other types of stress. There is usually concordance within families, meaning that if one member of a family has ulcerative colitis, another affected family member will usually have the same disease. In other words, having family members with mixed disease, for example, one member having ulcerative colitis and another having Crohn's disease, is unusual and often implies a misdiagnosis.

PRESENTING SYMPTOMS AND DIAGNOSIS

Diarrhea is the most common symptom of ulcerative colitis. This is often bloody diarrhea, accompanied by significant urgency. Patients often need to rush to get to the bathroom to avoid having episodes of incontinence. In addition, there is a great amount of tenesmus, where patients have a sensation of constantly needing to go to the bathroom as a result of significant mucosal irritation in the lower rectum. It is important to obtain stool cultures for ova and parasites, culture, and sensitivity as well as *C. difficile* toxin to exclude an infectious cause. Once this is done, endoscopy should be performed to obtain a visual inspection of the colon, to assess the extent of disease, and to obtain biopsy specimens for histologic diagnosis. Extent and severity of disease is graded using the Montreal Classification (Table 1). According to this system, the extent of ulcerative colitis can have one of three classifications, depending on the degree or extent of colonic involvement: E1 refers to ulcerative proctitis, with involvement limited to the rectum, E2 refers to ulcerative colitis limited to the left colon, and E3 refers to ulcerative colitis extending proximal to the splenic flexure including patients with pancolitis. The Montreal Classification also has a stratification for symptom severity, with S0 referring to asymptomatic disease, S1 referring to mild disease with 4 or fewer bowel movements a day without blood, and normal inflammatory markers; S2 referring to moderate disease with more than 4 bowel movements a day, but no signs of systemic toxicity, and S3 referring to severe disease with at least 6 bloody bowel movements a day, a pulse rate 90 beats/min or greater, temperature 37.8°C or higher, hemoglobin less than 10.5 g/dL, and an erythrocyte sedimentation rate (ESR) greater than 30 mm/hr. The Mayo scoring system is one of the most common endoscopic scoring systems used to grade the severity of ulcerative colitis (Table 2). In cases where the delineation between ulcerative colitis and Crohn's disease is not clear based on endoscopic, biopsies or endoscopic appearance, the term *inflammatory bowel disease, unclassified* is used. This is in contrast to the term *indeterminate colitis*, a term that is based solely on histologic diagnosis of colectomy specimens. Typical histologic signs of ulcerative colitis include crypt abscess formation, polymorphonuclear cells in the lamina propria, and mucosal ulceration. In severe forms, widespread inflammation can even proceed to frank tissue necrosis.

TABLE 2 Mayo Endoscopic Subscore for Ulcerative Colitis

Score	Disease Activity	Endoscopic Finding
0	Inactive	Normal
1	Mild	Erythema, decreased vascular pattern, mild friability
2	Moderate	Marked erythema, absent vascular pattern, friability, erosions
3	Severe	Spontaneous bleeding, ulceration

Modified from Lémann T, Bommelaer T, Ollivier G, et al. The modified Mayo endoscopic score (MMES): a new index for the assessment of extension and severity of endoscopic activity in ulcerative colitis patients. J Crohns Colitis. 2011;5:466–862.

MEDICAL THERAPY

Once the diagnosis is established, treatment is usually begun with aminosalicylate preparations, as shown in Table 3. If the disease becomes more severe or is not responsive to aminosalicylates, patients may be treated with oral or intravenous steroids. At this point, however, patients are frequently escalated to biologic therapy. Several biologics are approved for treatment of ulcerative colitis. For longer term maintenance, another option is antimetabolite therapy, also shown in Table 3. Many of these treatments are associated with an increased risk of non-Hodgkin's lymphoma with prolonged use. The use of biologics in combination therapy with antimetabolites can be associated with much higher complication rates. Because colectomy can be curative in ulcerative colitis patients, many believe that such aggressive medical therapy should not be pursued.

INDICATIONS FOR SURGERY AND CHOICE OF OPERATION

The frequency with which patients with ulcerative colitis present for surgery has been decreasing with the advent of newer treatments for ulcerative colitis, as outlined in the preceding section. However, many patients still present for surgery for ulcerative colitis. The most common indication for surgery is failure of medications to control symptoms of the disease. Less common reasons for surgery are the presence of severe extraintestinal manifestations, growth failure in children, or the presence of cancer or dysplasia. It is thought that,

TABLE 3. Medical Treatment of Ulcerative Colitis

Category	Example	Application Form	Expense
Probiotics	Lactobacillus, Bifidobacterium	Food, capsules, pills, powders	---+
Antibiotics	Metronidazole, ciprofloxacin, rifaximin	PO, IV	--
Aminosalicylates	Sulfasalazine	PO	-
	5-ASA products	PO, suppositories, enemas	--

Biologics	Infliximab	IV	+++$
	Adalimumab	SC	$
	Golimumab	IV	+++$
	Vedolizumab	IV	+++$

5-ASA, 5-aminosalicylic acid; IV, intravenous; PO, by mouth; SC, subcutaneous.
(From Galandiuk S, Crohn disease: In: Ashley DW, editor. Surgery. Hamilton, ON: Decker Medicine; May 2014.)

with the increasing use of biologic medications that prevent ongoing mucosal inflammation, in the future the frequency of surgery for cancer or dysplasia will greatly be decreased. This is due to the fact that the pathogenesis of cancer development in inflammatory bowel disease is cancer arising in a field of chronic inflammation. If the chronic inflammation is stopped early on, there will perhaps be a reduction in cancer incidence in this population. This is an outcome that is very much to be hoped for.

FAILURE OF MEDICAL THERAPY

Patients in this category fall into two groups, those who present for elective surgery having failed multiple treatments, and those presenting with fulminant disease requiring urgent or emergency surgery. We will deal first with the emergency cases.

Fulminant Colitis

In hospitalized patients in whom one is consulted for evaluation, one must be on the watch for the development of toxic megacolon. Toxic megacolon can occur with any type of acute colitis in which the mucosa sloughs, and the patient becomes septic due to loss of the barrier function of their colonic mucosa. These patients will exhibit tachycardia, fever, leukocytosis, and, if their colitis is severe enough, development of a colonic ileus with distention of their transverse colon. This is readily apparent on a plain abdominal film. By definition, this distention should be 5 cm or more on a plain abdominal film (Fig. 1). It should, however, be stressed that this colonic distention does not have to be present for a patient to have a toxic megacolon. The most important part of this term is "toxic," meaning that they are septic from their colitis. These patients also frequently have hypoalbuminemia because they are extremely malnourished from diarrhea; that is, they have a protein losing enteropathy from the severity of their colitis. In many cases, patients in this category may already have a colon that is almost autolytic and need urgent colectomy, or their colon will perforate. In these cases, subtotal colectomy and end ileostomy is the treatment of choice.

FIG. 1. Toxic megacolon. Abdominal film shows significant distention of the transverse colon in a 20-year-old man with acute ulcerative colitis.

Severe Disease

For the patient coming for an assessment for an elective operation, the two operations that are typically performed for ulcerative colitis not responding to medical therapy include the total proctocolectomy (TPC) with ileal J pouch–anal anastomosis (IPAA) and TPC with end ileostomy. The choice of which operation to perform is determined by the patient's mobility and their sphincter function. For patients with an intact sphincter function who are mobile, ileal J pouch–anal anastomosis provides for a good quality of life with good function. Patients with poor sphincter function and poor mobility will, however, be better served with an end ileostomy. Other factors, such as a patient's employment and body habitus, should also be taken into consideration. If a patient's employment does not permit them ready use of bathroom facilities, permanent ileostomy may be a better choice. Before offering an operation, the surgeon must be aware that the "perfect" results after ileal pouch–anal anastomosis for ulcerative colitis typically consist of five or six bowel movements during the day and one at night. Although this is not associated with urgency, imagine what a fireman or a miner or someone working on machinery where they are unable to take a break for 12 hours would do with this type of operation. In such individuals ileal J pouch–anal anastomosis may not be the wisest choice but because you can do an operation, does not mean you should do it. In patients who are on biologic therapy, overall, increased infectious complications have been described after surgery. Generally speaking, the trend has been to go toward three stage operations in many patients. For example, first doing a subtotal colectomy and ileostomy, then proceeding with the proctectomy and ileal pouch–anal anastomosis and temporary ileostomy, and then a third operation to close the ileostomy.

DYSPLASIA/CANCER

The majority of data regarding frequency of malignancy in ulcerative colitis are based on older studies predating our current knowledge of

the increased risk of colon cancer in these patients. It is difficult to pinpoint accurate statistics regarding the frequency of dysplasia and cancer in ulcerative colitis. It is generally accepted that the risk of cancer in these patients is approximately 4 times the risk in the general population, beginning 8 years after disease onset. It is recommended that, beginning at 8 years of disease duration, these patients undergo an annual colonoscopy with surveillance biopsies. It formerly was believed that one would have to do at least 33 colonic biopsies to have a fairly good representative sample to detect dysplasia. However, today, the technique of chromoendoscopy is increasingly being used to perform targeted endoscopic biopsies. This involves spraying the colon as one withdraws the colonoscope with dyes such as indigo carmine to highlight suspicious areas for targeted biopsy. There have been long-term studies that have shown that polypoid areas of dysplasia can be safely resected, and these patients were followed up over time without undergoing colectomy and, more importantly, without developing colon cancer. Although this is still a controversial field, it appears that a select group of patients can be safely managed in this conservative manner without colectomy provided that they are willing to undergo close endoscopic surveillance. Patients with multifocal dysplasia, those with flat-elevating dysplasia, and patients with colorectal cancer obviously will require colectomy.

C. DIFFICILE INFECTIONS

An acute *C. difficile* infection can cause a significant exacerbation of inflammatory bowel disease and can lead to toxic megacolon. In a patient with an acute flare, stool cultures should always be obtained to exclude coexisting *C. difficile* infection.

BLEEDING

The presence of severe lower gastrointestinal bleeding is a relatively uncommon indication for emergency surgery in patients with ulcerative colitis.

GROWTH FAILURE IN CHILDREN

In children, 22% will present with growth failure, anemia, or other extraintestinal manifestations as their predominant initial feature. Although it is more common in children with Crohn's disease, growth failure occurs in approximately 10% of children with ulcerative colitis. The cause of this is multifactorial and can be due to issues such as malabsorption, decreased caloric intake, cytokine-induced growth hormone resistance, and use of corticosteroids among others. Inappropriate treatment and monitoring may result in failure of achieving optimal adult bone mass, placing them at risk of fractures and growth retardation. Obtaining bone densitometry to determine bone mineral density may be useful in monitoring pediatric patients. Failure to perform surgery in a timely manner may result in delayed onset of puberty, or short stature.

EXTRAINTESTINAL MANIFESTATIONS

In some cases, severe extraintestinal manifestations may be an indication for surgery. There are certain extraintestinal manifestations such as ankylosing spondylitis and primary sclerosing cholangitis that are not affected by surgery. Others, such as some types of mono-articular arthritis, may improve with surgery.

SURGERY

In the emergency setting, total abdominal colectomy with end ileostomy and Hartmann's pouch is the procedure of choice. In the semi-emergency setting, the most common choices include colectomy with ileal pouch–anal anastomosis, total proctocolectomy with end ileostomy, and, less commonly, total proctocolectomy with continent ileostomy. We will discuss each of these.

SUBTOTAL COLECTOMY WITH END ILEOSTOMY AND HARTMANN'S POUCH

In patients who present with toxic megacolon and need urgent surgery, a subtotal colectomy with end ileostomy and Hartmann's pouch is the preferred operation. If these patients have a significant amount of bowel distention and ileus, an open colectomy is often best, because there is less of danger in the abdomen, and laparoscopy is not safe. These colons can be extremely fragile. For this reason, it is not uncommon for the staple line in the Hartmann's stump to dehisce several days after surgery. It is often wise to keep a longer Hartmann's stump and incorporate this between the leaves of the fascia, as shown in Fig. 2, closing the subcutaneous tissue over this. In this manner, if the Hartmann's stump dehisces, one merely has a minor wound infection, which when opened, leaves one with controlled mucous fistula, rather than a pelvic abscess. In cases where the patient is less ill, this procedure can be performed laparoscopically, making the second surgery easier because fewer adhesions are present. Leaving a longer rectal stump also makes the performance of the next stage of the procedure, such as a J-pouch, easier, because the rectal dissection has not yet been started and all planes are virgin.

TPC AND IPAA

Route of Access and Type of Anastomosis

Ileal pouch–anal anastomosis, shown schematically in Fig. 3, can be done via several different routes of access: open, laparoscopically, or robotically. No matter the route of access, we refer readers to the chapter in the *7th Edition of Mastery of Surgery* in the Suggested Reading list. There are several technical components common to all types of access. The colectomy is performed with careful preservation of the ileocolic vessels. The ileal pouch–anal anastomosis can be performed either with a stapled or a hand-sewn approach. Conventionally, a stapled approach will be used because of its technical ease and rapidity. This depends on whether there is concern for dysplasia, cancer, or adenomatous polyp disease in the rectum and its location. If there is concern for dysplasia or cancer in the lower rectum, or polyposis extending to the dentate line, a hand-sewn approach with

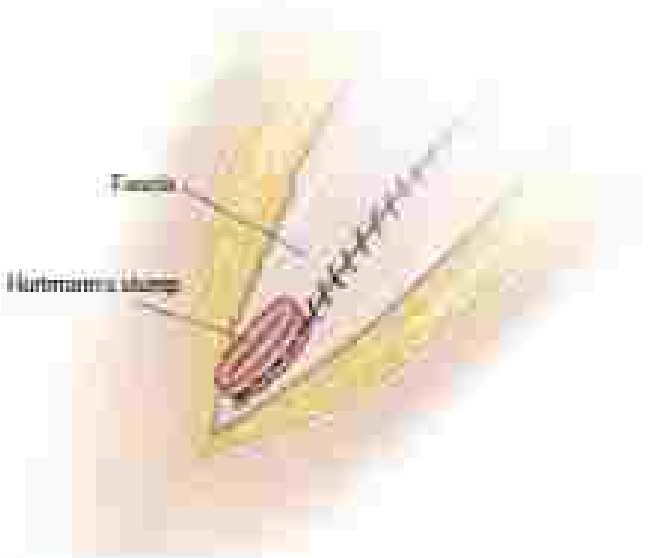

FIG. 2 Hartmann's stump between fascia. The rectal stump is interposed between the fascia during closure of a subtotal colectomy for toxic megacolon.

can moderate to often used. A hand-sewn approach is more technically challenging and much less commonly done than previously.

J-Pouch and Rectal Transection

A J pouch is typically constructed using two firings of a 100-mm linear stapler. The ideal length of the J pouch is 15 cm. I prefer to close the enterotomy in the apex of the J pouch through which the staplers have been fired, that is, common enterotomy, with another firing of a 75-mm linear stapler after the anvil of a 29-mm circular endoluminal stapler has been inserted into the pouch. Then, pierce the apex of the J pouch with the shaft of this anvil, which avoids having to place a purse-string suture. I use a curved stapler to divide the rectum. In cases that are performed laparoscopically or robotically, an Echelon or similar type of linear stapler can be used to divide the lower rectum. The plane of transection should always be verified by digital rectal examination. One would optimally like to have less than 1 cm of remaining rectum left. It must be that this remains, after surgery, patients can incur "cuffitis," which is inflammation due to residual inflammatory bowel disease in the remnant rectum distal to the ileal pouch rectal anastomosis. Ideally, one would like this to achieve an ileal pouch *anal* anastomosis, rather than an ileal pouch rectal anastomosis.

Mesenteric Lengthening Maneuvers

Many patients with ulcerative colitis may have gained weight due to steroid use or, just based on body habitus, may have a thick mesentery. For this reason, it may be difficult to get the small bowel to reach down to the pelvis. One easy tip is that if the apex of the J pouch can easily reach down to the symphysis pubis, there should be little tension on the anastomosis. It is important to mobilize the small bowel mesentery away from the retroperitoneum up to the level of the duodenum to allow it to stretch easily down to the pelvis. If there is tension, there are a number of techniques that can be used to provide additional mesenteric length. One of these is "peritoneal windowing." This can be achieved by tacking the peritoneum on the anterior and posterior aspects of the small bowel mesentery in a stepladder fashion (Fig. 4). This maneuver will provide significant additional mesenteric length. If these maneuvers alone do not provide adequate length, another maneuver that will frequently provide additional length is division of either the ileocolic or superior mesenteric arteries as shown schematically in Fig. 5. If tension is applied at the apex of the J pouch, one can feel which of these vessels is more taut. This vessel can then be divided. This typically will provide an extra 2 to 3 cm of additional mesenteric length. If none of these maneuvers are sufficient, configuration of a different type of pouch, for example, an S pouch, may be necessary, because this sometimes will reach, when a J pouch will not. S pouches are, however, associated with other emptying problems, such as efferent limb syndromes, and should generally be avoided, if possible.

Fecal Diversion

A loop ileostomy is generally constructed approximately 40 cm proximal to the J pouch or as distal as can be performed without undue tension. Because the superior mesenteric artery is fairly tethered along the spine, creating a loop ileostomy, especially in individuals with a short mesentery or those who are significantly above ideal body weight, can sometimes be a challenge. In patients in whom there is significant tension, use of an ileostomy rod is sometimes necessary. Because of the tension involved here, these ileostomies are often less than ideal, meaning that they sometimes are more recessed than end ileostomies and may require use of a convex ileostomy appliance to have significant eversion so that patients do not have postoperative skin irritation. The use of an ileostomy belt is necessary with these appliances as well. In creating a loop ileostomy, it is helpful to wrap the bowel with a sheet of hyaluronic film to reduce the amount of postoperative adhesions. This facilitates closure of the ileostomy at 8 weeks after surgery. The more proximal the ileostomy is located, the greater the likelihood that a higher amount of antidiarrheal medication will be required in the postoperative period. It is important not to discharge the patient from the hospital unless the stoma output is less than 1 L/24 h for most. The patient should also be instructed that, in general, he or she should not be emptying the ileostomy appliance more than 5 times a day if they let the ileostomy appliance get half full before emptying it. More than this will lead to dehydration. Dehydration is one of the most common reasons for readmission to the hospital, and, in this era where readmission is considered a parameter of bad care, this is particularly important. Technical postoperative complications include infectious complications, such as leaks, pelvic abscess, pouch vaginal fistulas, or "cuffitis" from leaving a too long rectal segment of residual inflammatory bowel disease in situ.

After surgery, in assessing these patients, digital examination will ensure that these patients are not developing an ileal pouch anal anastomotic stricture. Examination in the office is focused on signs of dehydration. Typically, a gastrografin enema is performed on these patients anywhere from 4 to 6 weeks after surgery. If this shows intact healing of the ileal pouch–anal anastomosis, closure of the loop ileostomy can be done anywhere after 8 weeks after the initial surgery. The most important view to obtain on gastrografin enema is a lateral view, because ileal pouch–anal anastomotic leaks typically occur posteriorly, and these may not be seen on studies that only show anterior projection views (Fig. 6).

Ileal pouch–anal anastomosis can be done in a one-stage approach, and this is largely an issue of surgeon judgment. These patients should not be on a dose of prednisone more than 20 mg and should not be on medications that significantly impair wound healing or increase the rate of infection, and, during surgery, there should be no tension on the ileal pouch–anal anastomosis. In patients with a loop ileostomy at the time of loop ileostomy reversal, closure can often be done without a resection by simply unwrapping the stoma and simply closing the enterotomy. The wounds can be closed primarily, left open, or closed in a purse-string manner.

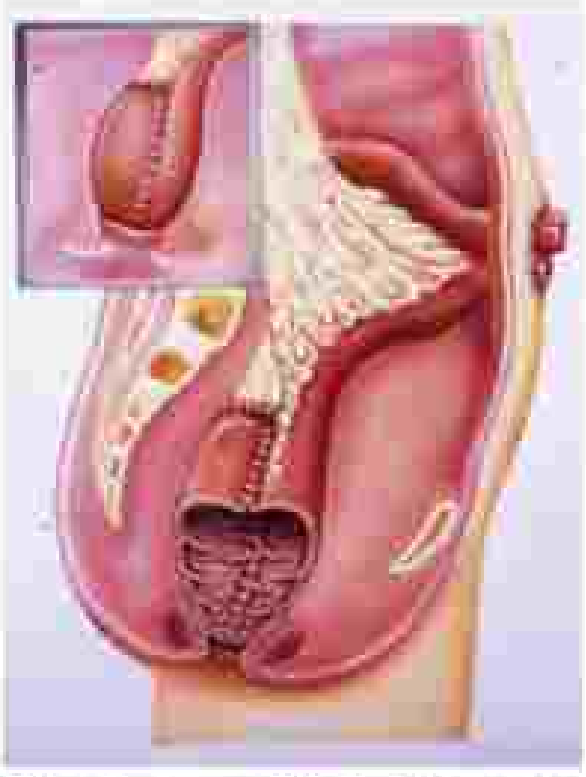

FIG. 3 Schematic representation of an ileal pouch–anal anastomosis with temporary diverting loop ileostomy.

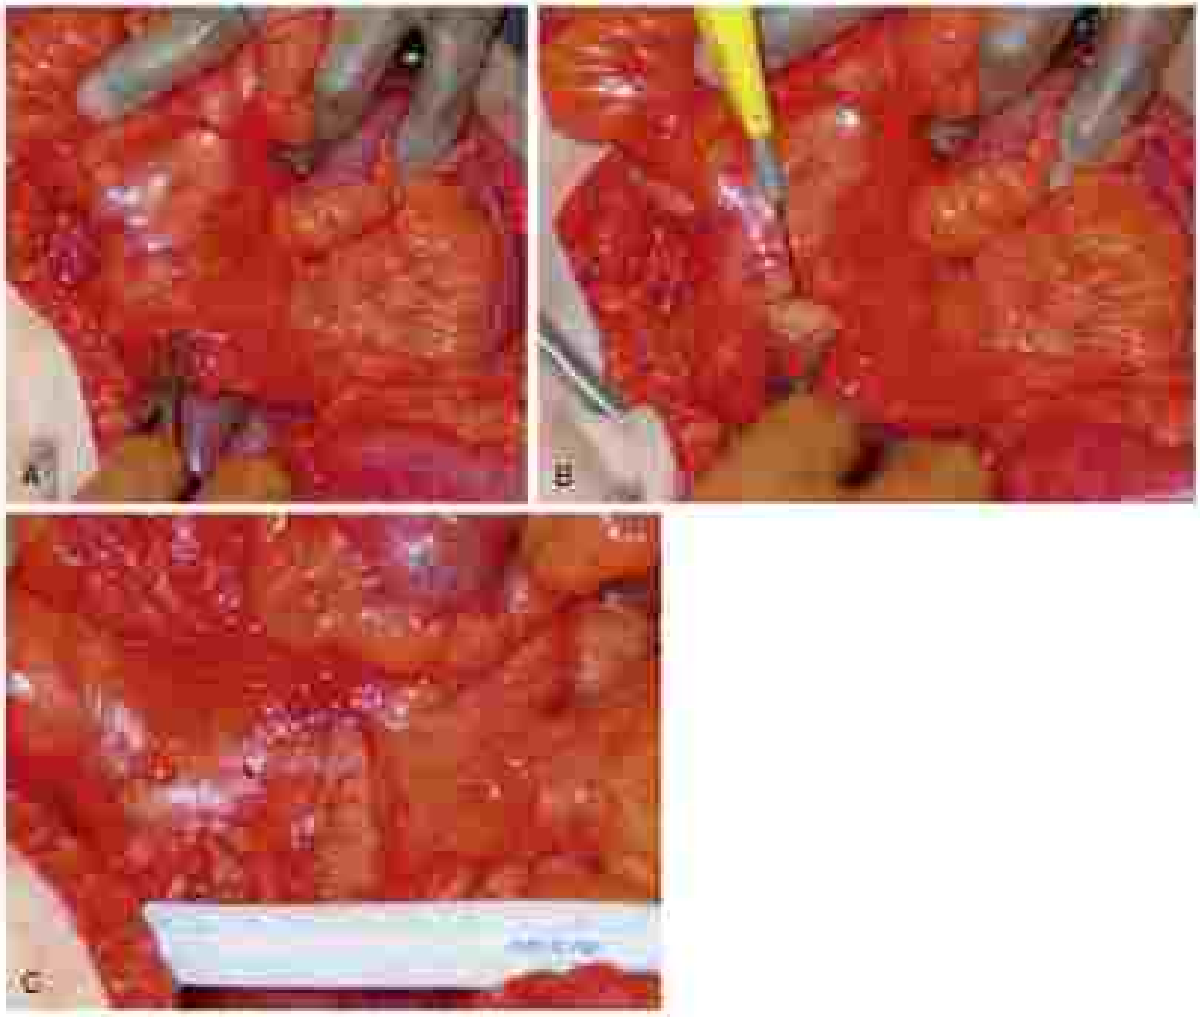

FIG. 4 Mesocolic lengthening maneuver. (A) The mesentery of the small bowel is elevated away from the underlying vessels using a hemostat. (B) Electrocautery is used for division of the mesenteric peritoneum on "peritoneal windowing." (C) Once the peritoneum has been divided, each of the areas of peritoneal windowing is shown to have resulted in more than 1 cm added length.

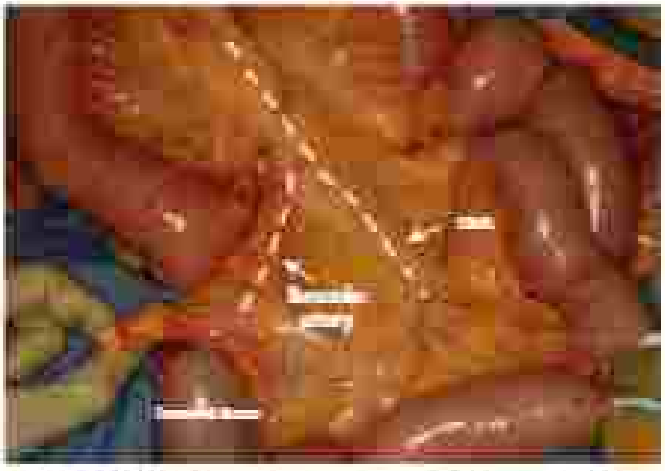

FIG. 5 Ileocolic and superior hemorrhoidal vessels. If tension is placed on the apex of the ileal pouch, the surgeon can assess width of these vessels to assess greater tension. (From Gonzalez S, Pemberton JH, Kelly KA, Dozois EJ, Ready JB, Sarr MG. Ileal pouch-anal anastomosis and ileoanal reservoir using the double-stapled technique: current status after 1,005 consecutive cases. J Am Coll Surg. 2005;201:735–740.)

Postoperative Course

In the postoperative period, the normal functional results of an ileal pouch anastomosis would be like to its bowel movements a day, with one nocturnal bowel movement. A majority of patients need to take antidiarrheal medications in the early postoperative period, because the ileal pouch only begins significant functional improvement in the first 6 months after surgery. The most common complication after surgery is pouchitis, characterized by episodes of frequent watery bowel movements and cramp abdominal pain, sometimes accompanied by low-grade fever. These symptoms are quickly ameliorated by antibiotics such as metronidazole or ciprofloxacin. Some patients may experience chronic pouchitis or repeated or continuing flares of pouchitis. Interestingly, patients undergoing ileal pouch anal anastomosis for familial polyposis rarely have these complications. Conversely, patients who have ulcerative colitis have a very high frequency of chronic pouchitis and, for that reason, are generally considered poor candidates for ileal pouch anal anastomosis. When undergoing this procedure, they must be counseled at length regarding the relatively poor expected functional results.

In patients who undergo this procedure for inflammatory disease or in whom indeterminate colitis is diagnosed on the colectomy specimen, there is a significant risk of being eventually diagnosed with Crohn's disease. Many of these patients can still retain their ileal pouch; however, a significant number of these patients do have to be maintained on immunosuppressive medication to do so.

FIG. 6 Pouchogram. A lateral view during gastrografin enema is obtained to assist in locating a posterior leak. The contrast is shown at the tip, the contrast-filled ileal pouch is in the middle.

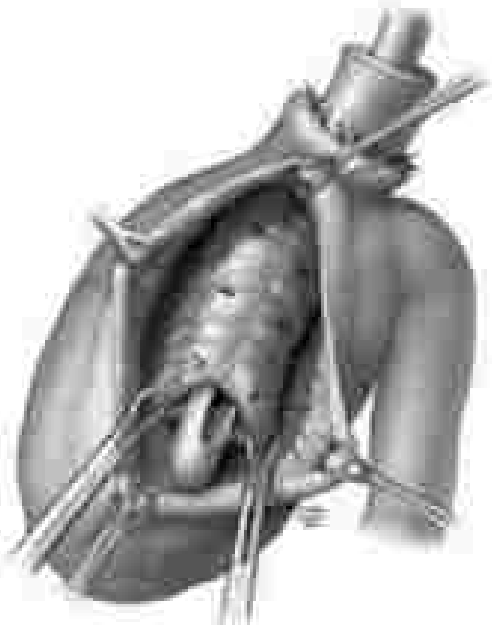

FIG. 7 Kock pouch, a continent pouch that allows patients to self-catheterize. The intussuscepted segment of ileum distal to the ileostomy provides for continence. A catheter is passed through the ileostomy during contraction of the pouch as shown. *(From Dukes C. J. Colon, Rectum and Anus. London: Butterworth's Medical Publications, 1957.)*

Impaired Fertility

One of the relatively recently discovered complications associated with ileal pouch–anal anastomosis is fertility impairment. Women undergoing this procedure should be counseled that undergoing this procedure may significantly impair their ability to become pregnant by natural means. Although women who undergo this procedure can become pregnant easily with in vitro fertilization, altered tubal anatomy due to adhesions may significantly reduce fertility. They should be made aware of this before surgery. In addition, because patients with an ileal pouch–anal anastomosis usually have bowel movements that are the consistency of pudding or oatmeal, intact sphincter function is imperative. Obstetric anal sphincter injury is always a risk with pregnancy. If there is any increased risk of sphincter damage, that is, with a prima gravida, a very large child, or breech delivery, women should be counseled regarding this, and this should be discussed with the patient's obstetrician. A cesarean section is preferable to a sphincter injury.

TPC AND END ILEOSTOMY

End ileostomy, although not popular among patients, can lead to an extremely good quality of life. It is associated with the need to wear a stoma appliance or drainage bag. Although there is a great amount of fear on the part of the patient before surgery, this can lead to a great improvement in quality of life. Stoma appliances are air and water tight. They typically need to be emptied four or five times a day. Patients can go swimming and participate in sports activities with a stoma appliance. For the patient who has had a sphincter injury, for those who are elderly with decreased mobility, or those who have jobs that do not allow them to have access to bathroom facilities, this operation is still the preferred option, and it has the advantage of being a one-stage operation. When this is performed for benign disease, it is performed with an intraphincteric proctectomy. Unlike an abdominal perineal resection, where the entire external anal sphincter is excised for cancer, here, dissection is performed between the internal and external anal sphincter, without excising the levator muscle, to create a smaller wound that will heal more rapidly and provide for stronger pelvic floor.

TPC WITH CONTINENT ILEOSTOMY (KOCK POUCH)

This operation was very popular in the early 1970s, before the development of the ileal pouch–anal anastomosis. It was originally developed by Nils Kock, from Sweden, in 1969. Many modifications, such as that by Barnett, exist, and it is sometimes performed for patients who have failed ileal pouch–anal anastomosis. In this operation an ileostomy is created with an intussuscepted segment of small bowel positioned between the ileostomy and the abdominal wall. This intussuscepted piece of bowel serves as a continence valve (Fig. 7). Patients "catheterize" the stoma using a special catheter multiple times a day to empty their ileostomy and avoid the need to wear a stoma appliance. These stomas are continent for air, gas, and liquid stool but have a high rate of requiring revisional surgery, and this surgery works best in thin individuals. This operation has fallen out of favor and is performed much less frequently today, because this continence inferring intussuscepted segment of bowel frequently tends to dysmotility, requiring operative revision. Furthermore, when this operation fails, a large amount of bowel is lost because of the amount of bowel needed to create the continent "nipple valve" and the stoma reservoir is typically 50 centimeters.

CONCLUSION

In conclusion, surgeons will likely be seeing fewer patients in consultation for surgery for ulcerative colitis in coming years because of more effective medical therapy. It is, however, expected that, when they do see these patients, many of these will be seen due to failed medical management. These patients will be significantly immunosuppressed. Performing staged procedures should be considered. There is a significant risk of these patients also having coexisting *C. difficile* infections, and this should always be checked for to ensure that therapy for coexisting *C. difficile* infection does not need to be instituted. Indications for surgery for cancer or dysplasia will likely be seen less often in the coming years. When selecting an operation, good patient selection is key. For ileal pouch–anal anastomosis, good sphincter function and good patient mobility are required.

Management of Toxic Megacolon

Madhavi V. Nishtala, MD, Gautam Bandoo, MD, and Scott A. Steele, MD, MBA, FACS, FASCRS

Toxic megacolon is a rare, life-threatening complication of colitis. It is defined by the total or segmental nonobstructive dilatation of the colon in the presence of sepsis. It is often a complication of Crohn's disease, ulcerative colitis, or various infectious colitis, most commonly *Clostridium difficile*–associated disease. Less common causes include ischemic colitis, volvulus, diverticulitis, and obstructive colon cancer. This chapter reviews the evaluation and management of patients with toxic megacolon.

The overall incidence of toxic megacolon (TM) is unknown, with different etiologies having varying rates of occurrence. Lifetime incidence of TM developing from ulcerative colitis (UC) ranges from 1% to 2.5%, with a slightly higher incidence in patients admitted to the hospital for UC, ranging from 4% to 17%. The incidence in patients with antibiotic-associated pseudomembranous colitis (*i.e.*, *Clostridium difficile*) is up to 3% and is expected to increase proportionately with increasing prevalence and potency of this disease.

It is important to understand that any inflammatory condition of the colon can lead to colonic dilation and TM. This occurs most commonly from the inflammatory bowel diseases (IBDs) of Crohn's colitis and UC, infectious causes including *C. difficile*, *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Escherichia coli* O157, and ischemic colitis. Less frequent causes of TM include parasitic infection with *Entamoeba histolytica* and cryptosporidium and cytomegalovirus colitis in patients with HIV or AIDS, pseudomembranous colitis secondary to methotrexate therapy, and Kaposi's sarcoma (Box 1). Additional risk factors are hypokalemia, hypomagnesemia, discontinuation of 5-aminosalicylate agents or steroids, barium enemas, and drugs that slow colonic motility, including narcotics and antiadrenergic and anticholinergic medications. Interestingly, colonoscopy has also previously been identified as an exacerbating factor to colitis, subsequently leading to TM, although it is unclear whether it is the bowel preparation or the actual scope that renders the colon susceptible.

Although the pathogenesis of TM is not fully understood, several mechanisms have been described that contribute to the disease process. In patients with IBD, it is thought that mucosal inflammation leads to the release of inflammatory mediators and bacterial products, increasing the amounts of inducible nitric oxide synthase in the muscularis propria, ultimately shifting excitatory nitric oxide–nitric oxide inhibitory smooth muscle tone, causing paralysis and dilatation of the colonic wall. Transmural extension of this inflammatory response beyond the mucosa into the smooth muscle layer with replacement by granulation tissue is characteristic of TM. Further, in TM, the muscle layer is invaded by neutrophils, which produce more nitric oxide, cytokines, proteolytic enzymes, and leukotriene B4. These inflammatory factors further damage the muscular layer, leading to bacterial translocation and bacteremia. While taken up systemically, these cytokines, in conjunction with bacteremia, lead to signs of toxicity, including tachycardia, hypotension, fever, altered mental status, lower abdominal tenderness and distention with or without peritonitis. Similar mechanisms are also at play with other inflammatory and infectious processes, although again, the definitive and universal pathogenesis is yet to be fully elucidated.

DIAGNOSIS

The diagnosis of TM relies on both clinical and radiologic findings. A thorough history and physical examination must first be obtained, including history of IBD diagnosis with extent of colonic involvement and medical therapy, recent hospitalizations and antibiotic use, and use of medications including corticosteroids or antimotility or chemotherapeutic agents. The majority of patients present with the signs and symptoms of colitis, including diarrhea (frequently bloody), fevers, chills, and abdominal cramping. As the onset of TM, constitutional signs such as fever, tachycardia, or hypotension develop. Altered mental status, abdominal distention and tenderness, constipation, obstipation, and reduced bowel sounds may also occur. Peritonitis is highly suspicious for perforation. A markedly decreased level of consciousness, analgesics, or high doses of corticosteroids may mask abdominal tenderness and other signs or symptoms of TM.

Jalan criteria is currently the best accepted criteria used to make a clinical diagnosis of TM. A clinical diagnosis of TM is made by fulfilling any three of Jalan's criteria: fever higher than 101.3°F (>38.5°C), heart rate greater than 120 beats/min, white blood cell count higher than 10.5 × 10⁹/L, or anemia. Additionally, patients must have one of these signs: dehydration, altered sensorium, electrolyte disturbances, or hypotension (Box 2).

Plain abdominal radiographs are highly useful in diagnosing and monitoring the progression of TM. On supine films, typical features include dilation of the transverse or right colon, usually between 6 and 15 cm (Fig. 1). The descending colon, sigmoid colon, and rectum rarely appear distended. On upright films, multiple air fluid levels in the colon and thickening of the colon wall are often present, with absence of normal haustral patterns. Air filled crevices between large pseudopolypoid projections in the colonic lumen may indicate deep mucosal ulcerations. Repeat radiographs are indicated for changing clinical status. Although the colonic absolute width on the radiograph aids with diagnosis of TM, the overall clinical picture of the patient is more important because systemic toxicity with colonic dilatation is seen in patients with acute obstruction from volvulus, polyps, tumors, and intraluminal obstructing tumors. For patients with obstructing disease, there is no air in the colon below the point of obstruction. Further investigation with barium enema or colonoscopy may be required to characterize the location and type of obstruction.

Ultrasonography and computed tomography (CT) may be used in addition to plain films to confirm diagnosis and identify the underlying cause of the colitis. Typical signs of severe colitis include diffuse colon wall thickening, thickened haustra with alternating bands of high and low density (accordion sign), multilayered appearance resulting from varied densities of edematous mucosa, hyperemic mucosa (target sign), and pericolic fat stranding (Fig. 2). CT imaging can also determine the extent and severity of disease, including

Management of Toxic Megacolon

Madhuri V. Nishtala, MD, Cigdem Bastaci, MD, and Scott R. Steele, MD, MBA, FACS, FASCRS

Toxic megacolon is a rare, life-threatening complication of colitis. It is defined by the total or segmental nonobstructive dilatation of the colon in the presence of sepsis. It is often a complication of Crohn's disease, ulcerative colitis, or various infectious colitis, most commonly *Clostridium difficile*–associated disease. Less common causes include ischemic colitis, volvulus, diverticulitis, and obstructive colon cancer. This chapter reviews the evaluation and management of patients with toxic megacolon.

The overall incidence of toxic megacolon (TM) is unknown, with different etiologies having varying rates of occurrence. Lifetime incidence of TM developing from ulcerative colitis (UC) ranges from 1% to 2.5%, with a slightly higher incidence in patients admitted to the hospital for UC, ranging from 4% to 17%. The incidence in patients with antibiotic-associated pseudomembranous colitis (*i.e.*, *Clostridium difficile*) is up to 3% and is expected to increase proportionately with increasing prevalence and potency of this disease.

It is important to understand that any inflammatory condition of the colon can lead to colonic dilation and TM. This occurs most commonly from the inflammatory bowel diseases (IBDs) of Crohn's colitis and UC, infectious causes including *C. difficile*, *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Escherichia coli* (*E. coli*), and ischemic colitis. Less frequent causes of TM include parasitic infection with *Entamoeba histolytica* and cryptosporidium and cytomegalovirus colitis in patients with HIV or AIDS, pseudomembranous colitis secondary to methotrexate therapy, and Kaposi's sarcoma (Box 1). Additional risk factors are hypokalemia, hypomagnesemia, discontinuation of 5-aminosalicylate agents or steroids, barium enemas, and drugs that slow colonic motility, including narcotics and antiadrenal and anticholinergic medications. Interestingly, colonoscopy has also previously been identified as an exacerbating factor to colitis, subsequently leading to TM, although it is unclear whether it is the bowel preparation or the actual scope that renders the colon susceptible.

Although the pathogenesis of TM is not fully understood, several mechanisms have been described that contribute to the disease process. In patients with IBD, it is thought that mucosal inflammation leads to the release of inflammatory mediators and bacterial products, increasing the amounts of inducible nitric oxide synthase in the muscularis propria, ultimately yielding excessive nitric oxide. Nitric oxide inhibits smooth muscle tone, causing paralysis and dilatation of the colonic wall. Transmural extension of this inflammatory response beyond the mucosa into the smooth muscle layer with replacement by granulation tissue is characteristic of TM. Further, in TM, the muscle layer is invaded by neutrophils, which produce more nitric oxide, cytokines, proteolytic enzymes, and leukotriene B4. These inflammatory factors further damage the muscular layer, leading to bacterial translocation and bacteremia. When taken up systemically, these cytokines, in conjunction with bacteremia, lead to signs of toxicity, including tachycardia, hypotension, fever, altered mental status, lower abdominal tenderness and distention with or without peritonitis. Similar mechanisms are also at play with other inflammatory and infectious processes, although again, the definitive and universal pathogenesis is yet to be fully elucidated.

DIAGNOSIS

The diagnosis of TM relies on both clinical and radiologic findings. A thorough history and physical examination must first be obtained, including history of IBD diagnosis with extent of colonic involvement and medical therapy, recent hospitalizations and antibiotic use, and use of medications including corticosteroids or antimotility or chemotherapeutic agents. The majority of patients present with the signs and symptoms of colitis, including diarrhea (frequently bloody), fevers, chills, and abdominal cramping. As the onset of TM, constitutional signs such as fever, tachycardia, or hypotension develop. Altered mental status, abdominal distention and tenderness, constipation, obstipation, and reduced bowel sounds may also occur. Peritonitis is highly suspicious for perforation. A markedly decreased level of consciousness, analgesics, or high doses of corticosteroids may mask abdominal tenderness and other signs or symptoms of TM.

Jalan criteria is currently the best accepted criteria used to make a clinical diagnosis of TM. A clinical diagnosis of TM is made by finding any three of Jalan's criteria: fever higher than 101.5°F (>38.5°C), heart rate greater than 120 beats/min, white blood cell count higher than 10.5 × 10⁹/L, or anemia. Additionally, patients must have one of these signs: dehydration, altered sensorium, electrolyte disturbances, or hypotension (Box 2).

Plain abdominal radiographs are highly useful in diagnosing and monitoring the progression of TM. On supine films, typical features include dilation of the transverse or right colon, usually between 6 and 15 cm (Fig. 1). The descending colon, sigmoid colon, and rectum rarely appear distended. On upright films, multiple air fluid levels in the colon and thickening of the colon wall are often present, with absence of normal haustral patterns. Air filled crevices between large pseudopolypoid projections in the colonic lumen may indicate deep mucosal ulcerations. Repeat radiographs are indicated for changing clinical status. Although the colonic absolute width on the radiograph aids with diagnosis of TM, the overall clinical picture of the patient is more important because systemic toxicity with colonic dilatation is seen in patients with acute obstruction from volvulus, polyp, tumors, and intraluminal obstructing tumors. For patients with obstructing disease, there is no air in the colon below the point of obstruction. Further investigation with barium enema or colonoscopy may be required to characterize the location and type of obstruction.

Ultrasonography and computed tomography (CT) may be used in addition to plain films to confirm diagnosis and identify the underlying cause of the colitis. Typical signs of severe colitis include diffuse colon wall thickening, thickened haustra with alternating bands of high and low density (accordion sign), multilayered appearance resulting from varied densities of edematous mucosa, hyperemic mucosa (target sign), and pericolic fat stranding (Fig. 2). CT imaging can also determine the extent and severity of disease, including

BOX 1 Etiologies of Toxic Megacolon

Inflammatory
- Crohn's disease
- Ulcerative colitis

Infectious
- *Clostridium difficile*
- *Salmonella, Shigella, Yersinia, Campylobacter*
- *Cryptosporidium*
- *Entamoeba*
- *Cytomegalovirus*

Ischemia

Malignancy: Kaposi's sarcoma

Medications
- Discontinuation of steroids
- Opioids
- Anticholinergics
- Chemotherapy

Other
- Hypokalemia, hypomagnesemia
- Barium enema
- Colonoscopy

BOX 2 Diagnosis of Toxic Megacolon

Clinical Presentation

Diarrhea, bloody diarrhea
Constipation, obstipation
Abdominal pain and tenderness
Abdominal cramping, distension
Decreased bowel sounds

Radiographic Findings

Dilation of transverse or ascending colon >6 cm
Small bowel and gastric distension
Computed tomography: colonic dilation, diffuse colonic wall thickening, submucosal edema, pericolic stranding, ascites, perforations, abscesses, ascending peritonitis

Jalan's Criteria (≥3 of the Following Signs)

Fever >100.2°F (>38.5°C)
Heart rate >120 beats/min
White blood cell count >10.5 ×10⁹/L
Anemia

Modified from Cast JE, Stark PL. A new look at toxic megacolon: an update and review of incidence, etiology, pathogenesis, and management. *Am J Gastroenterol* 2003;98(11):2320–31.

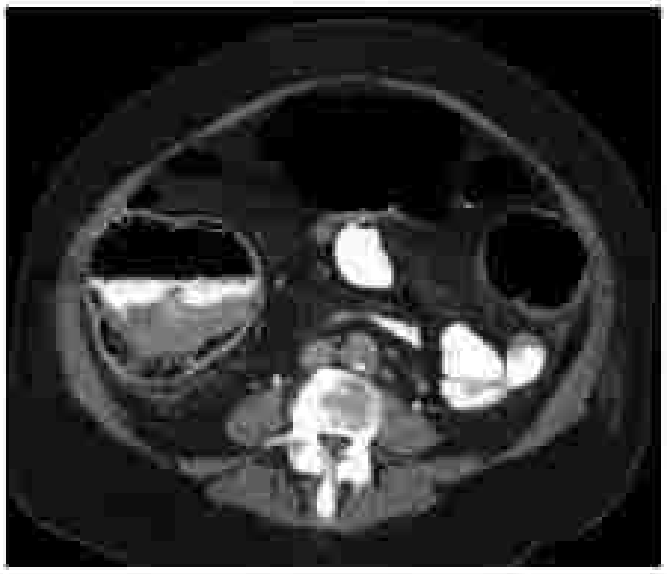

FIG. 2 Computed tomography scan demonstrating axial view of colonic dilation, diffuse colon wall thickening, mucosal edema, and pericolic fat stranding characteristic of toxic megacolon.

complications such as colonic perforation and vascular compromise. This imaging is particularly helpful in patients with AIDS who may have multiple simultaneous abdominal disease processes.

Laboratory studies may have nonspecific abnormalities that reveal the extent of the systemic toxicity in TM. Leukocytosis with a left shift is commonly found, particularly for patients with *C. difficile*–associated diarrhea, in which the white blood cells may commonly exceed 30,000. Steroid use may cause or exaggerate this shift. Immunocompromised patients will instead exhibit neutropenia. Anemia may occur because of occult blood loss. Electrolyte abnormalities are common, with metabolic alkalosis occurring from volume depletion, hypokalemia, and hypoalbuminemia (<3 g/dL), all of which indicate a poor prognosis. Metabolic acidosis suggests ischemic colitis. Elevations in the erythrocyte sedimentation rate and serum C-reactive protein are common. Stool samples must be sent for culture, ova and parasites, and *C. difficile* toxin detection. Although the most sensitive assay for *C. difficile* is stool culture, results are slow and can cause a delay in diagnosis. Real-time polymerase chain reaction (PCR) assay is a more expedient gold standard test used to detect *C. difficile* toxin. PCR is highly sensitive and can also identify incidental carriers of *C. difficile*, but does not distinguish between colonization and clinical infection. Enzyme immunoassays for *C. difficile* glutamate dehydrogenase are

rapid screening tests for infection, but cannot distinguish between toxigenic and nontoxigenic strains and must be followed by PCR testing in a two-step process. Enzyme immunoassays for *C. difficile* toxins A and B also yield results within hours; although this assay is inexpensive and commonly used, it has poor sensitivity. Because bacteremia occurs in 25% of patients with TM, blood cultures and antimicrobial must also be obtained.

Although endoscopy may be of value to determine the underlying diagnosis, it is highly risky and may perforate the colon. Limited sigmoidoscopy without bowel preparation is considered safe and can be used to differentiate between inflammatory or infectious disease in the rectum or sigmoid colon. It is recommended to only advance the endoscope to obtain histologic diagnosis; however, lower endoscopy is limited and may still miss disease processes that spare the rectum and sigmoid such as cytomegalovirus inclusion bodies in ascending colon ulcers and rectum-sparing pseudomembranous *C. difficile* colitis. Endoscopy must use minimal to no insufflation to prevent perforation or worsening ileus. Colonoscopy should never be used except for managerial patients who require endoscopic decompression. Colonoscopic decompression is a technically difficult procedure and contraindicated in patients with colonic perforation or peritonitis. A decompression tube should be placed at the time of colonoscopy to reduce the necessity for repeated colonoscopy in the future. Air is suctioned from the colon with the decompression tube in place as the colonoscope is gently removed. To minimize air infusion, the entire colon should not be examined and the decompression tube should not be delivered into the cecum. The decompression tube should be placed to gravity drainage and flushed every 4 to 6 hours.

Depending on the underlying disorder, gross endoscopic appearance may vary as well. *C. difficile* colitis can present with erythema, friability, and characteristic pseudomembranes. Crohn's disease appears as rectum-sparing discontinuous longitudinal ulcerations, small aphthous ulcers, and cobblestoning of the mucosa. The characteristics of UC include proximally spreading rectal ulcers, edematous mucosa, erythema, mucosal friability, and loss of vascular markings. Other underlying etiologies may simply demonstrate gross dilation with diffuse inflammatory changes and a lack of typical folds.

Medical Therapy

Close monitoring of the patient's weight and hemodynamic status, performing serial abdominal examinations, and obtaining plain abdominal radiographs every 12 to 24 hours are critical to determine the necessity and timing of surgical intervention. Fluid replacement should be aggressive, using crystalloids such as isotonic saline unless shock or severe hypoalbuminemia are present necessitating administration of colloids. In addition, electrolytes must be replaced, especially with avoidance of hypokalemia. The number and consistency of bowel movements are also critical indicators of the patient's status. Reduction in the number of bowel movements often means deterioration in patient status with further colonic dilation and ileus. Conversely, increasing diarrhea may indicate a positive response to therapy. Surgery is indicated for patients who show no improvement in the first 48 to 72 hours after developing TM.

Patients should be placed on complete bowel rest and should receive adequate supplementation with intravenous (IV) fluids. Bowel rest is started with the patient receiving nothing by mouth and a nasogastric or longer tube inserted into the small intestine for bowel decompression. Long intestinal tubes are reported to be more effective than nasogastric tubes in colonic decompression, but also must be placed into the ileum under fluoroscopic guidance; therefore, their practical use is often limited. Although there is no firm evidence that decompression changes prognosis and outcome, it does have theoretical benefit and may facilitate surgery, if required. Because of risk of perforation, use of rectal tube for decompression is controversial. All narcotics, antidiarrheal, and anticholinergic agents (including, for example, antidepressants) that may slow gastric motility should be discontinued.

Total parenteral nutrition is controversial and has shown no proven benefit in preventing surgery or decreasing length of hospital stay. It may be administered in patients who are malnourished or have taken no nourishment for an extended period.

Antibiotics are recommended, not as primary therapy for IBD or for toxic dilation, but rather to reduce mortality should the perforation occur. Furthermore, bacteremia can be present even in the absence of perforation and carries with it a high mortality. Patients are typically placed on broad-spectrum antibiotics; however, there is no evidence to support this. Conversely, antibiotics should be discontinued in pseudomembranous colitis and oral/IV metronidazole and oral vancomycin should be initiated if *C. difficile* is positive.

Medical Management of Patients with IBD

IV corticosteroids are the mainstay of conventional medical therapy and their usage should not be delayed while awaiting microbiologic tests. In patients who have been on prior steroid therapy, hydrocortisone is administered in a standard dose of 100 mg every 6 to 8 hours (or methylprednisone is to 15 mg every 6 hours), which is usually given for 3 days. Higher doses of steroids or extension of therapy have no effect on outcomes or colectomy rates. Sulfasalazine or 5-aminosalicylate play no role in the treatment of TM caused by IBD. Neither 6-mercaptopurine nor azathioprine are indicated in patients with IBD and TM due to their slow onset of action. Due to the inherent risk of colonic perforation, it is recommended to start antibiotics in TM even without evidence for infectious etiology.

Medical Management of Patients With Clostridium difficile–Associated Disease

Medical therapy for TM related to non-IBD related colitis is directed specifically to the disease process. In particular, pseudomembranous colitis should be aggressively treated with withdrawal of offending antibiotics and oral or IV metronidazole or oral vancomycin should be initiated. Surgery should not be delayed if clinical parameters continue to worsen. Vancomycin enemas have been recommended recently for inadequate intraileum concentrations resulting from poor intestinal motility; however, enemas may fail to treat right-sided colonic disease. For this particular case, in addition to the previously mentioned bowel decompression techniques for TM, colonoscopic decompression with intraileostomic perfusion of vancomycin can be used (though as stated previously—endoscopy use in TM needs to be performed on an individual base and with extreme caution). This technique is contraindicated for the other causes of TM.

Surgical intervention may be necessary in up to 40% of patients with TM from *C. difficile* colitis. Indications for surgery include peritonitis, progressive dilation of the colon, lack of clinical improvement over the first 48 to 72 hours, and uncontrolled bleeding.

Surgical Therapy

Timing of surgery to patients with TM remains controversial. Because mortality continues to be high, several investigators have proposed that surgery should be performed as soon as possible, especially in case of rapid clinical deterioration and the presence of signs of end-organ failure. Absolute indications for surgery include perforation, uncontrollable rectal bleeding, and clinical deterioration with progressive dilation.

Diverting ileostomy was the most commonly used surgery for fulminant colitis with TM before the 1960s, which was complicated by high rates of perforation resulting from dilated colon despite proximal diversion. Soon after, surgical therapy for TM shifted to total abdominal colectomy and ileostomy; this approach reduced the mortality rate to 14.3% from 67% associated with ileostomy alone. For selected patients at risk for iatrogenic perforation because of friable and edematous colon during colectomy, Turnbull advocated colonic decompression and proximal diversion using a skin level colostomy and loop ileostomy with definitive surgery planned 6 months later (Fig. 3). The blow-hole procedure is now rarely performed except

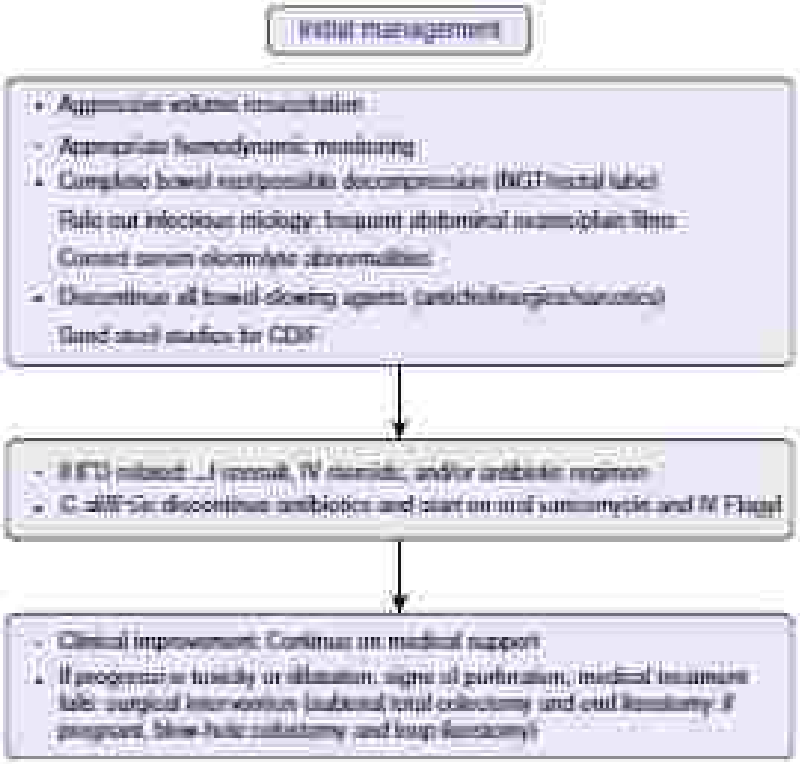

FIG. 3. Management algorithm for toxic megacolon. *CDF*, Clostridium difficile; *GI*, gastrointestinal; *IBD*, inflammatory bowel disease; *IV*, intravenous; *NGT*, nasogastric tube.

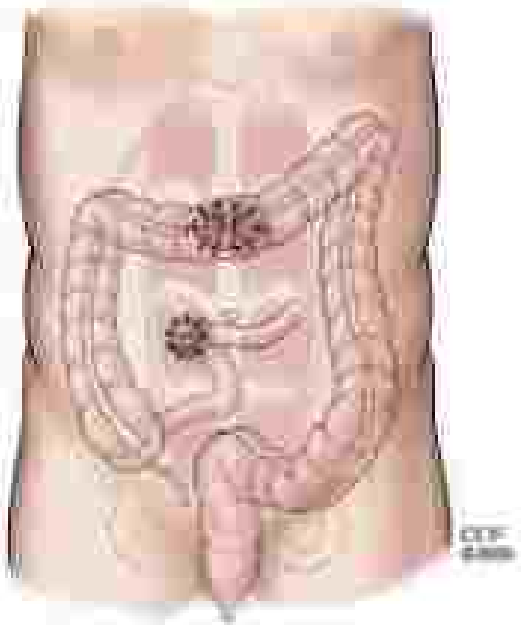

FIG. 4 Blow-hole colostomy and loop ileostomy. (Courtesy Cleveland Clinic Center for Medical Art & Photography. Copyright 2002-2010.)

to a few high-risk situations, including pregnant women, patients with colonic microperforations, high lying splenic flexure and dense adhesions, or prohibitive comorbidity. The operation is contraindicated in cases of abscess, hemorrhage, or free perforation.

Currently, the most commonly used surgical procedure for TM is the subtotal/total colectomy, mucous fistula, and end ileostomy, as this approach is associated with a lower morbidity and mortality than other techniques (Figs. 5 and 6). There are several options for the management of the rectal stump. If the stump is left intraperitoneally, a rectal tube may be placed for decompression to prevent blowout. If the stump left for an extended period, mucous fistula can be created or the stump can be placed subcutaneously (Fig. 6).

The open approach is the standard of care in the most severely ill patients (Fig. 7). Careful mobilization of the colon and vascular hypotenuse to the colonic wall minimizes injuries during difficult dissection. This technique removes the focus of bacterial translocation and preserves the rectum and local continence. This is especially true in cases for which the differential diagnosis of UC or Crohn's disease is not obvious before surgery. Patients with a pathophysiologic diagnosis of Crohn's disease should be required to undergo reconstruction with an ileoproctostomy or rectectomy if rectal disease is absent or well controlled (Fig. 8). If the diagnosis of UC is established, the remaining rectum should be resected on an elective basis and a restorative proctectomy with an ileal pouch and anastomosis should be the method of choice. The unmatched pelvic floor and perineal region after subtotal colectomy offers ideal anatomic conditions for preservation of the autonomic sacral nerves (bladder, erectile function), thus making it possible to achieve a satisfying postoperative quality of life. In cases of *C. difficile* colitis with TM, end ileostomy with colonic lavage of vancomycin, mitigate enemas have been recently described as an emerging technique.

OUTCOMES

Timing of surgery is still unclear in the literature because of the high mortality of TM when surgery is delayed; therefore, the consensus is that surgical management should be performed as soon as the diagnosis of TM is made. It has been shown that 67% of patients with severe UC had surgery even after initially successful medical management. In patients without perforation, Bjuderow and Winner reported an 8.7% mortality rate while in 51% of emergency patients with perforation. Given this information, signs of progression of the disease must be treated aggressively with surgical intervention, and perforation should be avoided. Contrarily, some reports have shown preservation of the colon with successful

conservative management at long-term follow-up. These conflicting results in the literature may be related to the definition of TM and different initial presentations of patients, but there is an overall trend toward early surgical intervention. Over the years, different surgical approaches have been developed to manage TM, with subtotal colectomy with end ileostomy being the current operation of choice. Mortality has been improved markedly within the past 30 years.

Advances in intensive care management and early surgical intervention with close follow up have improved the prognosis for patients with TM.

SUMMARY

In summary, surgical intervention remains a mainstay in the management of TM. Medical therapy is directed toward treating the underlying cause, whether inflammatory or infectious. Although short trials of medical therapy are certainly warranted, any sign of complication (either clinically or on CT scan), worsening, or failure to improve is an indication for colectomy. The timing of surgery is crucial, and delay in surgical management can result in perforation and a poor prognosis. Surgeons should be consulted early in the course of the disease, and frequent surgical reevaluation is necessary. The long-term prognosis of medically managed UC related TM is poor, with high rates of eventual colectomy and recurrence, and causes consideration as to the futility of medical therapy.

MANAGEMENT OF CROHN'S COLITIS

Isabelle C. Le Leannec, MD, MEng, and Elizabeth Wick, MD

Crohn's disease (CD) is a chronic, incurable, transmural inflammatory disorder that has myriad presentations, affecting any segment of the gastrointestinal tract from the mouth to the perianal area as well as extraintestinal sites. Crohn's colitis (CC) is one of its most common presentations. Approximately 50% of patients with Crohn's have ileocolitis, involving both the terminal ileum and colon; 20% have disease limited to the colon. As an important distinction from patients with ulcerative colitis (UC), approximately half of CD patients with CC will have rectal sparing. Perianal disease occurs in approximately one third of patients. CD is seen primarily in the United States and Europe, with an incidence of 6 patients per 100,000, but Asian and South American countries are seeing a higher recent incidence of CC as well.

Crohn's patients have a bimodal age-distribution at the time of presentation (20s to 30s or 50s to 60s) and with a female predominance. CD is a complex disease whose etiology is still not clear. Genetic and environmental factors both play a role. Patients with a family history of Crohn's are 20 times more likely to develop CD. There is a higher incidence of CD in whites, especially Ashkenazi Jews. *NOD2/CARD15* gene mutations are present in a minority of patients with CD, but testing for this gene is not currently recommended as a clinical diagnostic. Cigarette smoking is the environmental factor found to have the strongest association with Crohn's risk and severity. Similar to other long-standing inflammatory conditions of the gastrointestinal tract that are associated with malignancy, patients with CC are at increased risk of carcinomas, especially colorectal cancer (CRC). The median duration from diagnosis of CC to the development of CRC is 15 years. Patients with CC who undergo operations for CRC are more likely to have advanced CRC than patients with UC. The transmural nature and variable anatomic location of CD and CC leads to a variety of clinical presentations that necessitate differing management strategies. The acuity of disease presentation, anatomic distribution, and nature of the disease process (inflammatory, obstructing/stricturing, or fistulizing) all guide medical and surgical management of CC.

CLINICAL FEATURES

Patients with CC have a variety of clinical presentations. Patients commonly report intermittent, vague, crampy abdominal pain accompanied by diarrhea, with symptoms often occurring for several years before diagnosis. They may describe hematochezia or, less frequently, melena. Fatigue, weight loss, and fever can also be features. The process of transmural inflammation in Crohn's causes strictures and sinus tracts. Strictures from fibrotic change of the bowel lumen can cause intermittent obstruction symptoms. Sinus tracts can evolve into enteroenteric fistulas or enteric fistulas to other organs. These diseases also precede the development of phlegmon or abscess, which are sometimes palpable on examination as an inflammatory mass. Diarrhea occurs as a result of many processes, including excessive fluid secretion and impaired fluid absorption by inflamed bowel. We see malabsorption resulting from inflamed terminal ileum, sometimes related to the loss of bile salts, small intestinal bacterial overgrowth, overlapping irritable bowel syndrome, or effective short gut from extensive fistulas or areas of bypassed absorptive capacity. Perianal disease in the form of fissures, skin tags, abscesses, and fistulas occurs in one third of patients with CD. Extraintestinal manifestations tend to be more concurrent with colonic involvement and include venous and arterial thromboembolism from hypercoagulability, arthritis or arthropathy, eye and skin disorders, primary sclerosing cholangitis, renal stones, bone loss and osteoporosis, pulmonary disease, vitamin B12 deficiency, and secondary amyloidosis. Episodic colitis symptoms are often recognized by patients with Crohn's as flares. Advanced colitis may present with major lower gastrointestinal bleeding, colonic perforation, large bowel obstruction, or fulminant colitis. The Working Party of the World Congress of Gastroenterology has determined successive criteria for classification of CD. Schinna for the predominant clinical forms of CD were first codified in Vienna (1998) and then later updated in Montreal (2005) (Table 1).

DIAGNOSIS

A broader differential diagnosis for CC includes infectious diarrhea, lactose intolerance, irritable bowel syndrome, and UC. *Clostridium difficile* infection is common in patients with CD and should be ruled out. Patients with concomitant extracolonic CD (EC) simplify diagnosis. However, patients frequently present with isolated colonic disease, making the underlying differentiation between CD and UC difficult. The term *indeterminate colitis* has been used to describe patients whose clinical and pathologic diagnoses remain indistinguishable even after resection, from having overlapping features of each disease and/or severe active inflammation that obscures diagnosis. The path to diagnosis should be determined by the acuity and type of presentation, with colonoscopy and biopsy being the first step to diagnosis in patients who present with predominant diarrhea and more chronic symptoms. Endoscopic evaluation can classically reveal skip lesions, or

Advances in intensive care management and early surgical intervention with close follow up have improved the prognosis for patients with TM.

SUMMARY

In summary, surgical intervention remains a mainstay in the management of TM. Medical therapy is directed toward treating the underlying cause, whether inflammatory or infectious. Although short trials of medical therapy are certainly warranted, any sign of complication (either clinically or on CT scan), worsening, or failure to improve is an indication for colectomy. The timing of surgery is crucial, and delay in surgical management can result in perforation and a poor prognosis. Surgeons should be consulted early in the course of the disease, and frequent surgical reevaluation is necessary. The long-term prognosis of medically managed UC related TM is poor, with high rates of eventual colectomy and recurrence, and causes consideration as to the futility of medical therapy.

MANAGEMENT OF CROHN'S COLITIS

Isabelle C. Le Leannec, MD, MEng, and Elizabeth Wick, MD

Crohn's disease (CD) is a chronic, incurable, unremitting inflammatory disorder that has myriad presentations, affecting any segment of the gastrointestinal tract from the mouth to the perianal area as well as extraintestinal sites. Crohn's colitis (CC) is one of its most common presentations. Approximately 50% of patients with Crohn's have ileocolitis, involving both the terminal ileum and colon; 20% have disease limited to the colon. As an important distinction from patients with ulcerative colitis (UC), approximately half of CD patients with CC will have rectal sparing. Perianal disease occurs in approximately one third of patients. CD is seen primarily in the United States and Europe, with an incidence of 6 patients per 100,000, but Asian and South American countries are seeing a higher recent incidence of CC as well.

Crohn's patients have a bimodal age-distribution at the time of presentation (20s to 30s or 50s to 60s) and with a female predominance. CD is a complex disease whose etiology is still not clear. Genetic and environmental factors both play a role. Patients with a family history of Crohn's are 20 times more likely to develop CD. There is a higher incidence of CD in whites, especially Ashkenazi Jews. *NOD2/CARD15* gene mutations are present in a minority of patients with CD, but testing for this gene is not currently recommended as a clinical diagnostic. Cigarette smoking is the environmental factor found to have the strongest association with Crohn's risk and severity. Similar to other long-standing inflammatory conditions of the gastrointestinal tract that are associated with malignancy, patients with CC are at increased risk of carcinomas, especially colorectal cancer (CRC). The median duration from diagnosis of CC to the development of CRC is 15 years. Patients with CC who undergo operations for CRC are more likely to have advanced CRC than patients with UC. The transmural nature and variable anatomic location of CD and CC leads to a variety of clinical presentations that necessitate differing management strategies. The acuity of disease presentation, anatomic distribution, and nature of the disease process (inflammatory, obstructing/stricturing, or fistulizing) all guide medical and surgical management of CC.

CLINICAL FEATURES

Patients with CC have a variety of clinical presentations. Patients commonly report intermittent, vague, crampy abdominal pain accompanied by diarrhea, with symptoms often occurring for several years before diagnosis. They may describe hematochezia or, less frequently, melena. Fatigue, weight loss, and fever can also be features. The process of transmural inflammation in Crohn's causes strictures and sinus tracts. Strictures from fibrotic change of the bowel lumen can cause intermittent obstruction symptoms. Sinus tracts can evolve into enterocutaneous fistulas or enteric fistulas to other organs. These diseases also precede the development of phlegmon or abscess, which are sometimes palpable on examination as an inflammatory mass. Diarrhea occurs as a result of many processes, including excessive fluid secretion and impaired fluid absorption by inflamed bowel. We see malabsorption resulting from inflamed terminal ileum, sometimes related to the loss of bile salts, small intestinal bacterial overgrowth, overlapping irritable bowel syndrome, or effective short gut from enterocutaneous fistulas or areas of bypassed absorptive capacity. Perianal disease in the form of fissures, skin tags, abscesses, and fistulas occurs in one third of patients with CD. Extraintestinal manifestations tend to be more concurrent with colonic involvement and include venous and arterial thromboembolism from hypercoagulability, arthritis or arthropathy, eye and skin disorders, primary sclerosing cholangitis, renal stones, bone loss and osteoporosis, pulmonary disease, vitamin B12 deficiency, and secondary amyloidosis. Episodic colitis symptoms are often recognized by patients with Crohn's as flares. Advanced colitis may present with major lower gastrointestinal bleeding, colonic perforation, large bowel obstruction, or fulminant colitis. The Working Party of the World Congress of Gastroenterology has determined successive criteria for classification of CD. Schinna for the predominant clinical forms of CD were first codified in Vienna (1998) and then later updated in Montreal (2005) (Table 1).

DIAGNOSIS

A broader differential diagnosis for CC includes infectious diarrhea, lactose intolerance, irritable bowel syndrome, and UC. *Clostridium difficile* infection is common in patients with CD and should be ruled out. Patients with concomitant extracolonic CD (EC) simplify diagnosis. However, patients frequently present with isolated colonic disease, making the underlying differentiation between CD and UC difficult. The term *indeterminate colitis* has been used to describe patients whose clinical and pathologic diagnoses remain indistinguishable even after resection, from having overlapping features of each disease and/or severe active inflammation that obscures diagnosis. The path to diagnosis should be determined by the acuity and type of presentation, with colonoscopy and biopsy being the first step to diagnosis in patients who present with predominant diarrhea and more chronic symptoms. Endoscopic evaluation can classically reveal skip lesions, or

TABLE 1 Classification Schemes

	Vienna (1998)	Montreal (2005)
Age at diagnosis (y)	A1: <40 A2: >40	A1: ≤16 A2: 17–40 A3: >40
Location	L1: Ileal L2: Colonic L3: Ileocolonic L4: Upper gastrointestinal tract	L1: Ileal L2: Colonic L3: Ileocolonic L4: Isolated upper disease
Behavior	B1: Nonstricturing, nonpenetrating B2: Stricturing B3: Penetrating	B1: Nonstricturing, nonpenetrating B2: Stricturing B3: Penetrating Perianal disease

segments of intestine that appear inflamed and thickened with intervening normal segments. Although rectal sparing is more typical of CC, pancolitis with continuous disease extending from the rectum proximally can mimic the typical findings of UC. Also commonly seen in UC, pseudopolyps (superficial masses of mucosa, granulomas, resembling polyps) are often present in CC as well. On biopsy, up to 30% of CD patients will demonstrate granulomas; these are diagnostic of the disorder if other causes of granulomas, such as Yersinia infection, Behçet syndrome, tuberculosis, and lymphoma, are excluded. Computed tomographic (CT) imaging can help identify extraluminal disease and extraintestinal abscesses but has limited value in evaluating the intestinal wall or mucosal pathology. CT enterography (CTE) and magnetic resonance enterography (MRE) are increasingly used to evaluate the latter purpose. MRE has the advantage of similar accuracy with no ionizing radiation exposure and can be also used serially to follow treatment response. Small bowel follow-through or enteroclysis with barium have also been used to evaluate for active disease in patients with known CD but have been largely been replaced by MRE and CTE.

Sometimes, patients with no known diagnosis of CD present with acute abdominal pain. In this setting, it is safer to start with cross-sectional imaging, such as a CT scan with intravenous contrast. Usually, patients can be stabilized and are able to undergo further evaluation and medical therapy avoiding emergency surgery. If this is not the case, intraoperative gross examination might reveal extraluminal "creeping fat," in which mesenteric fat has begun to encircle the bowel in areas of active disease or fibrotic, thickened stretches of colon. Importantly, it can be difficult to distinguish colorectal cancer from CC in this setting, so surgical planning should take this into consideration. Intraluminally, the colon features classic findings of deep linear ulcers, also called linear claw or cobblestoning, along the mesenteric border (Fig. 1).

Serologic tests with clinical utility in diagnosing CD include perinuclear antineutrophil cytoplasmic antibodies (pANCA) and anti-*Saccharomyces cerevisiae* antibodies (ASCA). These tests, included on many inflammatory prognostic panels, are most useful as an adjunct to other diagnostic modalities and are not diagnostic on their own. C-reactive protein levels are often higher in CD than UC and can be checked serially to monitor for evidence of active disease or treatment response. An elevation in fecal calprotectin, a marker of neutrophil activity within the bowel, can be used to distinguish CD from functional bowel disease. Clinical testing for CD-associated genetic markers, such as NOD2/CARD15, is not currently recommended.

TREATMENT

The first step in deciding how to approach treatment of the patient with CC is to stratify the patient as low or high risk (Table 2). Low-risk

FIG. 1 (A) Linear ulcer, or long linear ulcers in the colon of a patient undergoing resection for Crohn's colitis. (B) Close-up view of colonic mucosa showing cobblestoning indicative of severe Crohn's with a combination of linear and transverse ulcerations. The raised areas consist of residual mucosa.

TABLE 2 Low- and High-Risk Features of Crohn's Disease

Low-Risk Features	High-Risk Features
• No or mild symptoms • Normal or mild elevation in C-reactive protein and/or fecal calprotectin levels • Dx. made at age >30 years • Limited distribution of bowel inflammation • Superficial or no ulcerations on colonoscopy • Lack of perianal complications • No prior intestinal resections • Absence of penetrating or stricturing disease	• Diagnosis at a younger age (<30 years) • Tobacco use • Elevated C-reactive protein and/or fecal calprotectin levels • Deep ulcers on colonoscopy • Long segments of small and or large bowel involvement • Perianal disease • Extraintestinal manifestations • History of bowel resections

CD patients have no or mild symptoms, normal or mild elevation in C-reactive protein and/or fecal calprotectin levels, diagnosis after 30 years of age, limited distribution of bowel inflammation, superficial or no ulcerations on colonoscopy, lack of perianal complications, no prior intestinal resections, and an absence of penetrating or stricturing disease. High risk patients with moderate to severe CD may have the following features: diagnosis at a younger age (<30 years), tobacco use, elevated C-reactive protein and/or fecal calprotectin levels, deep ulcers on colonoscopy, long segments of bowel involvement, perianal disease, extraintestinal manifestations, and history of bowel resections. Patients initially classified as lower risk may be subsequently reclassified as high risk if they develop complications or show lack of improvement with initial treatment. Frequency and number of flares, need for glucocorticoids, and history of hospitalizations should also be considered in a patient's risk stratification. Of note, patients who present with symptomatic fibrotic disease, particularly with preextensive dilation, are unlikely to have resolution of these end-stage structural changes with anti-inflammatory medications alone and are more likely to require surgery. Surgical intervention or endoscopic dilation is an important first step for patients with anal or lower rectal fibrotic strictures from Crohn's as distal obstruction can limit the efficacy of medical therapies on the proximal gastrointestinal tract.

Medical Management

Choice of medical therapy depends on the severity of disease, anatomic location, and whether the treatment goal is to induce remission or maintain remission. Two approaches for medical management of CD have come to prominence in the recent past: the step-up (or bottom-up) and top-down strategies. In a step-up approach, patients are started on medications with less potency but fewer side effects first. If treatment goals are not met on the lower potency regimen, these patients are then advanced to drugs that are more potent and potentially more toxic. A top-down strategy starts with placing patients on more powerful agents as first line therapy early in the course of disease before patients become glucocorticoid dependent, or possibly before patients even receive glucocorticoids. There are pros and cons to either approach. Advocates of a top-down strategy hope to disrupt the cycle of chronic inflammation and scar formation associated with chronic CD and limit permanent architectural damage to tissue. More potent therapies such as biologics have been associated with more rapid onset of clinical remission and more favorable long-term side effect profiles when compared with glucocorticoids. The downside to biologics is that they are more expensive, and insurers may limit access to these medications unless patients have tried steroid or antimetabolite therapies first, although access is improving. For the patient with severe ulceration, significant penetrating disease, and other high-risk features, biologic therapy should be the first line.

Low-risk patients are often managed with a step-up approach. First-line therapy for inducing remission in patients with mildly active disease limited to the ileum and right colon is budesonide, an enteric-coated corticosteroid that has a high first-pass rate of hepatic metabolism. Budesonide acts primarily in the bowel lumen, with a smaller systemic effect. Typical course length with subsequent taper is 8 to 12 weeks of therapy. Once remission is achieved with pulse therapy, patients move on to maintenance therapy. Systemic side effects, such as hyperglycemia, hypertension, cataracts, aseptic hip necrosis, striae, and cushingoid appearance, are less common with budesonide than with conventional glucocorticoids such as prednisone. However, prednisone is a useful first line therapy for patients with diffuse colitis, left-sided colonic disease, or for patients with extraintestinal CD who do not respond to budesonide. Typically, patients are started on 40 to 60 mg per day and tapered by 5 to 10 mg per week with a goal to complete the course by 4 to 8 months. For patients who are unable to taper off oral corticosteroids, their disease burden is reclassified as high risk and treatment is often escalated to a biologic medication.

Sulfasalazine, a general anti-inflammatory medication that is cleaved to its active form by colonic bacteria, has been shown to be effective mainly in patients with mild disease limited to the colon. It is less effective than steroids for induction therapy and may be poorly tolerated because of side effects including fever, leukopenia, and agranulocytosis. It is therefore increasingly used for initial treatment mainly in low-risk patients who wish to avoid glucocorticoids and those with extraintestinal manifestation of arthralgias and arthritis. The 5-aminosalicylate (5-ASA) drugs are modifications of sulfasalazine without the sulfapyridine ring. These drugs have been modified into various forms to deliver their therapeutic effects to different sites in the gastrointestinal tract. For colonic drug release in patients with limited ileitis and mild symptoms, this includes slow- or delayed-release oral formulations of mesalamine (e.g., Asacol, Pentasa, Apriso, Lialda, Canasa). There are also topical drugs in the form of a suppository (Canasa) or small volume enema (Rowasa) for delivery to the rectosigmoid. For patients with CC, some data suggest that long-term use of 5-ASA agents may decrease the risk of colon cancer. At this time, the US Food and Drug Administration has not approved 5-ASA agents for the treatment of CD because of lack of efficacy. In the patient with anything other than mild CC, it should not be used.

Once low-risk patients have successfully completed a steroid pulse, they are surveilled for clinical and endoscopic relapse with ileocolonoscopy in 6 to 12 months. Antimetabolite immunomodulator drugs such as azathioprine and 6-mercaptopurine (i.e., thiopurines) or methotrexate may also have a role in maintenance therapy for patients with CC, especially in those who become glucocorticoid dependent. These agents take up to 4 months to have a treatment effect, and as such, they are not useful for treating flares. Dietary interventions such as avoiding lactose and eliminating certain pro-inflammatory foods may also help patients maintain remission, though data are very limited.

A top-down approach is best suited for high-risk patients. Patients who have moderate to severe symptoms of CC should initially be started on a biologic medication with or without a concomitant immunomodulator. There are three anti-tumor necrosis factor (TNF) monoclonal antibody drugs approved for use in CD in the United States, including infliximab (Remicade), adalimumab (Humira), and certolizumab pegol (Cimzia). Anti-TNF medications are initiated in combination with antimetabolites for improved pharmacokinetics and to reduce immunogenicity against the biologic drugs. They are typically initiated with a loading dose and then given in a series of subsequent maintenance doses. Side effects of anti-TNF agents include reactivation of tuberculosis or histoplasmosis, as well as a twofold increased risk of Hodgkin's lymphoma (less than 1 in 1000). However, the introduction of biologics has generally decreased the incidence of CD patients requiring surgery. Next line biologics include ustekinumab (Stelara), an anti-interleukin (IL)23 antibody, and vedolizumab (Entyvio), an anti-alpha 4 beta 7 integrin antibody. These drugs can also be used first line in CD. Once patients have achieved remission with a biologic agent, they are generally maintained on therapy indefinitely with regular monitoring for adverse events and disease remission (Fig. 2). Thiopurines should not be used long term, especially in young men, who have an increased risk of developing hepatosplenic T-cell lymphoma. Patients older than age 40 also have increased risk of infection and malignancy with combination anti-TNF and thiopurine therapy and may be better suited to initial monotherapy with vedolizumab. High-risk patients who present acutely ill and require hospitalization are typically treated with intravenous steroids, fluid and electrolyte replacement, broad-spectrum antibiotics if indicated, nutritional assessment, and biologic therapy. If this fails or if an obstruction is noted, surgical consultation is warranted.

SURGICAL MANAGEMENT BY INDICATION

Surgical management is necessary when complications of CD arise that cannot be mitigated by medical therapy alone. Given that there is no surgical cure for CD, there must be clearly defined short- and long-term goals for any surgical intervention in these patients. Goals

FIG. 1. (A) Colonoscopic view of a patient with severe Crohn colitis before and (B) 1 year after beginning infliximab therapy.

and techniques are driven by the indication for surgery, which is wide ranging in CC. There are many factors that should be considered when selecting the most appropriate operation for a given patient. This includes the condition of the anal sphincter, coexistence of perianal disease, presence or absence of a lower rectal or anal canal stricture, history of fecal incontinence, whether the patient has small bowel disease, patient age and body habitus, and the patient's lifestyle and goals. In addition, before surgical planning, the patient should have a full colonoscopy, if possible, to evaluate for dysplasia, malignancy, and to determine the burden of inflamed and uninflamed mucosa.

Stricture or Obstruction

A significant majority of CC patients will present with stricture as the initial sign of disease. Standard of care is nasogastric decompression, correction of electrolyte and fluid imbalance, and nutritional support. In many cases, this can help to shift surgery from emergent to urgent or semielective. Interventional endoscopists may be able to dilate or stent a colonic stricture to allow for preoperative bowel decongestion and preparation, but this carries a risk of perforation. Malignancy in the structured segment is also of real concern; if the affected area is not resected, biopsies should be taken to exclude cancer. In the end, most strictures that lead to bowel obstruction will need surgery, but decompression and even temporary relief of the stricture can mean that the patient is a candidate for a segmental colectomy as opposed to total abdominal colectomy. Given the complexity of these patients' status (malnutrition, medications, obstruction), frequently the pathology is resected and a stoma is created at the time of surgery as opposed to a primary anastomosis with reversal of possibly at a later operation.

Perforation, Fistulae, and Abscess

Colonic perforations and their sequelae are also common manifestations of CC requiring surgical intervention. Patients will frequently present with chronic perforation that has resulted in abscess, phlegmon, or fistula formation. These are best diagnosed with CT scan, especially in the setting of chronic steroid use, which masks associated inflammation and chronic leukocytosis. Fatty inflammation is often seen in the area of ongoing fistula or perforation. The preferred management of pericolonic abscess in this setting is bowel rest, nutritional support, parenteral antibiotics, and image-guided percutaneous drainage. Urgent operation is required if there is free fecal or purulent peritonitis, if the abscess is not amenable to percutaneous drainage, or if percutaneous drainage fails to adequately resolve the process. Approximately 30% of pericolonic Crohn's abscesses are managed with percutaneous drainage. If there is involvement of the abdominal wall, however, most patients will eventually require a surgical drainage procedure. Following resolution of an intraabdominal abscess, the involved bowel segment is typically resected in up to 30% of patients will have recurrent sepsis. Patients with long segment disease, however, may be managed medically to avoid postsurgical complications such as diarrhea or short gut syndrome.

Massive Lower Gastrointestinal Bleeding

Although massive lower gastrointestinal bleeding is a rare presentation of CC, patients may present with melena or hematochezia severe enough to require surgical intervention. Hemodynamically stable patients may be managed endoscopically or with angiography. Unstable patients require surgical resection, the extent of which is determined by whether the bleeding can be localized to a specific bowel segment.

Severe Colitis, Fulminant Colitis/Toxic Megacolon

In severe colitis, patients may develop ileus from inflammation leading to significant dilation of the colon (i.e., a toxic megacolon) and subsequent worsening perfusion of the bowel wall. These patients may develop fever, tachycardia, leukocytosis, and hypoalbuminemia, which are frequently accompanied by hemodynamic instability. Initial care of these patients is supportive, with the potential addition of steroids, antibiotics, and volume resuscitation to avoid the use of vasopressors. Urgent colectomy may be indicated if the patient does not improve with conservative management to avoid progression to perforation and intraabdominal catastrophe.

Extracolonic Manifestations of CD

Patients with small bowel disease are best treated with resections designed to preserve absorptive capacity and small intestinal length such as strictureplasty. Multiple resections for recurrent small bowel obstructions place patients at risk for short gut syndrome. Perianal Crohn's and cutaneous pyoderma gangrenosum are manifestations of CD that can improve with surgical intervention. Crohn's uveitis, ankylosing spondylitis, and primary sclerosing cholangitis do not improve with intestinal surgery and tend to be progressive. Growth retardation from malabsorption and chronic inflammation is of specific concern in children and an indication for earlier surgical intervention.

Surgical Management by Technique

The extent of surgical resection for CC is defined by the anatomic distribution of disease as well as the nature of the inflammation. Preoperative preparation should include correction of fluid and electrolyte imbalances, anemia, and malnutrition before surgery if possible. It is controversial whether patients requiring surgery who are being treated long term with steroids or biologics should be continued on

these medications to avoid worsening inflammation in the perioperative setting or discontinued to avoid surgical complications. Steroids should be continued through surgery and tapered off gradually after. Evidence suggests there is no increase in adverse outcomes for patients undergoing colectomy for CD in the presence of biologics; however, there have been no studies of how these drugs influence intraoperative decision making.

Patients should be prepared for the possibility of diversion and appropriately marked for a stoma. Extra care is warranted in stoma planning because many CD patients will have these stomas permanently. Mechanical bowel preparation with oral antibiotic preparation should be given in advance of colectomy to reduce the chance of infectious complications (superficial, deep, and organ space infections). Patients with CD are at increased risk for venous thromboembolism and should be given perioperative primary prophylaxis with heparin or low molecular weight heparin.

Emergent Operation

Emergent operation for CC is rare. Indications include perforation, abdominal or pelvic sepsis, obstruction, or major bleeding. The operation of choice is a subtotal colectomy with a long rectal stump and mucous fistula. A mucous fistula brought up in the abdominal wall will not prevent wound complications if the rectal staple line dehisces but will hopefully avoid the complications of a pelvic abscess. The surgeon could also elect to place a rectal drainage tube secured across the anus to prevent rectal stump blow out. Intraoperatively, the safe technique is to work from normal to abnormal tissue. The mesentery tends to be very friable and less amenable to dissection with energy devices and should instead be divided between clamps and ligated.

Segmental Colectomy

Segmental colectomy is an option for patients with CC when there is an area of limited, localized disease. The surgeon should identify proximal and distal areas of healthy bowel and mesentery suitable for anastomosis. Preoperative endoscopic tattooing of the margins can be helpful. Recurrent colitis is higher in patients who have had segmental colectomy so the use of postoperative adjunctive biologic medications is essential. Colonic strictures resulting from CD should generally be resected except in the rare circumstance of a contiguous proximal colonic and short segment terminal ileum stricture, which may be amenable to stricturoplasty.

Ileorectal Anastomosis

Primary ileorectal anastomosis (IRA) following a subtotal colectomy is an option for patients with no evidence of rectal disease who prefer to not have an ileostomy. Patients should be interviewed about their preoperative continence and educated that ileorectal anastomoses are associated with an increase in stool volume and frequency. If a patient already has poor resting rectal tone or a compliant rectum, postoperative bowel function may be intolerable. In patients who are candidates for IRA, digital rectal examination should demonstrate adequate sphincter tone and the rectum should appear distensible on proctoscopy or flexible sigmoidoscopy. Additionally, they should not have perianal CD. Patients with IRA will require ongoing surveillance of the rectum to assess for recurrence of CD as well as for evidence of dysplasia or cancer. Up to 40% to 50% of patients undergoing IRA will eventually require completion proctectomy with end ileostomy.

Total Proctocolectomy with End Ileostomy

Total proctocolectomy with end ileostomy is the treatment of choice for several presentations of CD, including penicillitis and perianal Crohn's, colonic dysplasia, and those with multiply recurrent disease. Removing the entire colon, rectum, and anus is associated with the lowest recurrence risk of any operation performed for CD. The operation is performed with the patient in the modified lithotomy position to allow the surgeon access to the abdomen and perineum. The perineal dissection is typically performed in the plane between the external and external sphincters as an intersphincteric proctectomy. This decreases the size of the perineal wound and minimizes the risk of poor wound healing and sexual dysfunction. The perineal wound is closed in layers with absorbable suture to provide multiple barriers in the event of superficial wound breakdown, which can happen in approximately 25% of patients.

Total Proctocolectomy with Ileal Pouch Anal Anastomosis

Patients with CC have a nontrivial lifetime risk of developing CD in the small intestine; therefore, a restorative procedure such as an ileal pouch anal anastomosis should generally not be performed in patients with CD. Patients may present with perianal or small bowel fistulizing disease after having had proctectomy for what was initially diagnosed as UC but subsequently determined to be Crohn's. Pouch complications from Crohn's may be successfully managed with medical therapy and frequent surveillance endoscopy, but significant complications may require excision of the pouch and conversion to end ileostomy.

Proctectomy

Completion proctectomy is often performed when there is recurrent disease in the rectum or severe perianal disease following subtotal colectomy for CC. Patients should undergo manometric dysfunction as described previously, unless there is suspicion or evidence of malignancy. In that case, patients should undergo a conventional abdominoperineal resection including removal of the internal and external sphincters. If a patient has isolated rectal disease or extraintestinal CD with the rectum as the only colonic site of disease, a proctectomy and end colostomy may be performed with the understanding that restoration may be necessary in the future should there be progression of the colonic disease.

Laparoscopic and Robotic Surgery for CC

The role of minimally invasive surgical techniques in treating CC is still evolving. Compared with open surgery, laparoscopy has short-term benefits of reduced wound morbidity, expedited recovery, and lower cost. Long-term benefits include lower rates of bowel obstruction and lower incidence of incisional hernias. When the appropriate expertise is available, laparoscopic or robotic surgical management is indicated. CD has been demonstrated to have comparable recurrence rates after open and laparoscopic surgery.

PERIOPERATIVE MANAGEMENT AND CARE AFTER SURGERY

Following surgical resection, multidisciplinary care with gastroenterology is essential. Endoscopic recurrence rates have been reported as high as 80% at 1 year following surgical resection. The yearly rate of recurrence approaches 10% to 15%. These statistics reemphasize that surgery is not a cure for CD, and returning patients on their maintenance medications and surveillance regimens is critical to their long-term outcomes. Patient should get repeat endoscopy at least by 6 months postoperatively to stage risk of recurrence and determine whether a change in therapy is indicated.

Management of Ischemic Colitis

Ian Soisky, MD, MPH, and Farhad Nawras, MD

Ischemic colitis—a condition that occurs in settings when the blood supply to the colon is insufficient to meet cellular metabolic needs resulting in mucosal injury or full thickness necrosis—is the most common form of gastrointestinal ischemia. Although the incidence of ischemic colitis has previously been reported to range from 4.5 to 44 cases per 100,000 person-years, studies more recently have reported a range of approximately 15 to 18 cases per 100,000 person-years. These rates, however, may be underestimated because they tend to be based on hospitalized patients, and it is believed that a significant number of patients with mild disease are not captured because they never present for medical attention or are misdiagnosed. Ischemic colitis can present on a spectrum from self-limiting to life-threatening disease, and diagnosis requires a high index of clinical suspicion. Severity of disease dictates subsequent management. Most patients have a less severe form of disease (approximately 80%) and can be managed medically, whereas the remainder has a more critical form of disease requiring surgical intervention. Those treated medically have an overall mortality rate of approximately 6%, whereas those requiring surgery have a mortality rate nearing 50%. The wide difference in these mortality rates underscores the importance of early diagnosis and timely treatment. This chapter outlines the key considerations pertinent to the diagnosis and management of ischemic colitis.

ANATOMIC AND PATHOPHYSIOLOGIC CONSIDERATIONS

Understanding the presentation and pathophysiology of ischemic colitis requires a working knowledge of the blood supply to the colon. Fig. 1 shows the arterial supply to the colon. The superior mesenteric artery (SMA) via the ileocolic, right colic, and middle colic arteries supplies the right colon; the transverse colon is predominantly supplied by the middle colic artery, and the distal transverse colon to proximal rectum is supplied by the inferior mesenteric artery (IMA), which branches into the left colic, sigmoid, and superior rectal arteries. An extensive collateral circulation including the marginal artery of Drummond and the arch of Riolan (also referred to as the *meandering mesenteric artery*) connects the SMA and IMA, which is critical to ensuring that the colon is adequately perfused, even in cases of SMA or IMA stenosis or occlusion. The collateral circulation is of particular importance to the so-called watershed areas of the colon, which are the parts of the colon most at risk for hypoperfusion and thus ischemia because of their anatomic location at the distal end of an arterial supply. These watershed areas include the splenic flexure (Griffith's point), which receives its blood supply at the junction of the SMA and IMA, and the sigmoid colon (Sudeck's point), which receives its blood supply at the junction of the sigmoid and superior rectal arteries.

The colon has an inherently lower blood flow than the small bowel, which puts it at risk for ischemia. Colonic ischemia can develop as a result of two different processes, which can be described as nonocclusive and occlusive. The predominant mechanism is nonocclusive, which occurs in conditions that cause low flow states in the colon, and most commonly affects the watershed areas. However, the right side of the colon is also at risk from ischemia in low flow states because the vasa recta are believed to be less developed in the right colon compared with the left. Although many causes of nonocclusive disease have been identified (see the following section), in most cases, no specific cause is defined, and these cases are largely believed to result from small-vessel disease. Although less common, colonic ischemia can also result from embolic and thrombotic arterial occlusion. The straight take-off of the ileocolic artery from the SMA puts the right colon at risk for ischemia from embolic events. Whether the colon becomes ischemic because of an occlusive or nonocclusive process, the extent of disease can include transient ischemia, chronic ischemia, or gangrene. Transient ischemia tends to be limited to the colonic mucosa and often recovers. A chronic colonic ischemia picture may involve the muscularis layer, which can result in scarring and stricture. Transmural involvement of the colon, which can develop within 8 to 16 hours, can lead to perforation, peritonitis, sepsis, and death. The left colon is the most commonly affected segment, followed by the sigmoid colon, but right-sided and pan-colonic ischemia, colitis can occur and are associated with poorer prognosis.

It is important to understand the differences in pathophysiology between ischemic colitis and mesenteric ischemia (discussed elsewhere) because it dictates differences in management. In contrast to ischemic colitis, which tends to be a problem because of a low flow state, mesenteric ischemia is commonly caused by a vascular obstruction, which may require a revascularization procedure, thrombolysis, or anticoagulation, treatments that are rarely used for ischemic colitis.

CLINICAL PRESENTATION AND CAUSES

Identifying ischemic colitis can be a challenge because it often presents with nonspecific signs and symptoms requiring high clinical suspicion for diagnosis. It can also sometimes present in critically ill patients who may be misdiagnosed and missed, which can further complicate the identification of symptoms. Clinical presentation can vary based on whether a patient has acute or chronic colonic ischemia. In acute cases, patients may rapidly develop abdominal pain or cramping, which can also be associated with hematochezia or bloody diarrhea within 24 hours (usually transient and rarely requiring transfusion), as well as the sudden urge to defecate. Approximately half of the patients with ischemic colitis will have these symptoms. Others may have nausea, vomiting, and fever. Patients who present with right-sided ischemic colitis are more likely to have abdominal pain without associated bleeding, whereas bleeding is more common with left-sided disease. Although most cases of mild ischemic colitis resolve, approximately 10% of patients will have a recurrent episode that tends to be similar in intensity and location to the initial one. There is some debate about whether chronic ischemic colitis should be considered a unique entity. Chronic ischemic colitis is associated with a prolonged time course and milder symptoms, which may include recurrent abdominal pain and bloody stools that may last greater than 3 months. Chronic ischemic colitis can also be associated with malnutrition and recurrent episodes of sepsis.

Because the symptoms described above are not pathognomonic for ischemic colitis, consideration of patients' medical histories become equally as important in making this diagnosis. There are a number of medical, surgical, and pharmacologic risk factors, which should make clinicians suspicious for ischemic colitis when they are present in a patient who develops abdominal pain, hematochezia, or bloody diarrhea. Box 1 summarizes the common medical conditions, surgical conditions, and drugs associated with ischemic colitis.

Medical conditions that are commonly associated with ischemic colitis include myocardial infarction, renal disease requiring hemodialysis, and diseases of hypercoagulability. Colonic ischemia after myocardial infarction or dialysis is secondary to the low flow states caused by these conditions. Several hypercoagulable disorders including the presence of antiphospholipid antibodies and mutations in factor V Leiden and plasminogen activator inhibitor have been noted to be more prevalent in patients with colonic ischemia than the general population, but the extent to which hypercoagulable states contribute to this disease process has yet to be fully elucidated. Other medical comorbidities that have been reported to be prevalent in

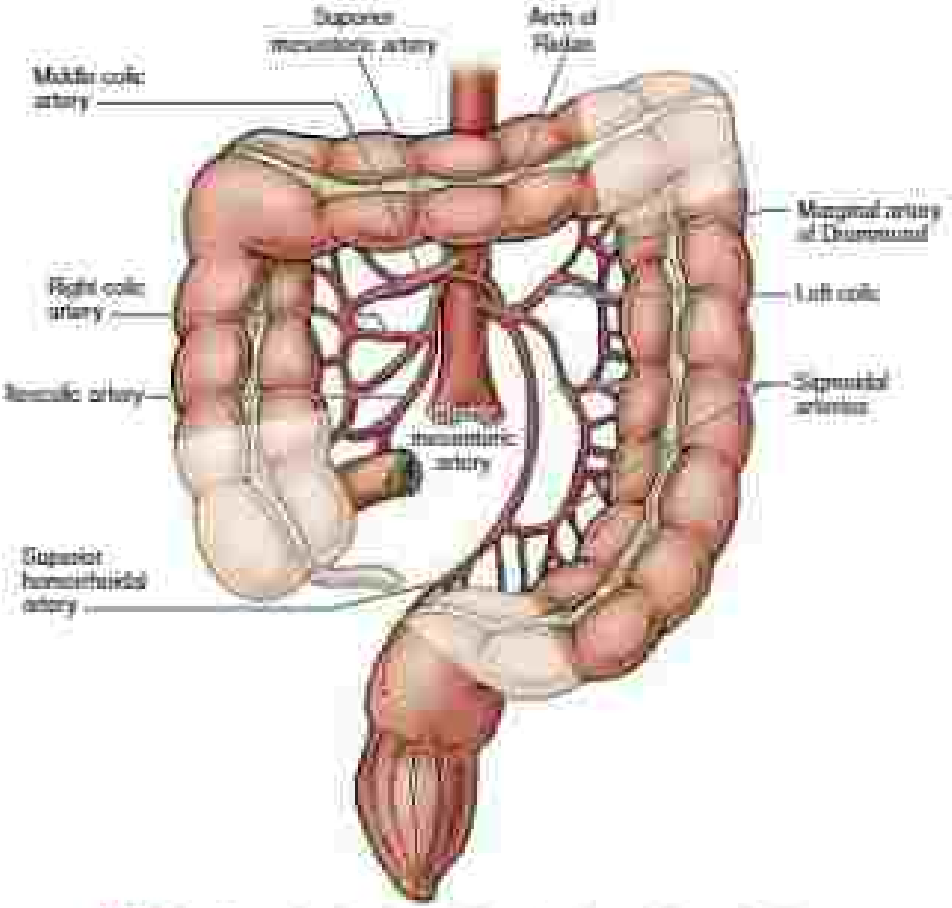

FIG. 1 Arterial supply to the colon. Dashed areas depict potential watershed regions.

patients with ischemic colitis include hypertension, diabetes mellitus, coronary artery disease, dyslipidemia, chronic obstructive pulmonary disease, congestive heart failure, atrial fibrillation, and peripheral vascular disease, which makes sense given the occlusive and nonocclusive causes of colonic ischemia. One more rare but reported cause of ischemic colitis is extreme exercise as in marathon runners and is believed to develop as a result of blood flow being diverted away from the splanchnic circulation.

Surgical and procedural conditions that may predispose patients to colonic ischemia include aortoiliac surgery and surgeries involving cardiopulmonary bypass. Whether performed open or endovascularly, aortoiliac surgeries such as those performed for abdominal aortic aneurysms may involve ligation of vessels to the colon (such as the IMA or iliac artery), emboli events, hypotension, or surgical instrumentation leading to vascular compression, all of which can compromise the collateral blood flow to the left colon and result in ischemia. Whereas aortoiliac surgery can induce ischemic colitis through alterations to the collateral blood flow, procedures involving cardiopulmonary bypass can cause it through the induction of a low flow state. Bypass is also sometimes associated with the use of inotropic/vasoactive agents or intraaortic balloon pumps, which further can create a low flow state putting patients at risk for ischemia. Furthermore, bypass, in exposing the patient's blood to foreign surfaces, can result in hypercoagulability, microemboli, and the release of vasoactive substances. Also, although it is a rare phenomenon, colonic ischemia has been reported after colonoscopy, which is believed to be the result of excessive luminal distention via insufflation.

Many pharmacologic agents are also believed to contribute to the development of ischemic colitis. Although there are many classes of drugs that have been implicated, the offenders with the greatest supportive evidence include constipation inducing drugs, immunomodulators, and illicit drugs. Opioid and nonopioid drugs that induce constipation are believed to contribute to the development of ischemic colitis by causing increased intraluminal pressure, which can result in reduced blood flow. Immunomodulator drugs such as tumor necrosis factor α inhibitors for rheumatoid arthritis may trigger ischemic colitis through the release of cytokines that can affect thromboregulation. Illicit drugs such as cocaine and amphetamine can cause vasoconstriction, hypercoagulation, and direct endothelial injury, which also may contribute to the development of ischemic colitis. The wide spectrum of factors that may contribute to this disease emphasizes that the cause of ischemic colitis is likely multifactorial, requiring clinicians to take the patient's entire clinical picture into consideration when assessing for the presence of ischemic colitis.

DIAGNOSIS

Given the nonspecific symptoms and wide range of potential causes of ischemic colitis, clinicians who are considering ischemic colitis in a patient will often have a large differential diagnosis, which may also include acute mesenteric ischemia, diverticulitis, inflammatory bowel disease, infectious colitis, and colon cancer. As such, a workup, including laboratory testing, diagnostic imaging, and endoscopy, is usually performed to rule out other causes.

Routine laboratory studies such as complete blood count, basic metabolic panel, and coagulation studies will be ordered for patients and may show an elevated white blood cell count or decreased hemoglobin in cases of bleeding. Other studies that may aid in the assessment of disease severity include increased lactate dehydrogenase or creatinine phosphokinase. If an arterial blood gas is obtained in a critical patient, an elevated lactate and decreased bicarbonate may be indicative of a case of severe ischemic colitis. A decreased albumin may indicate malnutrition. Nonetheless, no laboratory findings are specific for ischemic colitis, and minimal abnormalities may be seen

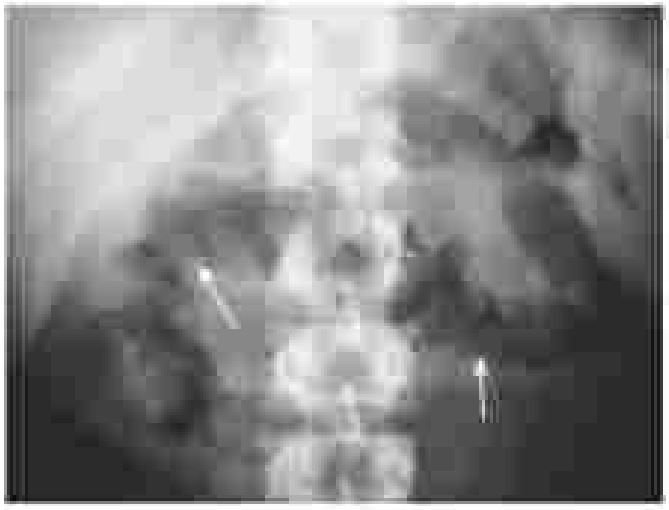

FIG. 1 Plain abdominal radiograph of patient with colonic ischemia showing sentinel and thumbprinting signs. [Text illegible] Am J Roentgenol Radium Ther Nucl Med. 1966;96:[illegible].

in mild cases. If there is a concern for a possible infectious colitis, it is also important to send off stool culture studies to evaluate for invasive bacteria, including *Escherichia coli* O157:H7, *Salmonella*, and *Shigella* species. A workup for *Clostridium difficile* colitis should also be considered in patients who have recently been hospitalized or used antibiotics.

Imaging studies also are generally obtained in patients who present with abdominal pain, hematochezia, and leukocytosis. Plain films such as a chest radiograph serve as a fast and appropriate initial study in cases when there is concern for perforation to identify pneumoperitoneum. Otherwise, obtaining an abdominal radiograph generally will show nonspecific findings that may not be helpful, but the presence of abnormalities may indicate more severe disease. The most common radiographic finding in ischemic colitis is thumbprinting (rounded densities along the side of a gas filled colon), which is indicative of submucosal edema (Fig. 2). Other findings on radiograph can include colonic dilation or mural thickening. Abdominal and pelvic computed tomographic (CT) scans are now the most common method for initial diagnosis and tend to be more helpful. They should be performed with both intravenous and oral contrast to identify the regions of involvement and the severity of disease. Findings from CT scans are also nonspecific, but those that are suggestive of ischemic colitis include segmental wall thickening, pericolonic fat stranding, thumbprinting, and ascites (Fig. 3). Worrisome findings that may prompt urgent surgical intervention include pneumatosis, portal venous gas, and stenosis. CT will also allow for the exclusion of other disease processes such as diverticulitis. CT angiography may be performed as part of a workup in cases where acute mesenteric ischemia is believed to be higher on the differential diagnosis to identify potential IMA occlusion; however, in general, this is not the appropriate test to evaluate for ischemic colitis, which is a disease of small vessels. Of note, isolated IMA occlusion typically is not believed to result in ischemic colitis because of the robust collateral blood supply, and, as such, this finding on CT angiography has uncertain significance. Other imaging modalities such as barium enema, ultrasound with Doppler flow, and MRI are available but have started to fall out of favor as CT imaging has improved.

The gold standard test for the diagnosis of ischemic colitis is lower endoscopy, typically with colonoscopy, which allows for the visualization of the colonic mucosa for signs of ulceration or ischemic change. Outside of extremely severe cases in which urgent surgical intervention may be warranted, such as peritonitis on clinical examination with imaging findings showing pneumoperitoneum, pneumatosis, or portal venous gas, early endoscopy should be performed to try to confirm the diagnosis. Although there do not seem to be higher rates of perforation for patients with colonic ischemia undergoing colonoscopy, insufflation should be minimized during the procedure, the scope should not be advanced beyond the distal extent of disease, and preprocedure bowel preparation should be avoided because this may induce toxic dilation or perforation. Endoscopy will usually reveal the segmental nature of ischemic colitis with an abrupt junction between normal and involved regions of the mucosa. Other endoscopic findings will vary based on the severity of disease. Mild disease may be associated with mucosal edema, erythema, ulceration, or petechial hemorrhage, whereas more severe disease may show dusky mucosa or hemorrhagic ulcerations (Fig. 4). The single stripe sign, a single linear ulcer along the longitudinal axis of the colon, may be more indicative of ischemic colitis than the other findings. During endoscopy, biopsies in areas of concern should be taken unless gangrene is present. The most common histologic changes include signs of inflammation, mucosal edema, hemorrhage, and destruction of crypt structures (Fig. 5). Although rarely seen, mucosal infarction and ghost cells on biopsy are pathognomonic for ischemic colitis. Endoscopy is also helpful in the evaluation of ischemic colitis because it will allow for the identification of other disease processes that could be confusing the clinical picture such as inflammatory bowel disease or infectious processes.

TREATMENT

Treatment of colonic ischemia is dictated by the severity of disease and its cause. Even if the diagnosis of ischemic colitis is not confirmed from laboratory, radiographic, or endoscopic tests, treatment begins once it is determined whether a surgical intervention is needed. Patients with clinical or diagnostic signs of perforation, unstable bowel, or massive hemorrhage should proceed immediately to the operating room for exploration, even if the workup is not complete. Timely diagnosis and treatment are important to limiting morbidity and death associated with surgical treatment. If a patient is without these ominous signs, as is the case for most patients with ischemic colitis, supportive medical management is an appropriate approach, and remaining diagnostic tests can be performed. Fig. 4 shows the treatment algorithm for ischemic colitis.

For the majority of patients who can initially be managed nonsurgically, treatment begins with fluid resuscitation, bowel rest, and observation. Conditions that may induce ischemic colitis should be treated, and drugs that may trigger it should be stopped. Nasogastric tube decompression is not needed unless the patient has nausea and vomiting. Other important treatment principles to follow include the limitation of vasopressor use and the optimization of cardiac output to ensure adequate blood flow to the colon. Noninvasive hemodynamic monitoring tools are generally appropriate to guide fluid resuscitation. Parenteral nutrition may be needed in cases of prolonged bowel rest. While these supportive measures are being implemented, it is important for the clinical team to remain vigilant for signs of worsening bowel ischemia, which may warrant surgical intervention. Serial abdominal examination should be performed, careful monitoring of vital signs is needed, and repeat diagnostic testing may be appropriate in certain circumstances to evaluate for the resolution or worsening of disease. For example, patients who have undergone aortoiliac surgery and who develop fever, leukocytosis, hematochezia, or abdominal pain would require an urgent flexible sigmoidoscopy to assess for colonic ischemia. Early empiric broad-spectrum antibiotics have also been recommended for use in patients with ischemic colitis except in its mildest forms. Although there is limited evidence to support the use of antibiotics, this recommendation is based on studies that have suggested that colonic ischemia can disrupt the intestinal epithelial barrier leading to bacterial translocation and that antibiotics may thus play a protective role.

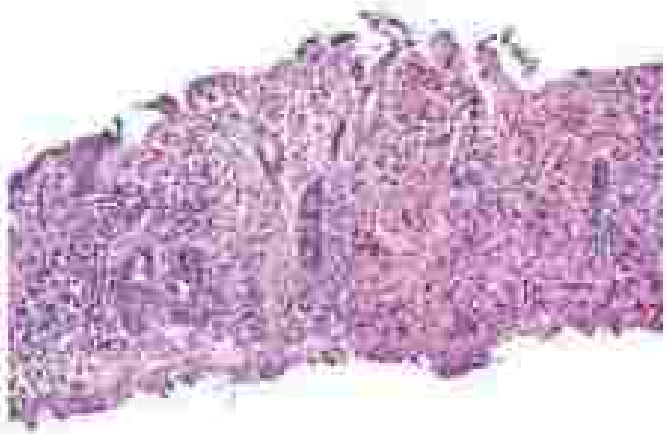

FIG. 1 Ischemic colitis histology. Injury and disturbance of the surface epithelium with preservation of the basal portion of the crypts and hyalinization and hemorrhage of the lamina propria are characteristic features of ischemia. Inflammatory cells may be present but are not a necessary component of the ischemic pattern. *(From [source].)* No other more definite diagnosis of acute colitis, such as [illegible] Clin Gastroenterol Clin. 2012;(1):[illegible].)

those patients who fail to improve with medical management or who initially present with signs of peritonitis, pneumoperitoneum, massive hemorrhage or gangrenous bowel would require urgent surgical intervention. Approximately 20% of ischemic colitis cases require surgical intervention. The standard surgical approach is to begin with a midline laparotomy incision to visualize the entire small intestine and colon from the ligament of Treitz to the peritoneal reflection over the rectum, but laparoscopic exploration may be appropriate in select cases to confirm the diagnosis. If laparoscopy is to be performed, lower than normally used intraperitoneal pressure (10 mm Hg) is sometimes advised to avoid the theoretical concern that pneumoperitoneum can further worsen blood flow. Grossly necrotic and perforated bowel should be resected. However, the viability of a spastic portion of the colon can sometimes be difficult to determine, especially if the bowel has a dusky appearance. In some instances, temporary abdominal closure with planned second look exploration after 12 to 24 hours is the appropriate next move. Intraoperative endoscopy can also be performed to assist with the determination of the extent of ischemia. Other adjuncts to the visual examination of bowel have been developed, which may assist with decision making regarding whether to resect a particular portion of bowel. The intravenous injection of indocyanine green coupled with a commercially available imaging system allows for the real-time evaluation of tissue perfusion (Fig. 2). This method, though still not universally practiced, has started to replace the older method of intravenous injection of

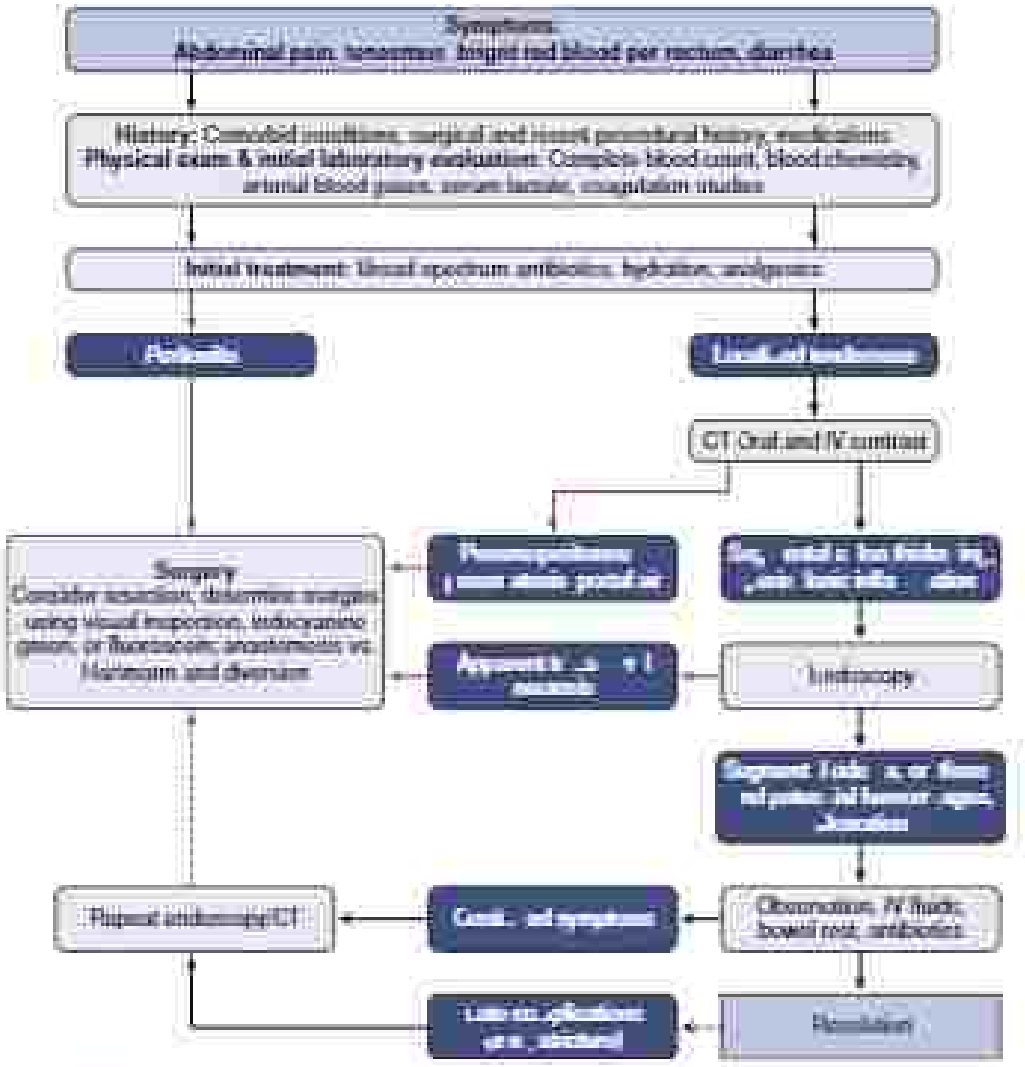

FIG. 3 Treatment algorithm for ischemic colitis. CT, Computed tomography; IV, intravenous.

fluorescein, which was limited in that repeated assessments could not be performed because of the dye remaining in the tissue. Once the extent of ischemia is determined, resection can be performed. The surgical procedure performed is determined by the location of the affected colon. In general, it is advised that a primary anastomosis should not be performed because its integrity would be at risk due to inadequate blood flow and other physiologic derangements that exist in the setting of an emergency surgery. However, there may be circumstances in which a primary anastomosis would be appropriate given the patient's clinical condition. Right-sided disease is treated with resection followed by ileostomy and transverse colon mucous fistula or primary anastomosis. Left-sided disease is treated with segmental or left colon resection, followed by either a proximal colostomy and distal mucous fistula or a Hartmann's procedure. Subtotal colectomy with terminal ileostomy is indicated for cases of fulminant colonic ischemia. Fig. 8 shows the gross pathologic condition of patients with ischemic colitis.

After treatment, whether medical or surgical, it is important that patients be closely monitored to ensure resolution of ischemia. Most patients with mild, nonobstructive colonic ischemia clinically improve in 1 to 2 days. However, there are cases in which patients can continue to have prolonged symptoms. Some patients may have recurrent septic episodes if they have an unhealed segment of colon, which would require resection for cure. Others can develop a colonic stricture, which may be asymptomatic, but it can also lead to obstructive symptoms, which would require resection or stenting

for poor surgical candidates. Patients with chronic ischemic colitis need close attention paid to their nutritional status. For those patients who have undergone ileostomy or colostomy creation, reversal can be performed in healthy patients after 6 to 6 months. However, in this patient population, ostomy reversal was found to be associated with an in-hospitality mortality rate of 18%. For this reason, it is no surprise that approximately two-thirds of patients are never reversed due to their comorbidities.

SUMMARY

Ischemic colitis is a disease that can present with nonspecific symptoms and, on workup, is frequently associated with diagnostic results that are not pathognomonic. It can therefore be an extremely challenging disease to diagnose. Although most cases are mild in severity and can be managed medically, high clinical suspicion is needed to identify it early so that it does not escalate to a severe form requiring surgery, which is associated with much higher mortality and morbidity rates. Successful management of ischemic colitis requires the careful coordination of a healthcare team that may include internists, gastroenterologists, critical care specialists, radiologists, and surgeons.

MANAGEMENT OF *CLOSTRIDIUM DIFFICILE* COLITIS

Rachel L. Chorun, MD, and Pamela A. Lipsett, MD, MHPE, MCCM

Pseudomembranous colitis was rare in the preantibiotic era and was first recognized in 1893 by J.M. Finney and William Oliver. It became more prominent in the 1970s when it was known as clindamycin colitis secondary to its association with antibiotics. In 1978, John Bartlett and others identified *Clostridium difficile* as the causative agent for antibiotic-associated pseudomembranous colitis.

EPIDEMIOLOGY

The incidence of *Clostridium difficile* infection (CDI) has increased rapidly in the past 2 decades. The Society for Healthcare Epidemiology of America (SHEA) estimates there are nine 500,000 cases of CDI in the United States each year compared with 139,000 cases in the year 2000. This expanding rate of CDI is due to the aging population, evolving usage of antibiotics, emergence of hypervirulent strains, and antibiotic resistance. Additionally, the risk of inpatient CDI has been directly related to hospital length of stay with a colonization rate of 13% at 2 weeks and 60% at 8 weeks. Overall, CDI results in $3 billion of hospitalization costs per year nationwide.

Not only has the incidence of CDI increased, but also the severity of disease and mortality has increased as well. The epidemic outbreaks of CDI in the 2000s were secondary to hypervirulent strains, most commonly ribotype 027, which caused increasingly severe infections and recurrence. Although ribotype 027 has declined markedly in parts of Europe, it is still one of the most commonly identified strains in the United States.

PATHOGENESIS

C. difficile is a gram-positive, spore-forming anaerobic bacillus that is highly resistant. It is the No. 1 cause of nosocomial infectious colitis and pseudomembranous colitis. Additionally, CDI is the major cause of nosocomial and antibiotic-associated diarrhea (10%–30%).

Transmission and Progression to Active Disease

C. difficile is transmitted by asymptomatic carriers (3% of adults) or by patients with active CDI via the fecal-oral route from hand-to-hand contact or indirectly from the colonization of patient environment. In the community, *C. difficile* has been cultured from soil, swimming pools, and both salt water and fresh bodies of water. Spores can survive weeks to years on inanimate objects. In the hospital, *C. difficile* has been cultured from telephones, call buttons, and shoes and can therefore be transmitted via healthcare providers from patient to patient.

Colonization with *C. difficile* can progress to CDI if the intestinal ecosystem is altered by antibiotics, antineoplastic agents, bowel preparations, or other agents. Postoperative patients are particularly at risk after perioperative antibiotic exposure, hospitalization, and relative immunosuppression.

Toxins

Patients with CDI typically have both toxin A and B, but they can have just one toxin. Toxin A, encoded by gene *TcdA*, is primarily an enterotoxin with many cytotoxic properties, whereas Toxin B, encoded by gene *TcdB*, is a cytotoxin that induces cytopathogenic effects. Both toxins interfere with actin cytoskeletons of intestinal epithelial cells and render them nonfunctional. They stimulate the inflammatory cascade and pro-inflammatory cytokines (tumor necrosis factor-α, interleukin [IL]-1, IL-6, IL-8, IL-23), chemokines (CXCL1, CXCL2, IL-8), and the prostaglandin pathway leading to massive infiltration of neutrophils, macrophages, and lymphocytes in the colonic mucosa. This disrupts the intestinal epithelium with excessive leakage of fluid through the cytoskeleton and tight junctions. It also causes the appearance of pseudomembrane formation. The clinical manifestation of CDI is a result of the toxin production.

Hypervirulent Strains

The degree of toxin production is 16 to 20 times higher in hypervirulent strains of *C. difficile*. In turn, these hypervirulent strains have a fivefold increase in mortality. The most common hypervirulent strain, NAP1/027 or polymerase chain reaction ribotype 027, was discovered in 1981 and has been associated with fluoroquinolone resistance, a lower response to felodipine, epidemic outbreaks, and increased mortality. Cytolethal distending toxin, also known as binary toxin, has been found in 6% to 12% of toxinogenic strains and the ribotype 027 hypervirulent strain. There is a polymerase chain reaction test for cytolethal distending toxin that can help identify the ribotype 027 strain.

for poor surgical candidates. Patients with chronic ischemic colitis need close attention paid to their nutritional status. For those patients who have undergone ileostomy or colostomy creation, reversal can be performed in healthy patients after 6 to 6 months. However, in this patient population, ostomy reversal was found to be associated with an in-hospital mortality rate of 18%. Cytolethal distending toxin, also known as binary toxin, has been found in 6% to 12% of toxinogenic strains and the ribotype 027 hypervirulent strain. There is a polymerase chain reaction test for cytolethal distending toxin that can help identify the ribotype 027 strain.

BOX 1 Risk Factors Associated with *Clostridium difficile* Infection

Primary Risk Factors

Age >65 years
Recent antibiotic use
Hospitalization

Secondary Risk Factors

Female gender
Double occupancy room
Intensive care unit admission
Long-term care facility admission
Acid-reducing therapy (proton pump inhibitors or histamine (receptor blockers)
Gastrointestinal procedures
Immunosuppression
Chemotherapy
Renal disorders
Organ transplantation
HIV infection
Autoimmune disease
Hypoalbuminemia
Inflammatory bowel disease

Primary Risk Factors

Patients are at increased risk for CDI if they have a source of colonization along with a change in their intestinal microbiogenesis, especially in the setting of immunocompromise or debility. Altered immunity can determine colonization versus clinical disease. Patients are also at greater risk for CDI when exposed to longer antibiotic durations, although a single antibiotic dose has been reported to cause CDI as well. Although initially attributed to clindamycin, any antibiotic can cause CDI; most commonly, penicillins, cephalosporins, and fluoroquinolones are responsible.

There is an epidemiologic association between proton pump inhibitor use and CDI; therefore, it is recommended to discontinue any unnecessary proton pump inhibitors.

The recurrence rate of CDI has been reported as high as 20%. Risks associated with recurrence are prolonged antibiotic use, prolonged hospitalization, age greater than 65 years, diverticulosis, and comorbid issues (Box 1).

Mortality

The incidence, severity, and mortality of CDI continue to increase over time. Predictors of mortality identified prospectively are older age, elevated lactate, delayed operative intervention, vasopressor use, and acute renal failure.

CLINICAL PRESENTATION

Because *C difficile* is a normal isolate from the gastrointestinal track, the stool presence does not signify the presence of disease. The clinical manifestations of CDI can vary with a wide spectrum of symptoms. Some patients have mild diarrhea compared with others with more severe disease, including toxic megacolon, multisystem organ failure, and death. Symptoms can manifest as early as the first day of antibiotic use; alternatively, symptoms can begin up to 4 weeks after completion of antibiotics.

CDI is now classified as nonsevere disease, severe disease, fulminant disease, and recurrence (Table 1).

Nonsevere Disease

Nonsevere disease has been described as diarrhea without systemic symptoms. Patients with nonsevere CDI typically have a white blood cell (WBC) count less than 15,000 cells/mL and a serum creatinine level lower than 1.5 mg/dL. These patients have less than 10 nonbloody stools per day and cramping.

TABLE 1 Differentiating CDI Based on Severity of Illness

Nonsevere CDI	Hemodynamically stable (HR <90 beats/min, SBP >100 mm Hg) Afebrile (<101.5°F) WBC 12,000–15,000 cells/mL Normal lactate Oliguria, but volume responsive Mild abdominal tenderness Pseudomembranes on colonoscopy Colonic thickening on CT scan
Severe CDI	Tachycardic without hypotension (HR >90 beats/min, SBP >100 mm Hg) Febrile WBC >15,000 cells/mL Creatinine >1.5 mg/dL Moderate abdominal tenderness
Fulminant CDI	Shock with hypotension Need for vasopressors Ventilator dependence Severe oliguria Perforation Toxic megacolon

CDI, *Clostridium difficile* infection; HR, heart rate; SBP, systolic blood pressure; WBC, white blood cell.

Severe Disease

Severe disease presents with profuse diarrhea, abdominal distention or pain, fever, tachycardia, oliguria, WBC greater than 15,000 cells/mL, and serum creatinine greater than 1.5 mg/dL. These patients are typically volume responsive to resuscitation.

Fulminant Disease

Fulminant disease has been previously called severe or complicated CDI. It is associated with hypotension or shock. Patients with fulminant CDI can also have an ileus, toxic megacolon, occult bleeding, or severe oliguria. These patients often require vasopressor support and mechanical ventilation. Fulminant disease has been increasing in incidence and severity and now accounts for 3% to 5% of all *C difficile* infections.

If not present initially, fulminant disease can lead to ileus, toxic megacolon, intestinal perforation, and death. Mortality rates for patients with fulminant CDI range from 30% to 90%. When fulminant CDI is concomitant with organ failure, shock, hypotension, ileus, or megacolon, CDI should be considered life threatening.

CDI does not always manifest with diarrheal symptoms and is often underdiagnosed in that patient population. CDI should be considered in patients with a fever without a known source, unexplained leukocytosis, distended abdomen, recent antibiotic use, or admitted to the intensive care unit. Up to 37% of patients with fulminant CDI can present without diarrhea secondary to an ileus.

Recurrence

Rates of CDI recurrence range between 6% and 67% within the first 2 weeks after completion of initial antibiotic treatment. The risk of recurrence increases further with each subsequent case of recurrence.

TABLE 2 Available Diagnostic Tests for CDI

Test	Sensitivity	Specificity	Substance Detected
Toxigenic culture	High	Low	*C. difficile* vegetative cells or spores
Nucleic acid amplification tests	High	Low/moderate	*C. difficile* toxin genes
Glutamate dehydrogenase	High	Low	*C. difficile* common antigen
Cell culture cytotoxicity neutralization assay	High	High	Free toxins
Toxin A and B enzyme immunoassays	Low	Moderate	Free toxins

CDI, *Clostridium difficile* infection.
Modified from the 2017 update by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA).

DIAGNOSIS OF CDI

Prompt diagnosis of CDI is imperative because a delay in diagnosis and treatment correlates with increased mortality. Current recommendations suggest diagnostic testing should be pursued in patients with three or more new, unexplained, unformed stools over 24 hours.

Stool Studies

There are multiple types of stool studies to detect CDI (Table 2). The Nucleic Acid Amplification Test (NAAT) is the most sensitive test for patients likely to have CDI based on their clinical symptoms; however, it can also detect *C. difficile* carriers without infection. The glutamate dehydrogenase (GDH) antigen test is less commonly used but is rapid, inexpensive, and easy to perform. It has poor sensitivity but a negative result strongly rules out CDI. A positive GDH result alone does not meet criteria to diagnose CDI. Enzyme immunoassays for toxins A and B are commonly used. This test has a specificity of 94% to 100% for the presence of clinically relevant CDI, but it is less sensitive (65%–94%).

Overall, stool studies in patients with CDI have the best positive and negative predictive values for detecting CDI. The use of a stool toxin test should be used in a multistep algorithm: GDH plus toxin, GDH plus toxin arbitrated by NAAT, or NAAT plus toxin.

Laboratory Tests

A leukocytosis greater than 30,000 is typically uncommon in most bacterial infection. An elevated leukocytosis of this magnitude should raise suspicion for CDI. An elevated lactate and abnormal albumin can help identify patients with severe and fulminant CDI.

Imaging

X-ray imaging can detect ileus, colonic dilation, colonic wall edema, thumb printing, haustral thickening, and toxic megacolon, which can be findings consistent with CDI. Computed tomography (CT) scan is a sensitive test for patients presenting with severe or fulminant CDI. Findings consistent with CDI found on CT scan include diffuse colonic thickening, pericolonic stranding, pancolitis, and megacolon. The entire colon may be involved with CDI even when fulminant CDI may be isolated to the right colon on imaging (Fig. 1). The accordion sign can also be identified on CT scan, which is intraluminal contrast or air outlined by a thickened mucosa.

Endoscopy

When evaluating the colon for CDI via endoscopy, colonoscopy is preferred over sigmoidoscopy because colitis, as noted previously can be limited to the right colon in up to one third of patients with CDI. Ulcers, plaques, and pseudomembranes can be seen in 50% of patients with fulminant CDI and 25% of patients with mild CDI. Pseudomembranes are pathognomonic and appear as raised, yellowish lesions that are 2 to 10 mm in size with skipped areas of normal mucosa. In fulminant CDI these lesions coalesce to form plaques. Colonoscopy can be diagnostic but also therapeutic when a large colonic decompression tube is placed that can also be used for vancomycin enema irrigation.

Diagnostic Recommendations

Current recommendations published in 2018 from SHEA and Infectious Diseases Society of America define CDI as the presence of symptoms (typically diarrhea) and either a stool test positive for toxin or new detection of toxigenic *C. difficile* or colonoscopic or histopathologic findings revealing pseudomembranous colitis.

A multidisciplinary approach with surgical consultation to evaluate the severity of CDI is a critical strategy to determine appropriate medical and surgical management. Literature has revealed early surgical consultation has shown to be beneficial even when not resulting in a surgical procedure.

MEDICAL TREATMENT

With the increase in resistance of *C. difficile*, there has been increased incidence, severity, and mortality of CDI over time. The treatment of CDI is based on the severity of disease (Table 3).

Infection Prevention and Control

A critical aspect of CDI management is a robust prevention program with two tiers. The first is focused on the avoidance of inoculation via measures such as hand washing and isolation precautions. The second is minimizing medical interventions that put patients at risk for developing CDI (Box 2).

Medical Therapy

Offending antibiotic agents should be stopped in patients with CDI if it is deemed medically safe and appropriate to do so; this will in turn decrease the risk of CDI recurrence. Antidiarrheals as well as narcotics should be avoided to minimize the development of toxic megacolon. Empiric antibiotic therapy should be initiated if there is high suspicion for CDI because delay in confirmatory diagnostic testing and treatment leads to increased mortality.

Nonsevere Disease

A patient with an initial episode of nonsevere CDI should receive oral vancomycin 125 mg every 6 hours or oral fidaxomicin 200 mg every 12 hours for 10 days. Although oral metronidazole is no longer considered a first-line agent for CDI, if vancomycin nor fidaxomicin is available, oral metronidazole 500 mg every 8 hours can be prescribed.

Severe Disease

In patients with an initial episode of severe CDI, oral vancomycin 125 mg every 6 hours or oral fidaxomicin 200 mg every 12 hours should be initiated for 10 days.

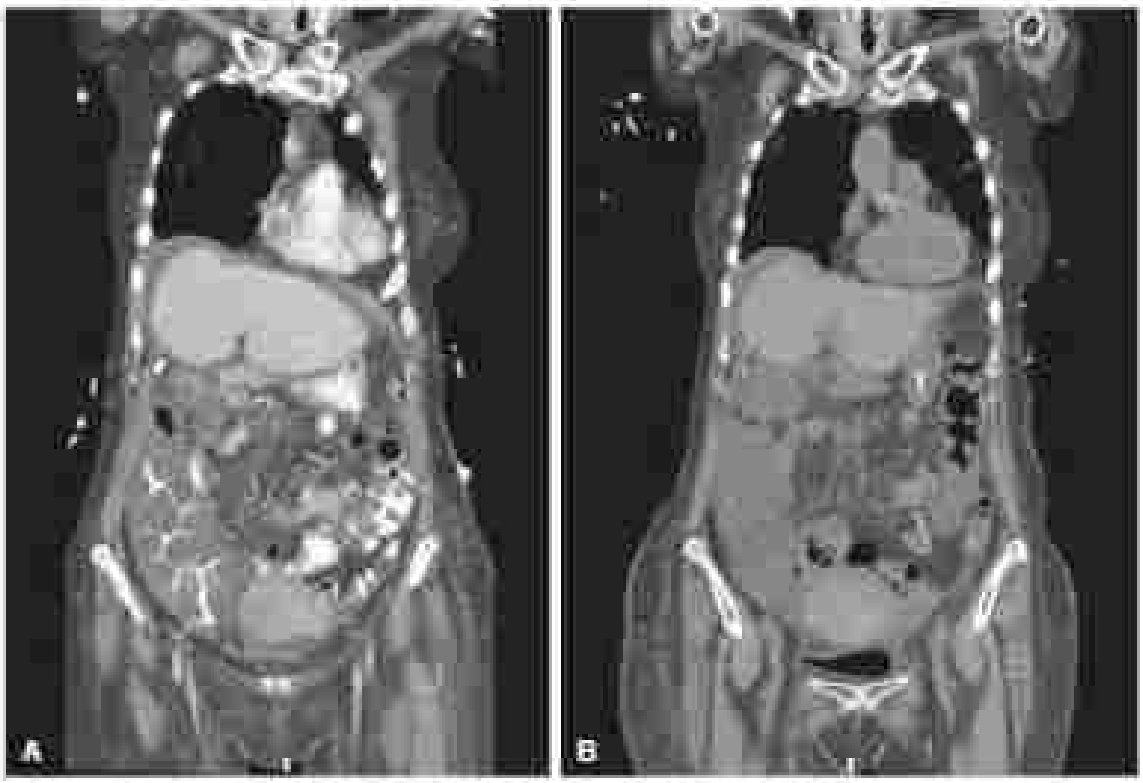

FIG. 1 Computed tomography scan showing fulminant Clostridium difficile infection of the right colon. (A) With contrast versus (B) without contrast reveals the importance of contrast utilization with imaging for diagnosis.

TABLE 3 Medical Management of CDI

Clinical Presentation	Recommended Treatment
Nonsevere, initial episode	1. Oral vancomycin 125 mg every 6 hours for 10 days, *or* 2. Fidaxomicin 200 mg every 12 hours for 10 days 3. If agents 1 and 2 are unavailable, oral metronidazole 500 mg every 8 hours for 10 days
Severe, initial episode	1. Oral vancomycin 125 mg every 6 hours for 10 days, *or* 2. Fidaxomicin 200 mg every 12 hours for 10 days
Fulminant, initial episode	1. Oral vancomycin 500 mg every 6 hours, and 2. Intravenous metronidazole 500 mg every 8 hours 3. If ileus present, consider rectal vancomycin
First recurrence	1. Prolonged tapered and pulsed oral vancomycin regimen if vancomycin was used for initial episode 2. Fidaxomicin 200 mg every 12 hours for 10 days if vancomycin was used for initial episode 3. Oral vancomycin 125 mg every 6 hours for 10 days if metronidazole was used for initial episode
Second or subsequent recurrence	1. Vancomycin in a tapered pulsed regimen, *or* 2. Vancomycin 125 mg every 6 hours for 10 days followed by rifaximin 400 mg every 8 hours for 20 days, *or* 3. Fidaxomicin 200 mg every 12 hours for 10 days, *or* 4. Fecal microbial transplantation

CDI, *Clostridium difficile* infection.
Modified from the 2017 Update by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA).

Fulminant CDI

In the setting of fulminant CDI, the patient should be started on oral vancomycin 500 mg every 6 hours and intravenous metronidazole 500 mg every 8 hours. If the patient is unable to take oral medications, oral vancomycin can be administered via a nasogastric tube. If the patient has an ileus, the addition of rectal vancomycin enemas can be considered. In critically ill patients with fulminant CDI, studies have shown combination therapy decreases mortality.

Recurrence

Treatment of the first recurrence is based on what the patient was treated with during the initial episode. If oral vancomycin was used initially, oral fidaxomicin 200 mg every 12 hours for 10 days can be used or a prolonged taper of pulsed oral vancomycin (i.e., 125 mg every 6 hours for 10–14 days, every 12 hours for 7 days, every 2–3 days for 2–8 weeks). Although metronidazole is no longer recommended as a first-line agent in the treatment of CDI, if this was given

BOX 1 Infection Prevention and Control

Prevention/Avoidance of Inoculation

Minimize frequency and duration of antibiotics
Minimize number of antibiotics prescribed
Implement antibiotic stewardship program
- Consider restriction of fluoroquinolones, clindamycin, and cephalosporins (when not used for surgical prophylaxis)
- Discontinue unnecessary anti-acid reducing therapies

Patients With C. difficile Infection

Hand hygiene with soap and water before and after contact
Private room with dedicated toilet
If cohorting is required, cohort infected/colonized patients with the same organism
Preemptive contact precautions once C. difficile testing is ordered
Healthcare personnel must use gloves and gowns
Prolong contact precautions until discharge
Patients should wash their hands and shower to reduce spore burden
Use disposable patient equipment (stethoscopes, etc.)
Daily and terminal room cleaning with sporicidal disinfectant

for the initial episode, the patient should receive oral vancomycin 125 mg every 6 hours for 10 days.

In patients that have a second or subsequent recurrence, there are three medical regimens (therapies currently recommended: a prolonged taper of pulsed oral vancomycin, oral vancomycin 125 mg every 6 hours for 10 days followed by rifaximin 400 mg every 8 hours for 20 days, or fidaxomicin 200 mg every 12 hours for 10 days.

Fecal Microbial Transplant

If antibiotic therapy has failed after multiple recurrences, fecal microbial transplant (FMT) has been reported as safe and effective. It was first described in 1983 and has a reported success rate of greater than 90%. Donor FMT has proved safe and more effective than autologous FMT and therefore careful donor selection is important when considering and managing a communicable disease.

FMT can be administered via nasogastric tube, upper endoscopy, enema, or colonoscopy. A randomized controlled trial published in 2017 determined FMT delivered via oral capsule was not inferior to delivery via colonoscopy in preventing CDI over 12 weeks.

SURGICAL TREATMENT

Although an average of only 1% of all patients with CDI undergo emergent surgical intervention, about 30% of patients with fulminant CDI require urgent surgery. Surgical intervention is becoming even more important in the setting of increasingly resistant *C. difficile* spores and hypervirulent strain evolution resulting in an increased incidence of fulminant CDI. A meta-analysis published in 2012 revealed 41% mortality in patients requiring emergency surgery for CDI.

Despite multiple attempts to create and identify early markers indicating the need for surgical intervention, high morbidity and mortality rates remain. Therefore, a multidisciplinary approach with early surgical consultation to evaluate severity of CDI and determine the need for surgical management is critical.

Decision to Operate

If aggressive surgical treatment is needed, early identification of this is imperative because delayed intervention results in increased mortality. Patients diagnosed with fulminant CDI should be adequately resuscitated and empiric combination antibiotic therapy should be initiated to decrease mortality.

The decision to operate on a patient with CDI should be well thought out. The strongest predictors of postoperative mortality are related to preoperative physiologic status. Patients presenting with preoperative acute renal failure, intubation, multisystem organ failure, or shock requiring vasopressor have high postoperative mortality and should therefore prompt serious consideration for early surgical intervention.

Indications

Immediate indications for operative intervention include peritonitis, perforation, toxic megacolon, and recalcitrant severe colitis. Typically, toxic megacolon that presents with a cecal diameter greater than 12 cm or a colonic diameter greater than 6 cm on radiographic imaging should warrant surgical consideration. Additionally, and not uncommonly, patients with CDI and toxic megacolon may lack diarrheal symptoms and can present atypically. Therefore, there should be a low threshold for surgical management in the setting of toxic megacolon.

Additional indications for surgical management that are not as well defined include fulminant CDI or failure of medical therapy within 48 to 72 hours in the setting of continued toxicity. In patients with fulminant CDI that also have inflammatory bowel disease or are older than 65 years, failure of medical therapy after 12 hours should warrant consideration for operation.

Preparation for Operative Intervention

When preparing a patient with CDI for the operating room, invasive cardiopulmonary monitoring with an arterial line and central venous access is recommended. Aggressive fluid resuscitation is critical and antibiotic delivery is imperative. Although it is not always possible, consultation with an interventional specialist is ideal for operative intervention planning. Additionally, reservation of an intensive care unit bed should be pursued for postoperative management of these critically ill patients.

Total Colectomy with End Ileostomy

Historically open total colectomy with end ileostomy has been the procedure of choice for fulminant CDI. It has been established segmental resection should not be considered even if disease is believed to be confined to one area of the colon. Ugwuh et al. found significantly improved mortality when total colectomy was performed in comparison to segmental resection.

Operative Approach

Open resection is typically recommended to facilitate the most expedient resection; however, a laparoscopic approach could be considered in a stable subset of patients. On entry into the abdomen, the colon typically will not appear necrotic; it can be edematous and boggy with significant inflammation and ascites. Nonetheless, a total colectomy should be performed by removing the intraperitoneal portion of the colon and dividing the rectum at the peritoneal reflection with a stapling device. The mesentery can be ligated with a clamp and tie technique or bipolar or ultrasonic tissue sealing and cutting devices. The omentum can be removed from the colon or divided and resected from the colon, whichever suits expedition.

In the setting of fulminant CDI in critically ill patients, anastomosis is not recommended. The distal ileum should be brought through a facial opening and maturation of the stoma completed after abdominal closure. Occasionally, a patient may have such edematous bowel that fascial closure cannot be accomplished and a damage control technique needs to be used. In this scenario, the abdomen should be temporarily closed with a vacuum device with delayed maturation of the stoma and abdominal closure on take-back laparotomy.

Stoma Reversal

The overall stoma reversal rates in patients' status after total colectomy and end ileostomy for CDI are only 29% to 35% with a 258-day median interval of closure. Although most patients do not undergo

reversal, patients that have undergone a total colectomy and ileostomy in the setting of fulminant CDI can be considered for stoma reversal after full recovery.

Mortality after Colectomy

Patients who undergo colectomy for CDI have a 34% to 57% mortality. Some of the contributing factors that result in this mortality rate are delay in initial diagnosis, delay in surgical consultation, poor patient selection, and delay to surgical intervention. Other factors that are associated with mortality after colectomy for CDI are preoperative shock, preoperative dialysis dependence, chronic obstructive pulmonary disease, wound class III, thrombocytopenia with platelets less than 150 × 10⁹/L, coagulopathy with international normalized ratio greater than 2, and renal insufficiency with blood urea nitrogen greater than 40 mg/dL. Patients older than age 80 years have a threefold increase in mortality and patients requiring intubation or vasopressors have a mortality rate greater than 50% after colectomy for CDI.

Although mortality rates remain high for patients with CDI undergoing total colectomy, treatment with colectomy improves outcome over medical management alone in patients with fulminant CDI. Emergency colectomy has been shown to improve mortality in critically ill patients with fulminant CDI.

Overall, total colectomy can be a time consuming operative course with blood loss intraoperatively, which is challenging in physiologically disturbed patients. Long-term 5-year survival after surgery for fulminant CDI has been reported as low as 36%. Of those survivors, only 20% had bowel continuity restored with stoma reversal.

Antibiotic Therapy After Colectomy

Currently, there are no established practice guidelines for postoperative antibiotic use in fulminant CDI after total abdominal colectomy. A multicenter retrospective study in 2015 compared four different antibiotic regimens: oral vancomycin, intravenous metronidazole and oral vancomycin, intravenous metronidazole alone, or intravenous metronidazole and vancomycin per rectum in postoperative fulminant patients with CDI status post total colectomy with end ileostomy. They found intravenous metronidazole with or without oral vancomycin was associated with shorter intensive care unit length of stay and more ventilator free days. They did not find evidence to support routine treatment greater than 7 days. They concluded patients should be treated with either oral vancomycin or intravenous metronidazole and proctitis can be treated with the additional of vancomycin per rectum.

Laparoscopic Diverting Loop Ileostomy

Although total colectomy with end ileostomy has a survival advantage over medical management alone in patients with fulminant CDI, it is still associated with high mortality rate and low stoma reversal rates; therefore, alternative surgical approaches to this problem have been studied. University of Pittsburgh developed a protocol for this population of critically ill patients with fulminant CDI. It involves emergency surgery to construct a diverting loop ileostomy, typically completed laparoscopically. This is followed by colonic irrigation with warmed polyethylene glycol 3350 electrolyte solution via the ileostomy intraoperatively. Postoperative antegrade irrigation with vancomycin solution through the ileostomy for 10 days is performed. Their data published in 2011 showed decreased mortality using this surgical strategy with high stoma closure rates.

The loop ileostomy with colonic washout and high-dose vancomycin enemas presents an attractive surgical option because it results in a less intensive surgical procedure in unstable patients. Additionally, it is associated with decreased operative times and decreased blood loss as compared to total colectomy. Neal et al. found this protocol allowed for ostomy reversal procedures with relatively easy surgical reconstruction after life-threatening disease was resolved. They reported a colonic preservation rate of 93%. Most importantly, when comparing study patients with historical patients that underwent traditional total colectomy with end ileostomy for fulminant CDI, there was significantly decreased mortality in the diversion group.

A retrospective multicenter American Association for the Surgery of Trauma trial published in 2017 reviewed 10 centers' surgical experience in patients with CDI from 2010 through 2014. They compared patients who underwent total colectomy vs loop ileostomy. After adjusting for preoperative confounders, the loop ileostomy group was found to have a significantly lower mortality (17.2% versus 39.2%). The loop ileostomy group required fewer intraoperative transfusions and had less intraoperative blood loss. Although not reaching significance, they found a higher absolute reoperation rate and unplanned operation rate in the loop ileostomy group. They concluded loop ileostomy has survival benefit and should be considered for patients without contraindications to loop ileostomy.

Although these studies promote the use of loop ileostomy and vancomycin enema therapy in fulminant CDI, there are downsides to this intervention as well. Several studies have shown patients are at risk for CDI recurrence after ostomy reversal and reanastomosis. There have also been studies that did not reveal any mortality difference between loop ileostomy and total colectomy but did reveal a higher recurrence of CDI with colonic preservation.

Currently the role for surgical intervention in the setting of CDI recurrence is unclear.

Ongoing Studies

Although the surgical standard of care for patients with fulminant CDI has historically been a total colectomy with end ileostomy, the 30-day mortality following surgical intervention remains high ranging from 30% to 70%. Alternative approaches to management have been studied using fecal diversion via laparoscopic loop ileostomy creation followed by direct colonic lavage with polyethylene glycol and vancomycin. This has demonstrated a relative mortality reduction of about 50%.

There is a study underway that is building on this foundation of literature. The protocol involves bedside lavage with polyethylene glycol and vancomycin via nasojejunal tube in addition to usual antibiotic management compared with antibiotic management alone.

CDI IN INFLAMMATORY BOWEL DISEASE

It is well established that CDI is increased in patients with inflammatory bowel disease (IBD), particularly in ulcerative colitis. Patients with IBD contract CDI more often as an outpatient than patients without IBD. Patients with IBD with CDI have increased hospital length of stay, greater need for surgical intervention, higher mortality, and higher mortality independent of surgical intervention.

An IBD flare can mimic the symptoms of CDI; therefore, CDI should be considered in relapsing or worsening IBD. Additionally, patients with IBD with restorative proctocolectomy or diverting ileostomy are not immune to CDI. It can cause enteritis on the small bowel or the ileal pouch.

Treatment of CDI in IBD

Although oral vancomycin is a first-line treatment for all patients with CDI now, it is also established as the first-line therapy for patients with IBD with CDI. In the setting of fulminant CDI, intravenous metronidazole can be added to oral vancomycin.

Patients treated with a combination of immunomodulators and antibiotics have more adverse outcomes than those treated with antibiotics alone. Steroids, immunomodulators, and broad-spectrum antibiotics should be minimized if possible. Additionally, biologic agents do not appear to increase the acquisition of CDI. Overall, there should be a low threshold for total colectomy with ileostomy in severe and fulminant CDI to be followed by restorative surgery after full recovery.

C. DIFFICILE ENTERITIS

Although it is uncommon, CDI of the small bowel can manifest in a number of ways. It can occur as pouchitis in patients with an ileal J pouch after restorative proctocolectomy for familial polyposis or ulcerative colitis. It can even occur in patients after colectomy with end ileostomy. Persistent CDI enteritis should be considered in patients with high ostomy output with unexplained systemic inflammatory response.

Treatment for patients with CDI enteritis involves oral vancomycin or metronidazole as well as supportive care. Additionally, fecal microbial transplantation has been reported as successful in treating patients with CDI pouchitis.

CONCLUSION

With increasing incidence and severity of CDI, surgeons need to be familiar with the management of CDI. CDI should be considered in any patient with recent antibiotic use, unexplained abdominal pain, distention, fever, or leukocytosis, even in the absence of diarrhea. The need for early recognition of CDI that requires surgical management is important to improve outcomes and mortality; therefore, a multidisciplinary approach with early surgical consultation should be used to establish diagnosis and treatment.

Surgeons should be familiar with medical treatment, fecal microbial transplantation, and surgical treatment for CDI. If patients present with peritonitis, perforation, or fulminant CDI, the first consideration should be operative intervention. Additionally, there should be strong surgical consideration in patients who fail medical management. Although historically total colectomy with ileostomy is the accepted procedure of choice, laparoscopic diverting ileostomy with polyethylene glycol lavage and antegrade vancomycin is emerging as a promising treatment option for fulminant CDI.

MANAGEMENT OF LARGE BOWEL OBSTRUCTION

Susan L. Gearhart, MD, and Matthew P. Kelley, MD

Large bowel obstruction is a serious and common disorder that requires prompt attention. Emergency surgery for large bowel obstruction represents approximately 28% of the acute care surgeon's workload. The presentation is often inconsistent because of the variety of causes, and the diagnosis can easily be overlooked. The mortality associated with a large bowel obstruction is reportedly 14% to 17%. The surgeon should be able to establish a prompt diagnosis, be familiar with both benign and malignant causes, and be adept at determining the appropriate management plan.

ETIOLOGY

The cause of large bowel obstruction can be categorized broadly as mechanical or functional. Mechanical obstruction is more common and often results from a neoplastic process resulting in either an intrinsic or extrinsic compression. An intrinsic colorectal adenocarcinoma is the most common etiology and accounts for nearly 30% of large bowel obstructions. The most common site of an intrinsic malignant obstruction is the descending colon or rectosigmoid. Common etiologies for intrinsic and extrinsic lesions are shown in Box 1.

Diverticular disease is the second most common cause of large bowel obstruction. Chronic inflammation in the sigmoid colon can lead to a stricture in up to 17% of patients. The third most common cause of large bowel obstruction is volvulus and occurs in 5% of patients. Volvulus is the result of a long, redundant segment of colon that has developed an axial rotation of the bowel around the colonic mesentery. The most common location for volvulus is the sigmoid colon (60%–75%) followed by the cecum (25%–40%) and, rarely, the transverse colon (1%–8%).

Functional causes of large bowel obstruction include colonic pseudo-obstruction (Ogilvie's syndrome), narcotic-induced adynamic ileus, and an adynamic ileus caused by a systemic illness such as toxic ingestion from *Clostridium difficile* infection. Treating the underlying cause in functional large bowel obstruction often improves symptoms.

CLINICAL PRESENTATION

Large bowel obstruction can present with a wide range of symptoms depending on the acuity of the obstruction. The typical symptoms early on include lower abdominal pain, distention, and obstipation. Emesis is usually a late presentation of a large bowel obstruction and may not happen if the patient has a competent ileocecal valve. Often, acute large bowel obstruction is associated with signs of hypovolemia and electrolyte imbalances secondary to fluid sequestration in the intestines. Symptoms from chronic obstruction are typically mild and often associated with change in bowel habits, bloating, narrow caliber stools, and unintentional weight loss. The constellation of findings raises suspicion for malignancy.

DIAGNOSIS

History and Physical Examination

Rapid evaluation and diagnosis beginning with a focused history and physical examination should occur in patients presenting with signs and symptoms of a large bowel obstruction. Patients may report a rapid or slow progression of their symptoms depending on the etiology. Recent orthopedic or gynecologic procedures are commonly associated with the development of colonic pseudo-obstruction. A family or personal history of colonic neoplasms should be ascertained. A review of current medications may indicate prescription medications induced constipation.

C. DIFFICILE ENTERITIS

Although it is uncommon, CDI of the small bowel can manifest in a number of ways. It can occur as pouchitis in patients with an ileal J pouch after restorative proctocolectomy for familial polyposis or ulcerative colitis. It can even occur in patients after colectomy with end ileostomy. Persistent CDI enteritis should be considered in patients with high ostomy output with unexplained systemic inflammatory response.

Treatment for patients with CDI enteritis involves oral vancomycin or metronidazole as well as supportive care. Additionally, fecal microbial transplantation has been reported as successful in treating patients with CDI pouchitis.

CONCLUSION

With increasing incidence and severity of CDI, surgeons need to be familiar with the management of CDI. CDI should be considered in any patient with recent antibiotic use, unexplained abdominal pain, distention, fever, or leukocytosis, even in the absence of diarrhea. The need for early recognition of CDI that requires surgical management is important to improve outcomes and mortality; therefore, a multidisciplinary approach with early surgical consultation should be used to establish diagnosis and treatment.

Surgeons should be familiar with medical treatment, fecal microbial transplantation, and surgical treatment for CDI. If patients present with peritonitis, perforation, or fulminant CDI, the first consideration should be operative intervention. Additionally, there should be strong surgical consideration in patients who fail medical management. Although historically total colectomy with ileostomy is the accepted procedure of choice, laparoscopic diverting ileostomy with polyethylene glycol lavage and antegrade vancomycin is emerging as a promising treatment option for fulminant CDI.

MANAGEMENT OF LARGE BOWEL OBSTRUCTION

Susan L. Gearhart, MD, and Matthew P. Kelly, MD

Large bowel obstruction is a serious and common disorder that requires prompt attention. Emergency surgery for large bowel obstruction represents approximately 28% of the acute care surgeon's workload. The presentation is often inconsistent because of the variety of causes, and the diagnosis can easily be overlooked. The morbidity associated with a large bowel obstruction is reportedly 14% to 17%. The surgeon should be able to establish a prompt diagnosis, be familiar with both benign and malignant causes, and be adept at determining the appropriate management plan.

ETIOLOGY

The cause of large bowel obstruction can be categorized broadly as mechanical or functional. Mechanical obstruction is more common and often results from a neoplastic process resulting in either an intrinsic or extrinsic compression. An intrinsic colorectal adenocarcinoma is the most common etiology and accounts for nearly 30% of large bowel obstructions. The most common site of an intrinsic malignant obstruction is the descending colon or rectosigmoid. Common etiologies for intrinsic and extrinsic lesions are shown in Box 1.

Diverticular disease is the second most common cause of large bowel obstruction. Chronic inflammation in the sigmoid colon can lead to a stricture in up to 13% of patients. The third most common cause of large bowel obstruction is volvulus and occurs in 5% of patients. Volvulus is the result of a long, redundant segment of colon that has developed an axial rotation of the bowel around the colonic mesentery. The most common location for volvulus is the sigmoid colon (60%–75%) followed by the cecum (25%–40%) and, rarely, the transverse colon (1%–8%).

Functional causes of large bowel obstruction include colonic pseudo-obstruction (Ogilvie's syndrome), narcotic-induced adynamic ileus, and an adynamic ileus caused by a systemic illness such as toxic ingestion from Clostridium difficile infection. Treating the underlying cause in functional large bowel obstruction often improves symptoms.

CLINICAL PRESENTATION

Large bowel obstruction can present with a wide range of symptoms depending on the acuity of the obstruction. The typical symptoms early on include lower abdominal pain, distention, and obstipation. Emesis is usually a late presentation of a large bowel obstruction and may not happen if the patient has a competent ileocecal valve. Often, acute large bowel obstruction is associated with signs of hypovolemia and electrolyte imbalances secondary to fluid sequestration in the intestines. Symptoms from chronic obstruction are typically mild and often associated with change in bowel habits, bloating, narrow caliber stools, and unintentional weight loss. This constellation of findings raises suspicion for malignancy.

DIAGNOSIS

History and Physical Examination

Rapid evaluation and diagnosis beginning with a focused history and physical examination should occur in patients presenting with signs and symptoms of a large bowel obstruction. Patients may report a rapid or slow progression of their symptoms depending on the etiology. Recent orthopedic or gynecologic procedures are commonly associated with the development of colonic pseudo-obstruction. A family or personal history of colonic neoplasms should be ascertained. A review of current medications may indicate prescription medications induced constipation.

BOX 1 Common Etiologies for Intrinsic and Extrinsic Lesions

Extrinsic

Malignancy (e.g., ovarian cancer)
Endometriosis
Uterus
Pelvic abscess/inflammation

Intrinsic

Colon cancer
Diverticular stricture
Inflammatory bowel disease
Ischemia
Radiation

The physical examination classically reveals a tympanitic and distended abdomen. On occasion, a mass can be palpated through the abdominal wall. Diffuse tenderness is common and may raise the suspicion for possible peritonitis. Focal tenderness may suggest ischemia or localized perforation. Digital rectal examination should be performed on all patients to rule out fecal impaction, foreign body, or anorectal malignancy as the cause.

Imaging

When a patient presents acutely with abdominal pain, distension, obstipation, nausea, and vomiting, bowel obstruction is the leading consideration. Because of ease in accessibility, upright and supine abdominal (kidney, ureter, and bladder) radiographs are often the first images obtained. For the diagnosis of large bowel obstruction, kidney, ureter, and bladder radiographic images have a sensitivity and specificity of 88% and 72%, respectively. Abdominal radiographs can quickly assess the diameter of the colon and indicate the presence of pneumatosis coli or pneumoperitoneum, allowing for a quick decision regarding the care of the patient. Cecal dimension beyond 9 cm and colonic distension beyond 6 cm is indicative of a large bowel obstruction. Colonic volvulus can also be identified with abdominal radiographs. The classic findings of a sigmoid volvulus are seen in about two thirds of patients and are commonly described as the "bent inner tube" sign or "coffee bean" sign.

Contrast enemas (CEs) were once the gold standard in the diagnosis of large bowel obstruction. CEs have a 96% sensitivity and a 98% specificity for diagnosing large bowel obstruction. Classic findings is a "bird's beak" deformity at the site of a volvulus or an "apple core lesion" at the site of an obstructing cancer. However, because these tests are labor intensive and require additional time, CEs have mostly been abandoned. Computed tomography (CT) has become the most important imaging modality in the evaluation of a patient with signs and symptoms of a large bowel obstruction. CT confirms the diagnosis of large bowel obstruction with almost 100% sensitivity and 90% specificity, it also allows multiplanar reconstruction that further facilitates the definitive diagnosis. Finally, CT may have a substantial impact on the clinical management of a large bowel obstruction by demonstrating signs of intestinal ischemia, early perforations, or pneumoperitoneum leading to sooner interventions.

Although magnetic resonance imaging in the acute management of large bowel obstruction is not typically indicated, the emergence of magnetic resonance enterography with advanced cross-sectional characterization of the bowel particularly in inflammatory disease has been shown to be beneficial and correlates well with endoscopic findings. Furthermore, pelvic magnetic resonance imaging with rectal contrast is valuable in the diagnosis of rectal intussusception (dynamic imaging) and in the local staging of rectal cancer.

TREATMENT

Initial Management

In concert with the initial history and physical, laboratory assessment should include serum chemistry and electrolytes, complete blood count, and lactate level. Hypovolemia and electrolyte imbalances are common and should prompt aggressive resuscitation with accurate monitoring of intake and output with a urinary catheter. Decompression with a nasogastric tube should be performed early. If surgery is a consideration, preoperative antibiotics and stoma marking should occur as an entirety is frequently required.

Surgical Techniques: Colostomy

A diverting loop colostomy may be indicated if the patient is severely unstable, there is diffuse carcinomatosis, or a severe inflammatory/malignant process precludes resection. The best approach in this setting is a midline laparotomy that allows for decompression of the bowel, prompt identification of the lesion, and adequate exposure for a variety of procedures. Laparoscopic intervention may be difficult secondary to colonic distension. A loop colostomy is preferred over an end colostomy as the blind end that is left in the abdomen may perforate. A colostomy relieves patients of their symptoms and limits subsequent concerns for an anastomotic leak. However, colostomies can be associated with significant morbidity, including high rates of parastomal hernia (50%), decreased quality of life, and low rates of stoma closure.

Segmental Resection and Hartmann's Procedure

In patients with a right sided obstruction and the point of obstruction is proximal to the splenic flexure, urgent right hemicolectomy with primary anastomosis should be considered and can often be performed laparoscopically in a stable patient with limited bowel distension. This procedure is associated with low anastomotic leak rates (<5%) in a hemodynamically stable patient who has not undergone a bowel preparation.

There is more debate regarding the preferred surgical procedure for an obstructing lesion arising in the descending, sigmoid colon, rectum, or anus. Traditionally, primary anastomosis at the initial procedure was avoided because of the higher rates of anastomotic leak (20%). If the patient is unstable, has significant dilation of the proximal colon, or has multiple comorbidities (including pregnancy), Hartmann's procedure should be performed. Introduced in 1923 by Henri Hartmann specifically for the management of large bowel obstruction, Hartmann's procedure involves resection of the distal obstruction and the formation of an end colostomy. If the procedure is being performed for a suspected cancer, every attempt should be made to achieve and oncologic resection as this can enhance chances for cure.

To perform a Hartmann's procedure, the patient should be placed in the lithotomy position, which greatly enhances pelvic dissection and allows for access to the rectum if necessary. Following resection of the lesion, decompression of the colon is first achieved with an end colostomy (with or without a mucous fistula) In a review of 35 studies by van der Wall and colleagues, of the 4249 patients who underwent a Hartmann's procedure, only 48% underwent reversal with a mean time to reversal of 2.5 months. Morbidity rate was 3% to 60% (mean, 16.5%) and mortality rate from 0% to 7.1% (mean, 1%).

Segmental resection of the colon with primary anastomosis is a good option for carefully selected patients if the proximal colon is not dilated significantly. Retrospective reviews have shown similar rates of operative mortality and anastomotic leak in carefully selected patients undergoing left sided colectomy compared with right sided colectomy. Furthermore, quality of life is improved. A good option for a high risk patient is segmental colectomy, anastomosis, and a diverting loop ileostomy. This still allows for diversion of the fecal stream, and in the event of an anastomotic leak, intraabdominal

sepsis is contained and can usually be managed nonoperatively with percutaneous drainage and antibiotics. Loop ileostomy reversal is a less invasive operation and patients will more likely undergo this procedure to have their intestinal continuity restored as compared to reversing a Hartmann's procedure. The disadvantage is that ileostomy management in some patients (particularly the elderly) may be challenging with fluid and electrolyte shifts.

Colonic Lavage

In select patients, the use of an on table colonic lavage may permit a single stage surgery in the setting of a left sided large bowel obstruction. Following resection of the lesion, the colon should be fully mobilized at both flexures. Next, an appendectomy is performed and catheter passed into the cecum and secured with a purse string suture. This catheter is attached to a large bag of warmed saline and elevated on a pole. The staple line at the distal segment of colon is opened and a generous length of sterile corrugated tubing is placed into the lumen of the descending colon. The tubing is secured in place with umbilical tape or a purse string and then draped off the table into a basin. Warmed saline is then flushed through the colon. This is continued until the effluent clears and typically requires several liters. The catheter and tubing are removed and the site of the appendectomy is closed. Before the anastomosis, the colon is inspected for injuries that may have occurred during the lavage. The anastomosis is then performed in the standard fashion. A modified version of this method uses a Y shaped connector. One limb allows for retrograde infusion of saline through the descending colon and the other is attached to drainage tubing. This modification to appealing as it obviates the need for the appendectomy or ileostomy. In a study by Jung and colleagues, 171 patients with an obstructing left sided lesion received intraoperative colonic lavage with primary anastomosis. Compared with elective, nonobstructed patients during the same interval, anastomotic leakage and wound infection were not significantly different.

Subtotal Colectomy

Conversion from segmental resection to subtotal colectomy is rarely needed and determined by the integrity of the colon proximal to the obstruction. A subtotal colectomy is indicated when perforation, large serosal injuries or synchronous lesions are found at the time of exploration. When performing a subtotal colectomy in the emergent setting, creation of an end ileostomy is often necessary.

Endoscopic Stenting

In the past decade, endoscopic management of obstructing large bowel lesions has gained significant attention. In the appropriately selected patient, endoscopic stents can be tremendously beneficial. Indications for stent placement include palliation of an inoperable obstructing lesion (e.g., stage IV colorectal cancer) and as a temporizing "bridge" to definitive therapy in a patient with a curable, or potentially curable lesion. The ability to treat a curable, or potentially curable lesion, affords time for colonic decompression, medical optimization, endoscopic evaluation for synchronous lesions, and increases the likelihood of a single stage operation. Contraindications to stent placement include any of the previously discussed indications for emergent surgery, an abscess/infection closely associated with the lesion, short and tethered colon, and a lesion less than 5 cm from the anal verge.

Preoperative antibiotic coverage is unnecessary for stent placement. Gentle tap water enemas should be used to evacuate stool distal to the lesion. If an oral bowel preparation is desired, it may be attempted only if the obstruction is partial and the patient is closely monitored for the development of new or worsening symptoms. Colonoscopic evaluation of the lesion must be done with the utmost care; forceful attempts to traverse beyond the lesion are strictly avoided. Perforation is the most feared complication of stent placement. To mitigate the procedural risk of perforation, insufflation with carbon dioxide is preferred over room air because of the dramatically faster clearance time. The most common stents used in the United States are uncovered, self expanding metal stents. Through the scope (TTS) and over the wire, also referred to as non TTS, are the two conventional approaches to stent placement.

TTS is usually the first line approach (Fig. 1). The TTS system requires a colonoscope equipped with a working channel to pass the guidewire and stent. The scope is advanced and parked in an area immediately distal to the lesion. Contrast is administered and the lesion assessed with fluoroscopy. The guidewire is then advanced safely beyond the lesion followed by the stent (Seldinger's technique). Endoscopy and fluoroscopy confirm the correct location of the wire and the stent. Most TTS systems encourage a proximal and distal stent overlap of 2 cm. For longer lesions, additional stents can be placed in series. If assessment of the lesion shows anatomy unfavorable for TTS (e.g., available size of the stents), the procedure is converted to over the wire. With the guidewire fixed, the colonoscope is withdrawn entirely. The appropriate stent is selected and passed directly over the wire into position using fluoroscopy. Fluoroscopic or postprocedural abdominal films are obtained to confirm the typical wire appearance of a narrowed or waisted midportion with proximal and distal flaring. The flaring segments adequate overlap into normal, low resistance lumen. To reduce development of rapid restenosis, the luminal diameter at the mid portion of the stent should be at least 24 mm. Balloon dilation should not be attempted because of significant risk of perforation. If imaging does not demonstrate flaring at one or both ends of the stent, additional stenting is likely necessary and typically done to an end to end fashion.

Patients should expect gradual improvement of symptoms over 3 to 5 days as the stent reach maximal expansion and the colon decompresses. If the stented lesion was accurately or transitive colitis, patients can resume a regular diet immediately. For descending colon and beyond, patients are advised to consume a low residue, low fiber diet along with daily laxatives (e.g., polyethylene glycol) to promote soft stools that are unlikely to become impacted at the stent. It is important that definitive therapy is planned, it should be done within 7 to 14 days following placement of stent. Patients who receive stenting for palliation and the anticipated duration greater than 2 weeks have a significantly increased risk of perforation. Multidisciplinary discussion should weigh the possibility of surgical palliation in this high risk population.

Current literature reports successful stent placement for acute large bowel obstruction between 70% and 90%. In a pooled analysis by Sebastian et al., 25% of the 1198 patients who underwent stent placement for obstruction developed a complication. Most common complications include stent migration, restenosis, and perforation. The most serious complication is perforation and occurs in 4% to 5% of patients. Intrinsic factors that may increase the risk of stent related perforation include longer segment of obstruction (median length of 6 cm), benign etiology and extraluminal origin.

SPECIFIC SITUATIONS

Sigmoid Volvulus

Volvulus, from the Latin, volvere, means to roll. The classic patient with a sigmoid volvulus presents with sudden lower abdominal pain and obstipation. The demographic profile most affected by sigmoid volvulus is a black male older than 70 years with significant comorbidities. The gold standard in the management of sigmoid volvulus is endoscopic detorsion, gross inspection, and placement of a drainage catheter (successful in up to 80% of patients). Timing of definitive operation is based on the high rate of recurrence, most studies citing the rate in the 50% to 80% range. Atamanalp and colleagues published data from a single center review of 486 patients. They found morbidity and mortality of 35% and 16% for emergent surgery and 12.5% and 0% for elective surgery, respectively. Some suggest performing the definitive surgery as early as the index admission, but evidence for this is lacking. Regardless of timing, the approach can be either open or minimally invasive. The chronic process leading to

FIG. 2 Endoscopic stent placement for obstructing noncolorectal cancer. (A) Arrow indicates obstructing pelvic lesion. (B) Fluoroscopic guided passage of the wire across the obstructing lesion. (C) Poststent abdominal film with improvement of large bowel distention.

sigmoid volvulus results in an anatomical configuration that facilitates sigmoid resection with minimal difficulty. For isolated sigmoid volvulus and the elective sigmoid colectomy, the recurrence rates are very low.

Cecal Volvulus or Bascule

The second most common site of colonic volvulus is the cecum (Fig. 2). In patients with cecal volvulus, there is a female predominance, and typically patients are in the second and third decade of life. Presentation is similar to small bowel obstruction with abdominal distention, nausea, and vomiting; however, this can vary. There are three types of cecal volvulus.

1. Axial cecal volvulus. A twist of the mesentery on which the affected cecum remains in the right lower quadrant.
2. Loop cecal volvulus. The cecum and terminal ileum are twisted in the axial plane and the affected cecum typically lies in the left upper quadrant.
3. Cecal bascule. A redundant cecum folds in the sagittal plane onto itself and the proximal ascending colon leaving the affected cecum within the right upper quadrant.

All three types necessitate either an acquired or congenital hypermobile cecum and ascending colon. Types 1 and 2 are the most common, account for roughly 80% of cecal volvuli. Unlike types 1 and 2, type 3 does not exhibit torsion. Patients who present with type 3 typically have a much more tenuous presentation. Endoscopic management is not recommended for cecal volvulus or bascule because of a low rate of successful detorsion, and colonic ischemia can be missed in up to 25% of patients. For the patient presenting with a high probability of cecal volvulus, the operation of choice is

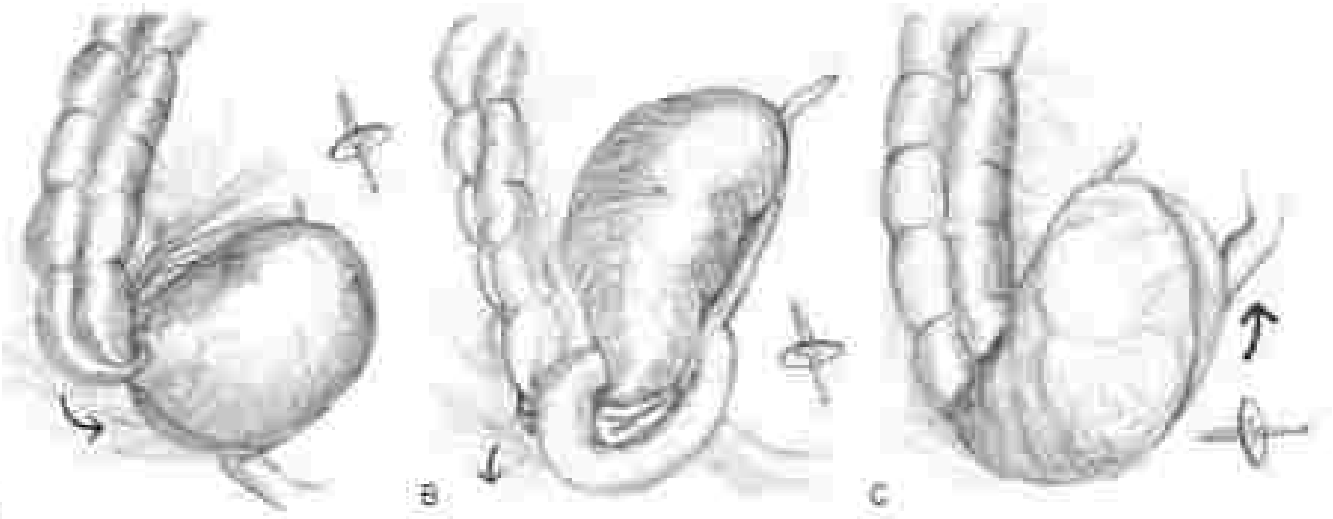

FIG. 1 Types of cecal volvulus. (A) Type 1, axial cecal volvulus. (B) Type 2, loop cecal volvulus. (C) Type 3, cecal bascule. (*Courtesy Matthew P. Kelly, MD.*)

an exploratory laparotomy. Severe ischemia, necrosis, or perforation occurs in up to 18% of patients with cecal volvulus; if present, mortality rates are equally as high. Management of the patient with nonviable cecum is resection and creation of end ileostomy, with consideration for mucous fistula. If the cecum is viable or with patchy ischemia, there is less consensus on the appropriate management. Nonresectional options include detorsion with cecopexy and cecostomy. Widely variable rates of recurrence, morbidity, and mortality have been demonstrated, although there is a paucity of recent data that compares these options and with respect to viable versus nonviable bowel. Devolution of the current data favors ileocecectomy with primary anastomosis for patients with acute cecal volvulus, even when bowel appears viable. Laparoscopic approach is an acceptable option in stable patients with limited bowel distension if performed by an experienced surgeon.

Acute Colonic Pseudo-obstruction

Acute colonic pseudo-obstruction (ACPO), is also referred to as Ogilvie's syndrome in homage to the British surgeon, Sir Heneage Ogilvie, who in 1948 identified two patients who presented with large bowel distension without an identifiable lesion. This syndrome is most commonly encountered in the hospitalized, elderly male patient. Hospitalization is usually unrelated to the presenting symptoms rather for unrelated surgical procedure (most commonly involving pelvic dissection) or traumatic brain injury. Additional predisposing factors include severe electrolyte disturbances, certain medications, and acute deconditioning. Presentation is consistent with other etiologies of large bowel obstruction, including nausea, vomiting, and persistent abdominal pain. A significant portion of these patients will continue to pass loose stool. Focal pericolonic confined to the right lower quadrant may be a warning sign of impending perforation because of the profound cecal distension. These findings should encourage expeditious intervention. Perforation at the time of presentation occurs in about 15% of patients and often is associated with abdominal tenderness, cecal diameter greater than 12 cm, fever, and leukocytosis.

Abdominal plain films are the best initial imaging study, although findings are nonspecific. Second line imaging has traditionally been with water soluble CE. Unfamiliarity with the technique coupled with the risk of perforation makes this option less favorable. The gold standard imaging modality is CT, findings include dilated colonic distension, possible transition point near splenic flexure, and importantly, no evidence of a mechanical obstruction.

Nonoperative management of ACPO is successful in more than two-thirds of patients. This consists of aggressive fluid resuscitation, repletion of serum electrolytes as necessary, cessation of possible offending medications (e.g., opioids, anticholinergics), and bowel rest. The use of nasogastric and rectal tubes for decompression may also encourage the passage of flatus. These principles of nonoperative management are continued for 2 to 4 days. During this period, it is essential to monitor the patient with the use of serial imaging and physical examinations.

Failure to improve over this period necessitates the next step in the algorithm, neostigmine. Neostigmine increases the availability of acetylcholine through its anti-acetylcholinesterase mechanism. In the colon, additional acetylcholine results in improved contractility and generalized motility. Before administration, the patient should be transferred to a unit with continuous cardiopulmonary monitoring and the ability to administer atropine, glycopyrrolate, or both. Neostigmine is contraindicated in patients in whom there is suspicion for ischemia or perforation, severe acute bronchospasm, poorly controlled cardiac dysrhythmia, or pregnancy. With the patient connected to continuous monitoring, the first dose of neostigmine of 2 to 3 mg given intravenously over 1 to 3 minutes. Success is achieved if passage of flatus, stool, or decreased abdominal distension. Patients are observed over the next 30 minutes. Atropine and glycopyrrolate should be readily available if there is development of bradycardia or bronchospasm, respectively. Neostigmine is successful at treating ACPO in more than 90% of cases. For patients who are partial responders or unresponsive after one dose, a second can be administered with high rates of success. For those who fail to respond to neostigmine, the next step in management is endoscopic decompression. Geller et al. reviewed 50 patients with ACPO treated with colonoscopic decompression and found clinical success in 92% following a single intervention, 18% needed at least one additional colonoscopy, for patients who did not receive a decompression tube at the time of the procedure, clinical success was only achieved in 25%. Regarding technical considerations, insufflation should be minimized and preferably with carbon dioxide. The scope should be advanced into the right colon. A decompression tube is strongly recommended and should originate from the right colon. The endoscopist should remove as much gas as possible during withdrawal of the scope. If endoscopic decompression is not possible or unsuccessful, percutaneous cecostomy can be used with variable success. When all these interventions have been unsuccessful, operative management is indicated. The surgery is dictated by the intraoperative findings. A cecostomy may be enough to assess the viability of the colon. If no evidence of perforation or ischemia, a tube cecostomy or surgical cecostomy may be sufficient. When ischemia is identified, the affected region should be

resected, including adrenal adenoma if indicated. Primary anastomosis is not recommended, but rather the creation of end colostomy with or without mucous fistula.

SUMMARY

Large bowel obstruction is a serious disorder that often necessitates surgical intervention. Rapid evaluation is essential to providing appropriate management. Emergent laparotomy should be performed on unstable patients with peritonitis and/or signs of symptoms of ischemia. Preoperative optimization of patients includes correction of electrolyte abnormalities with adequate hydration to correct acidosis. Segmental resection with primary anastomosis can be considered in patients who are stable and have minimal barriers to healing. Endoscopic stenting can be considered as a bridge to surgery or as palliation in select patients.

ENTERAL STENTS IN THE TREATMENT OF COLONIC OBSTRUCTION

Wissam J. Halabi, MD, and Maher A. Abbas, MD, FACS, FASCRS

Colonic stents were introduced as a treatment option for colorectal obstruction by Dohmoto in 1991. When first described, the stents were used as a palliative method in patients with malignant left sided colonic or rectal obstruction to avoid stoma formation. The use of a stent was advocated to decrease the morbidity of emergency colorectal surgery and the need for a stoma. Over the past 2 decades, the implementation of stent technology has grown and now includes treating proximal malignant colonic obstructions. Although stent effectiveness is highest when dealing with an intrinsic malignant structure from colon carcinoma, there has been an increasing interest to stent use to palliate obstructions of extrinsic origin. In addition to their use as a definitive palliative measure, the role of stents has evolved to include their use as a bridge to surgery intervention, allowing bowel decompression and decreasing the risks associated with emergency operation in a dilated colon filled with stool. Under such circumstances, stent decompression provides an opportunity to optimize the patient's condition from a medical and nutritional standpoint and allows the administration of bowel preparation. From an oncologic perspective, additional staging workup can be undertaken to identify synchronous lesions and, in the case of a select group of patients with rectal carcinoma, consideration can be made for neoadjuvant chemoradiation. Beyond malignant obstruction, colonic stents have been used in the management of benign colonic obstructions or stenosis caused by diverticular disease or inflammatory bowel disease as well as the management of postoperative complications such as anastomotic leaks or strictures, as previously reported by the senior author (M.A.A.) (Fig. 1A–E).

INDICATIONS FOR STENTS

Stenting of Malignant Obstruction

The primary indication for colorectal stenting is to relieve intraluminal obstruction caused by large bowel cancer. In a retrospective analysis of 183 procedures performed in 165 patients over a decade, the senior author found that 90% of procedures were performed for malignant disease. The majority of patients had an intrinsic stricture from a primary colorectal adenocarcinoma (82%) (Fig. 2A–E). The remaining subgroup of patients had extrinsic obstruction caused by gynecologic malignancies, gastrointestinal cancers of noncolorectal origin such as gastric, esophageal, and hepatobiliary, and extraabdominal origin such as breast. Extrinsic obstructions are challenging to treat for several associated factors: often, they can be multifocal compressing a long segment of large bowel and are associated with carcinomatosis in many patients. Furthermore, some patients, especially those with gynecologic malignancy, have an extensive surgical history, dense pelvic adhesions, and in some cases prior exposure to radiotherapy. Put together, these factors yield a lower technical and clinical success rate of stent deployment in patients with extrinsic obstruction compared with patients with intraluminal malignancy (Fig. 3). Technical success (immediate or short-term success) is defined as the ability to safely deploy and properly position the stent across the stricture without any immediate complication. Clinical success (long-term success) is defined as the ability to achieve long-term decompression without the need for operative intervention to treat long-term failure of the stent or related complications such as migration or erosion of the stent, or the development of obstruction. Thus, although stenting can be considered for patients with extracolonic malignancy, proper patient and family counseling is key in setting a realistic expectation and to prepare the patient emotionally for the potential need for surgical intervention in case of an immediate technical failure or long-term clinical failure. This issue will become even more challenging in the future as cancer specific survival becomes longer with more effective chemotherapeutic agents.

Stenting of Benign Disease

The role of stenting has been more limited to benign conditions, but there is a growing interest in exploring the effectiveness and durability of colonic stents in this setting. The senior author has previously described the role of colorectal stents in treating benign disorders such as obstructing strictures from diverticular disease or prior radiation therapy, complex colorectal fistulas including colovesical and colovaginal, and management of acute or chronic anastomotic complications including leak and obstruction. Despite such interest, the scientific literature is scarce in that regard and overall there has been a limited experience with the use of stents for benign conditions. From a technical standpoint, benign strictures can be technically difficult to tackle because of the lack of proper instrumentation and the use of soft metal stents that have been designed to apply a radial force against tumor tissue. The morphology of benign strictures is quite different, and they are often associated with a significant degree of extraluminal scarring and fibrosis. However, with an increasing interest in endoscopic intraluminal surgery, newer technologies will undoubtedly become available in the future. These anticipated advances will provide a new horizon with a future generation of platforms that will allow surgeons and endoscopists to expand the role of enteral stents.

resected, including adrenal adenoma if indicated. Primary anastomosis is not recommended, but rather the creation of end colostomy with or without mucous fistula.

SUMMARY

Large bowel obstruction is a serious disorder that often necessitates surgical intervention. Rapid evaluation is essential to providing appropriate management. Emergent laparotomy should be performed in unstable patients with peritonitis and/or signs of symptoms of ischemia. Preoperative optimization of patients including correction of electrolyte abnormalities with adequate hydration is correct acidosis. Segmental resection with primary anastomosis can be considered in patients who are stable and have minimal barriers to healing. Endoscopic stenting can be considered as a bridge to surgery or as palliation in select patients.

ENTERAL STENTS IN THE TREATMENT OF COLONIC OBSTRUCTION

Wissam J. Halabi, MD, and Maher A. Abbas, MD, FACS, FASCRS

Colonic stents were introduced as a treatment option for colorectal obstruction by Dohmoto in 1990. When first described, the stents were used as a palliative method in patients with malignant left sided colonic or rectal obstruction to avoid stoma formation. The use of a stent was advocated to decrease the morbidity of emergency colorectal surgery and the need for a stoma. Over the past 2 decades, the implementation of stent technology has grown and now includes treating proximal malignant colonic obstructions. Although stent effectiveness is highest when dealing with an intrinsic malignant structure from colon carcinoma, there has been an increasing interest to stent use to palliate obstructions of extrinsic origin. In addition to their use as a definitive palliative measure, the role of stents has evolved to include their use as a bridge to surgery intervention, allowing bowel decompression and decreasing the risks associated with emergency operation in a dilated colon filled with stool. Under such circumstances, stent decompression provides an opportunity to optimize the patient's condition from a medical and nutritional standpoint and allows the administration of bowel preparation. From an oncologic perspective, additional staging workup can be undertaken to identify synchronous lesions and, in the case of a select group of patients with rectal carcinoma, consideration can be made for neoadjuvant chemoradiation. Beyond malignant obstruction, colonic stents have been used in the management of benign colonic obstructions or stenosis caused by diverticular disease or inflammatory bowel disease as well as the management of postoperative complications such as anastomotic leaks or strictures, as previously reported by the senior author (M.A.A.) (Fig. 1A–E).

INDICATIONS FOR STENTS

Stenting of Malignant Obstruction

The primary indication for colorectal stenting is to relieve intraluminal obstruction caused by large bowel cancer. In a retrospective analysis of 183 procedures performed in 165 patients over a decade, the senior author found that 90% of procedures were performed for malignant disease. The majority of patients had an intrinsic stricture from a primary colorectal adenocarcinoma (82%) (Fig. 2A–E). The remaining subgroup of patients had extrinsic obstruction caused by gynecologic malignancies, gastrointestinal cancers of noncolorectal origin such as gastric, esophageal, and hepatobiliary, and extraabdominal origin such as breast. Extrinsic obstructions are challenging to treat for several associated factors: often, they can be multifocal compressing a long segment of large bowel and are associated with carcinomatosis in many patients. Furthermore, some patients, especially those with gynecologic malignancy, have an extensive surgical history, dense pelvic adhesions, and in some cases prior exposure to radiotherapy. Put together, these factors yield a lower technical and clinical success rate of stent deployment in patients with extrinsic obstruction compared with patients with intraluminal malignancy (Fig. 3). Technical success (immediate or short term success) is defined as the ability to safely deploy and properly position the stent across the stricture without any immediate complication. Clinical success (long term success) is defined as the ability to achieve long term decompression without the need for operative intervention to treat long term failure of the stent or related complications such as migration or erosion of the stent, or the development of obstruction. Thus, although stenting can be considered for patients with extracolonic malignancy, proper patient and family counseling is key in setting a realistic expectation and to prepare the patient emotionally for the potential need for surgical intervention in case of an immediate technical failure or long term clinical failure. This issue will become even more challenging in the future as cancer specific survival becomes longer with more effective chemotherapeutic agents.

Stenting of Benign Disease

The role of stenting has been more limited to benign conditions, but there is a growing interest in exploring the effectiveness and durability of colonic stents in this setting. The senior author has previously described the role of colorectal stents in treating benign disorders such as obstructing strictures from diverticular disease or prior radiation therapy, complex colorectal fistulas including colovesical and colovaginal, and management of acute or chronic anastomotic complications including leak and obstruction. Despite such interest, the scientific literature is scarce in this regard and overall there has been a limited experience with the use of stents for benign conditions. From a technical standpoint, benign strictures can be technically difficult to tackle because of the lack of proper instrumentation and the use of soft metal stents that have been designed to apply a radial force against tumor tissue. The morphology of benign strictures is quite different, and they are often associated with a significant degree of extraluminal scarring and fibrosis. However, with an increasing interest in endoscopic intraluminal surgery, newer technologies will undoubtedly become available in the future. These anticipated advances will provide a new horizon with a future generation of platforms that will allow surgeons and endoscopists to expand the role of enteral stents.

FIG. 2 (A) Endoscopic view of obstructing upper hemicolonic adenocarcinoma. (B) Immediate posterior deployment endoscopic view with decompression of the luminal obstruction.

Stenting as a Bridge to Surgery

The benefits of endoluminal stents inserted preoperatively as a bridge to a future definitive surgical intervention have been demonstrated in several series reporting on both malignant and benign disease. In patients presenting with acute large bowel obstruction from locally advanced disease with no evidence of metastasis or in the case of benign conditions such as a diverticular stricture, endoluminal stents provide an opportunity to convert the situation from an emergency setting into a more planned emergent or elective operation. Under such a scenario, stents confer a lower mortality and morbidity for patients in need of a curative or definitive operation. In the short term, stents are associated with a higher rate of primary anastomosis and avoidance of stoma in 42% to 77% of patients. Moreover, in patients with malignant obstruction, decompression with a stent allows for a proper staging workup to be performed as well as medical and nutritional optimization.

However, it is important to note that although numerous studies have advocated the use of stents as bridge to surgery in patients who are potentially candidates for a curative resection, the bulk of the data produced is limited by the retrospective nature of studies and small number of subjects. More recently, two multicenter randomized controlled trials comparing initial stent with surgery for acute left-sided malignant colonic obstruction were stopped because of a high rate of technical failure in the stent arm and a high perforation rate leading to an overall higher morbidity in the stent group. A further assessment of the available data on the outcomes of stents as a bridge to surgery at the meta-analysis level has yielded conflicting results. Endoluminal stents used as a bridge to surgery are associated with higher primary anastomosis rates and lower short-term stoma rates. Unfortunately, the reported permanent stoma rate is no different. Moreover, the morbidity and mortality rates in patients undergoing emergency surgery compared with those who had a stent were not significantly different. Complications inherent to stenting, such as colonic perforations, have been reported as 7% for clinical perforations and 10% for silent ones. Despite these complications, a relatively high technical success rate in the stent group has translated into a shorter hospital stay, lower rate of stoma formation, and lower mortality.

Beyond the technical and clinical success rates, it is important to appreciate the effect of stent placement on long-term oncologic outcomes in potentially curable patients. One of the concerns has been the potential risk of tumor spread in the bloodstream during endoscopic manipulation of the stent, and the potential for peritoneal seeding

in cases of clinical or silent perforations. Concerns expressed in the scientific literature include a higher rate of peritoneal invasion of the primary tumor in the stent group compared to the surgery group at time of resection. Furthermore, some studies have reported overall survival and a higher 5 year cancer specific mortality in patients receiving a stent compared with those managed with surgery. Such findings have led the European Society of Gastrointestinal Endoscopy to issue guidelines stating that the use of colonic self-expandable metal stent placement as a bridge to elective surgery is not recommended as a standard treatment for symptomatic left sided malignant colonic obstruction resulting from concerns of oncologic safety. These recommendations were subsequently endorsed by the Governing Board of the American Society for Gastrointestinal Endoscopy.

Based on experience of the senior author and the currently available data, we believe that stents should not be used as a bridge to surgery in low risk patients with potentially curable disease. Such patient is better served with surgical intervention. However, a consideration for stent placement can be made in a patient who has a poor functional status resulting from significant medical comorbidities and/or severe malnutrition or a recent significant medical event such as a cerebrovascular or cardiovascular accident. Under such circumstance, the use of a stent may be justifiable as a bridge to surgery when considering the risk and benefits of morbidity and mortality versus long term oncologic outcome. Furthermore, even though the intent in such patients is a bridge to surgery, in many of these patients the stent becomes permanent as the patient may succumb to factors others than the colorectal malignancy.

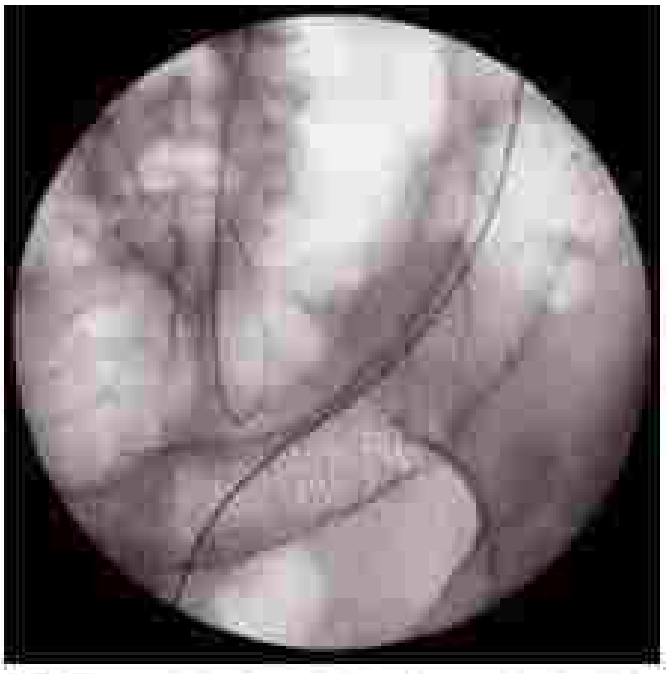

FIG. 3 Fluoroscopic view of successful stent decompression of anastomotic compression caused by recurrent ovarian cancer.

Stenting With Palliative Intent

Patients presenting with a malignant large bowel obstruction and metastatic disease often have a limited life expectancy especially in the setting of diffuse metastatic disease, cachexia, advanced age, and medical comorbidities. This patient population is often debilitated and considered as high risk for operative intervention. Under these circumstances, endoluminal stent placement is the intervention of choice in our opinion because it obviates the need for major surgery and associated recovery. Because chemotherapy is the mainstay of palliative treatment in patients with advanced cancer, it is of utmost importance to avoid delays in chemotherapy. There is a limited amount of data on the effect of stenting on the subsequent administration and timing of chemotherapy. As newer and more effective chemotherapeutic agents become available, this issue will become of increasing relevance. Before deploying a stent to patients with unresectable malignancy, a multidisciplinary discussion to build with medical oncology to determine which type of chemotherapy will be used. Bevacizumab is associated with a significant risk of colonic perforation and patients should be counseled regarding that risk.

The use of stents has been associated with a lower rate of short-term morbidity compared with palliative surgery. However, concerns remain about long term patency of stent in long term survivors. Several studies have reported on long-term complications of stent and the need for secondary endoscopic or surgical interventions (Fig. 4A–B). Such complications include perforation, occlusion, and migration (Fig. 5). Another important aspect of the team is consider is the patient's overall condition and life expectancy. Although in general most studies have failed to demonstrate a survival advantage of palliative stenting compared with surgery, it is important that future advances in chemotherapeutic agents will prolong survival that

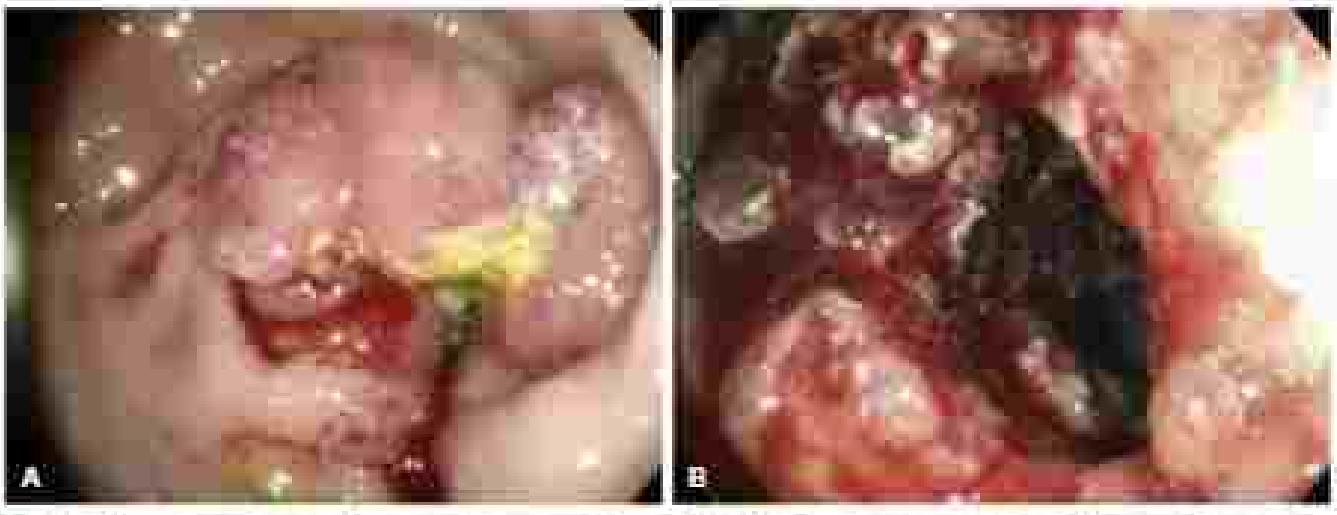

FIG. 4 (A) Endoscopic view of carcinoma ingrowth with obstruction of stent 4 months after initial deployment. (B) Successful fulguration of carcinoma ingrowth inside the stent using argon plasma coagulation.

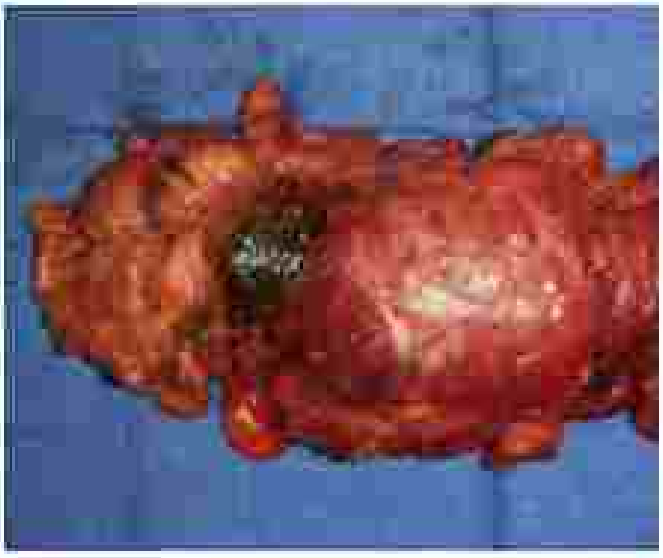

FIG. 5 Reconstructed transverse computed tomography image shows stent position.

FIG. 6 Contrast enema demonstrates an apple core lesion at the splenic flexure. The angulation in this part of the colon can make stent deployment challenging with higher migration and perforation rates.

may increase the relevancy of long-term stent patency and secondary interventions. Finally, although no long-term survival has been demonstrated in general with stenting, palliative stenting of advanced colorectal cancer is associated with improved quality of life. Therefore, in patients with incurable malignant colonic obstruction, stenting should be reserved for those with limited life expectancy who are high-risk operative candidates, whereas operative intervention should be considered in patients who are better fit for surgery and have a longer life expectancy.

CONTRAINDICATIONS TO STENT PLACEMENT

Clinical or radiologic evidence of acute perforation of the colon or significant ischemia or necrosis constitute absolute contraindications to the use of colonic stents in the management of malignant large bowel obstruction. Relative contraindications are the presence of a long structure (although a long stent or two tandem stents can be placed), a functional proximal obstruction may ensue because of the inability of the colon to push stool through a long metal segment), proximal lesions in the ascending colon (often can be palliated surgically with a low rate of stoma), distal lesions within 5 cm from the anal verge (painful and high risk for migration), and the presence of diffuse carcinomatosis (higher failure rate). Lesions in tortuous or angulated portions of the colon can be technically challenging and may have a higher failure rate. Such areas include splenic flexure lesions and masses in an angulated and redundant sigmoid colon (Fig. 6). The risk for migration and perforation can be higher. Stents are not recommended in patients who may be considered for treatment with antiangiogenic drugs such as bevacizumab. The use of prophylactic stents in patients with metastatic disease to prevent potential obstruction is not recommended.

TYPES OF STENTS

Colonic stents are self-expandable and are made of radiopaque, woven, metal mesh that has the shape of a cylinder resulting in self-expansion forces. Different types of stents are available based on the material used to manufacture them. They each may have advantages and disadvantages based on a specific design. Z-Stent (Cook Medical) is a stainless steel stent available in both covered and uncovered forms. Stainless steel stents are relatively stiff and may affect the quality of imaging studies such as magnetic resonance imaging. Wallstent (Boston Scientific) is made of Elgiloy, an alloy of chromium, cobalt, and nickel. The stent is thinner, more elastic, and flexible and is MRI compatible with less imaging artifact. Alimaxx E stents (Alveolus) and Ultraflex (Boston Scientific) are made of Nitinol, which is an alloy of nickel and titanium. Nitinol stents may be difficult to visualize under fluoroscopy and are used in conjunction with radiopaque markers; however, their characteristic shape memory and superelasticity makes them more flexible than stainless steel or Elgiloy stents. Metal stents can be uncovered and thus have bare wires or covered (Fig. 7). The latter have a silicone membrane over the bare wires. Although covered stents may reduce the risk of tumor ingrowth and can be used in the management of fistulas or anastomotic complications, they tend to migrate more often compared with uncovered stents. To overcome the issues associated with tumor ingrowth, drug-eluting stents are in development.

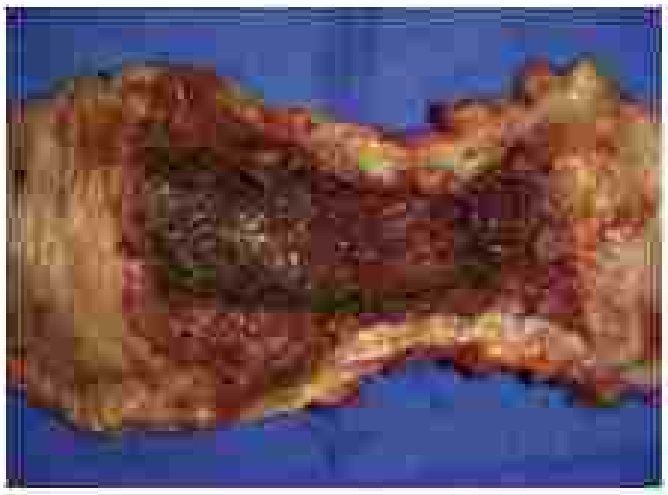

FIG. 7 Surgical specimen reveals the metal bare wires incorporated into the bowel wall and tumor.

In addition to metal stents, biodegradable stents made of polymers such as polydioxanone and biodegradable material (magnesium alloys) have recently been used to manage benign strictures such as

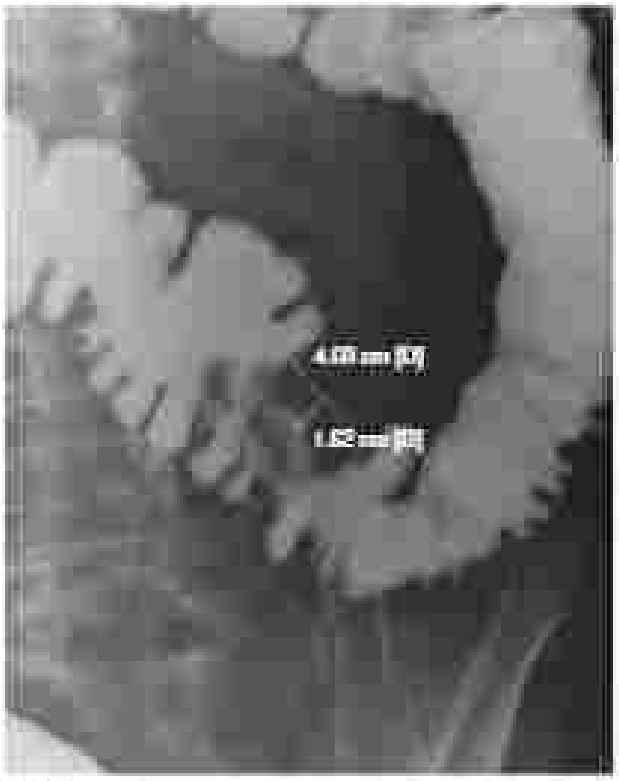

FIG. 8 Cancerous stoma now demonstrating the morphology of a malignant carcinoma.

in Crohn's disease or colorectal anastomotic strictures. These stents do not require surgical resection or endoscopic retrieval. The radial force of polyurethane stents is maintained for approximately 6 to 8 weeks following implantation and drops to 50% by week 9 with a mean degradation time of 4 months. Because most of these stents were designed to be used for esophageal pathology, their application to the colon while technically successful has had variable clinical success rates (0.4–100%) with a mean stent migration of 22% and symptom recurrence.

TECHNIQUES OF STENT PLACEMENT

Before placing a colonic stent, adequate assessment of the location, length, caliber, and morphology of the obstruction should be made (Fig. 8). Retrograde water soluble contrast enema can help delineate the anatomy and may sometimes reveal synchronous proximal lesions. It helps in evacuating retained luminal contents. Patients are usually given one or two cleansing enemas to prepare the distal colon. Oral mechanical bowel prep is discouraged because it may worsen the symptoms of obstruction.

In patients with complete obstruction and dilated colon proximally, intravenous antibiotics given prophylactically may be helpful because the insufflation during the procedure may cause microperforation and bacteremia. The procedure is usually performed in the operating room or the endoscopy suite under intravenous sedation. If the patient has severe abdominal distention with potential airway compromise, a general endotracheal anesthetic is safer. Before starting the procedure, the patient is placed in the left lateral decubitus position and the scope is inserted until the obstruction is reached. The patient is placed in the supine position for a better view under fluoroscopy, although this is not necessary with a rotating fluoroscope.

Stent insertion and deployment can be performed under endoscopic guidance without fluoroscopy if the distal aperture of the stricture is wide enough to allow passage of the endoscope and visualization of the colon proximal to the obstruction. A smaller caliber gastroscope may be used if needed. This approach is applicable mainly in distal left sided obstructions, however. Two techniques are used here: through the stent or over the wire technique. In the former, the endoscope is advanced to the level of the obstruction. A guidewire is placed through the scope and passed proximal to the lesion. The length of the stricture should be estimated based on pre-procedural contrast enema. The stent is passed through the scope channel and the scope is withdrawn to the level of the distal end of the stricture. The stent is deployed under direct visual guidance ensuring adequate proximal and distal overlap. In the over the wire technique, after passing the wire through the endoscope proximal to the lesion, the endoscope is withdrawn while the wire is left in place. The endoscope is then reinserted beside the guidewire and is used to observe the stent delivery device advancing. The stent crosses the stricture over the wire and is deployed under direct visualization. Typically, at least 1 to 2 cm of stent length should be kept distal to the lesion.

Stent insertion can be performed under fluoroscopy without endoscopy. This is mainly applicable for very distal left sided obstructions. In this approach, an angiography catheter is advanced over a guidewire proximal to the obstruction under fluoroscopy. Contrast is injected to confirm proper location and rule out perforation. The angiography catheter is then withdrawn and the stent is advanced over the guidewire and deployed across the lesion. This technique may be associated with higher radiation exposure. However, studies comparing it with the combined fluoroscopic endoscopic technique report similar technical and clinical success rates.

The combined fluoroscopic endoscopic approach for stent placement is currently our preferred method at surgeons. An endoscope is inserted to the level of the lesion. A hydrophilic, soft tipped guidewire is then loaded through an endoscopic retrograde cholangiopancreatography catheter passed through the endoscope channel. The guidewire is navigated across the obstruction under fluoroscopy. The endoscopic retrograde cholangiopancreatography catheter is then advanced over the wire through the obstruction and contrast is injected to confirm position and estimate the stricture length. A proper stent is chosen accordingly. The stent should be long enough to cover the entire obstructed area and have a 1 to 2 cm overlap proximally and distally. Symmetry is important because more coverage on one end versus another is associated with lower clinical success rate with the potential for migration and obstruction. If stent coverage is inadequate, an additional stent can be deployed in series to completely cover the lesion. This is rarely needed because most intrinsic malignant strictures are short. It is important to keep the wire in place across the lesion until the final position of the stent is assessed radiographically because trying to pass a wire through a newly deployed stent can technically challenging.

OUTCOMES

The technical success rate of endoluminal stents (defined as successful deployment across an obstruction without a complication) ranges between 70% and 100%. Clinical success (defined as long term resolution of the obstruction following stent placement) ranges between 70% and 100%.

Stent placement comes with its own set of complications, which can be divided into early and late. Early complications occur in less than 10% of cases. The most common early complications are bleeding and perforation. Overall, the rate of perforation in stents used for malignant obstruction is reported around 7% but is higher in patients with bevacizumab (17%). The perforation rate for benign etiology is higher at 18%. When perforations happen, they are difficult to treat endoscopically and are best managed operatively. Microperforation may be managed with bowel rest and intravenous antibiotics. Other early complications include failure of the stent to resolve the obstruction, which could be due to failure to cover the entire length of the stricture, synchronous colonic obstruction, early stent migration, fecal impaction, and early stent migration. Placing a second stent to

FIG. 9 Postprocedural abdominal radiograph demonstrating a well-positioned transverse colon stent across a malignant stricture.

correct this complication may be successful but is technically challenging. Pain and incontinence may occur if stents are placed within 2 cm of the anal verge. Such low placement is associated with a higher migration rate.

Late complications of stent placement are stent migration or occlusion by fecal impaction and/or tumor ingrowth. Tumor ingrowth has been reported in 15% of patients. Although most patients currently treated with palliative stents succumb to their disease before obstructing, the impact of newer chemotherapeutic agents on long-term survival may affect the rate of this long-term complication. Tumor ingrowth and fecal impaction of the stent can be managed endoscopically by placing another stent through the occluded stent, fulguration of the tumor, or disimpaction of the stent through balloon dilation.

Stent migration occurs in about 24% of cases and depends on several factors including treatment with chemotherapy or radiotherapy with subsequent tumor shrinkage, stent types, degree of stenosis, proximal and distant clearance, stent diameter impact the stent migration rate. Short stents, smaller diameter stents (<25 mm), and covered stents have higher rates of migration.

POSTSTENTING CARE AND SURVEILLANCE

The process of large bowel decompression starts after successful deployment of a stent. If a nasogastric tube is present, it can often be removed the following day. A postprocedural abdominal radiograph is obtained immediately after placement of the stent to check for location and exclude free air (Fig. 10). It is repeated within 24 to 48 hours when full expansion of the stent is expected. A liquid diet can typically be initiated within 24 to 48 hours of stent placement in most patients. Several days are needed for complete decompression in a normal size colon.

Acute Colonic Pseudo-obstruction (Ogilvie's Syndrome)

David F. Hutcheon, MD

Acute colonic pseudo-obstruction (ACPO), or Ogilvie's syndrome, is an acute dilation of the colon in the absence of mechanical obstruction. William Ogilvie described two patients with malignant invasion of the preaortic ganglia and acute colonic pseudo-obstruction in 1948.

ACPO occurs in about 0.1% of hospitalized patients and carries a mortality of approximately 8%. About 15% of these patients develop colonic ischemia or perforation with an attendant mortality of 40% to 60%. The goal of therapy is to intervene before development of these complications.

About one half of the patients have associated acute medical illnesses, the other half are postoperative patients. Ten percent of ACPO patients are postobstetric and postgynecologic procedures, with 93% of these presenting after cesarean section. Approximate incidences are various surgeries are: cardiac surgery, less than 1% and orthopedic surgery, 1% to 2%.

It is essential to differentiate ACPO from other causes of colonic dilation such as toxic megacolon, cecal or sigmoid volvulus, or chronic intestinal pseudo-obstruction. If there is a question of colonic obstruction, a limited water soluble enema is useful. Care must be taken not to fill the colon extensively—only through the site of possible obstruction.

Vanek et al. reviewed 400 patients in 1986. All patients had abdominal distention, and 83% had associated pain. Other associated symptoms and signs are listed in Table 1.

DIAGNOSIS

The diagnosis is usually made via abdominal and pelvis computed tomography (CT) scan without contrast. This can usually distinguish

Acute Colonic Pseudo-obstruction (Ogilvie's Syndrome)

David F. Hutcheon, MD

Acute colonic pseudo-obstruction (ACPO), or Ogilvie's syndrome, is an acute dilation of the colon in the absence of mechanical obstruction. William Ogilvie described two patients with malignant invasion of the preaortic ganglia and acute colonic pseudo-obstruction in 1948.

ACPO occurs in about 0.1% of hospitalized patients and carries a mortality of approximately 8%. About 15% of these patients develop colonic ischemia or perforation with an attendant mortality of 40% to 60%. The goal of therapy is to intervene before development of these complications.

About one half of the patients have associated acute medical illnesses, the other half are postoperative patients. Ten percent of ACPO patients are postobstetric and postgynecologic procedures, with 93% of these presenting after cesarean section. Approximate incidences are various surgeries are: cardiac surgery, less than 1% and orthopedic surgery, 1% to 2%.

It is essential to differentiate ACPO from other causes of colonic dilation such as toxic megacolon, cecal or sigmoid volvulus, or chronic intestinal pseudo-obstruction. If there is a question of colonic obstruction, a limited water soluble enema is useful. Care must be taken not to fill the colon extensively—only through the site of possible obstruction.

Vanek et al. reviewed 400 patients in 1986. All patients had abdominal distention, and 89% had associated pain. Other associated symptoms and signs are listed in Table 1.

DIAGNOSIS

The diagnosis is usually made via abdominal and pelvis computed tomography (CT) scan without contrast. This can usually distinguish

ACPO from colonic volvulus, obstruction, and toxic megacolon. Cecal diameter has been a measurement used in consideration of therapy. Cecal dilation greater than 12 cm frequently prompts therapeutic intervention. Bowel dilation increases colonic wall tension and may lead to decreased perfusion, ischemia, and perforation. In one series, ischemia perforation occurred in 0% of patients with cecal diameters of less than 12 cm, 7% with cecal diameters 12 to 14 cm, and 23% with diameters greater than 14 mL. The therapeutic goal is to rectify the colonic dilation before ischemia and perforation. Fever, leukocytosis, abdominal tenderness, and cecal dilation greater than 12 cm are indicators of possible ischemia and/or perforation.

In the Vanek series, colonic dilation extended to the hepatic flexure in 17% of patients, splenic flexure in 56%, and left colon in 27%.

After initial CT scan, the patient is usually followed with every 12 to 24 hour abdominal radiographs with particular attention to cecal diameter (Figs. 1 and 2).

TABLE 1 Acute Colonic Pseudo-obstruction

Signs and Symptoms	% Patients
Abdominal distention	100

Decreased	3
High pitched	17%

DIAGNOSTIC AND THERAPEUTIC OPTIONS

Conservative Management

- In all patients, correct metabolic abnormalities (i.e., serum sodium, potassium, calcium, phosphate, magnesium). Check thyroid stimulating hormone. Follow complete blood count, complete metabolic profile, magnesium, phosphate, and serum lactate levels. In patients with diarrhea, check stool for *Clostridium difficile*.
- Decompression with a nasogastric and rectal tube may be helpful. Diligent therapy of the underlying conditions is important.
- Maintain patient without food or water with adequate intravenous (IV) fluid hydration.
- Follow with serial physical examinations, serial abdominal radiographs, and CT scanning as clinically indicated.
- Discontinue or reverse medications that may contribute to colonic atony if possible. These include anticholinergics, antipsychotics, cytotoxic drugs, clonidine, and calcium channel blockers. Of particular importance, is the discontinuation of opiates if possible.

Methylnaltrexone is an opioid antagonist that binds to receptors in the gastrointestinal tract alone, without altering drug effect on pain. It is helpful in patients on narcotic agents who cannot have them discontinued, or that have just been discontinued recently, and are still having an effect. Dosing is subcutaneous and weight related: less than 38 kg, 0.15 mg/kg rounded off to the nearest 0.1 mL of volume; 38 to 62 kg, 8 mg subcutaneously; 62 to 114 kg, 12 mg subcutaneously; and more than 114 kg, 0.15 mg/kg rounded off to the nearest 0.1 mL of volume (Table 2).

A bowel movement frequently occurs within 30 minutes after methylnaltrexone administration, which may lead to colonic decompression. Side effects include abdominal pain, 14% to 29%; flatulence, 13%; and nausea, 9% to 12%.

Patients with progressive cecal dilation greater than 12 cm and/or those not responding to conservative therapy within 48 hours should be treated with neostigmine or colonic decompression.

Neostigmine Therapy

Neostigmine

Neostigmine is an acetylcholinesterase inhibitor that induces a potent parasympathetic response (Box 1). This leads to rapid restoration of colonic peristalsis and frequent resolution of ACPO. Controlled trials

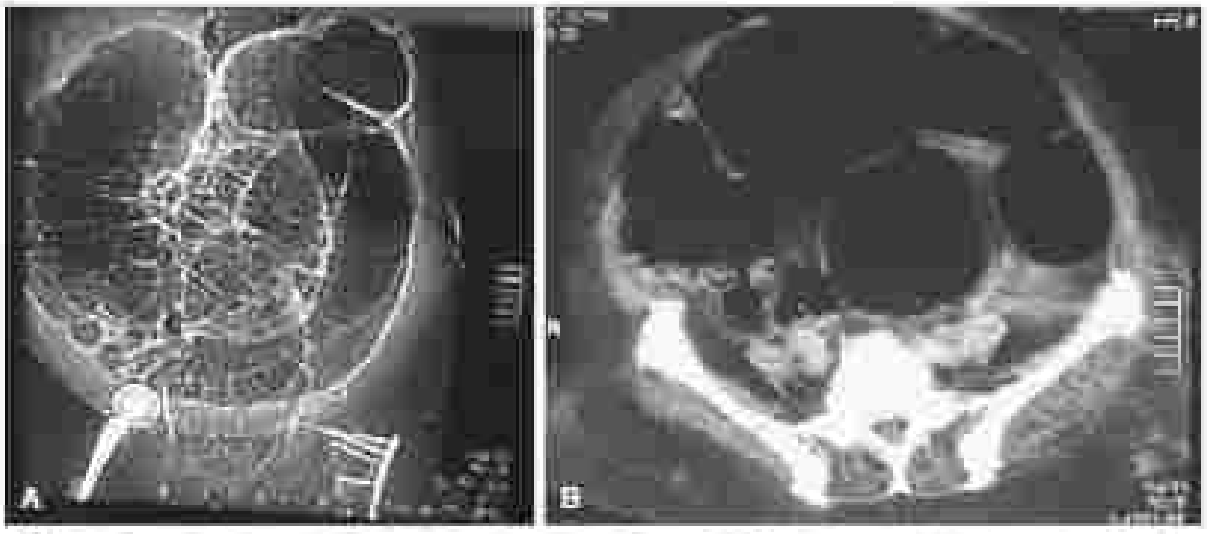

FIG. 1 CT scans illustrating marked dilation of the colon without significant wall thickening to suggest ischemia and without free air.

FIG. 2 Marked colonic dilation on upright radiograph of the abdomen.

TABLE 2 Dosing of Methylnaltrexone

38–<62 kg	8 mg subcutaneously
62–114 kg	12 mg subcutaneously
>114 kg	0.15 mg/kg, rounded off to the nearest 0.1 mL of volume

BOX 1 Neostigmine Therapy

Contraindications

- Mechanical colonic obstruction
- Bradycardia <60 beats/min, hypotension, systolic blood pressure <90 mm Hg
- Recent myocardial infarction
- Reactive airway disease
- β-Blocker therapy

Dosing

- 2 mg intravenously once, given slowly over 3 minutes, may repeat in 3 hours if inadequate response
- Consider simultaneous administration of glycopyrrolate 0.4 mg intravenously to attenuate side effects
- Decrease dose in setting of renal failure

Monitoring

- Continuous electrocardiogram, oxygen saturation, and blood pressure monitoring

have documented the effectiveness of neostigmine in the resolution of ACPO. Most series show successful colonic decompression in 85% to 90% after neostigmine administration. Dosing has varied in the series, from 2 to 5 mg administered over 1 to 3 minutes IV, 2 to 5 mg IV every 30 minutes, and 5 mg given over 1.2 hours. Most authors give 2.0 mg IV given slowly over 3 minutes. Patients usually respond with a large evacuation of gas and stool within 30 minutes of IV administration (Table 3).

TABLE 3 Neostigmine Dose Adjustments With Renal Impairment

Creatinine clearance 10–50 mL/min	Decrease dose by 50%
Creatinine clearance <10 mL/min	Decrease dose by 75%

Neostigmine should be avoided in patients with suspected perforation or ischemia, and in pregnant. Relative contraindications include bradycardia less than 60 beats/min, systolic blood pressure less than 90 mm Hg, reactive airway disease, recent myocardial infarction, and concomitant β-blocker therapy.

Side effects relate to cholinergic and parasympathetic stimulation and include abdominal pain in 5.9%, diarrhea in 3.9%, and vomiting in 1.6%.

The most concerning side effect is bradycardia, which occurs in 5% to 10% of patients. The patient should have continuous electrocardiography monitoring and oxygen saturation with frequent blood pressure measurements. Atropine and glycopyrrolate must be readily available in case of bradycardia or bronchospasm. Patients with a partial or poor response to neostigmine are frequently treated again 24 hours later.

ENDOSCOPIC COLONIC DECOMPRESSION

Decompression of the colon via colonoscopy is another nonoperative option. Colonoscopy is performed without colonic prepping and may be performed in the endoscopy suite or at the bedside in critically ill patients. Liquid stool is usually encountered, some of which can be aspirated. Care must be taken not to further distend the colon through air infusion, which may decrease perfusion to the right colon and lead to perforation. Use of CO_2 for insufflation is preferable to air.

Once the scope is passed into the right colon, air and fluid are aspirated. Abdominal distention usually improves acutely and dramatically. Reaching the ascending colon significantly increases the chances of adequate decompression, compared with aspiration of the transverse and left colon alone. Colonic decompression shows initial decompression rates of 61% to 95% with sustained decompression in 70% to 90% of cases.

Some endoscopists pass a guidewire through the colonoscope while in the right colon, with or without fluoroscopic guidance. The wire is left in place in the cecum or ascending colon while the colonoscope is removed. A decompression tube is passed over the guidewire into the right colon. Low intermittent suction is used for decompression.

A small nonrandomized study showed a 36% ACLO recurrence rate after colonic decompression alone, and no recurrences in the patients treated with decompression tubes. Colonic decompression has a complication rate of 5% including perforation (2%) and mortality (1%).

The initial intervention of ACLO, whether neostigmine or colonic decompression, has not been determined. Attendant medical conditions such as asthma, cardiac ischemia, arrhythmias, and heart block should be weighed in considering administration of neostigmine. A recent retrospective study by Peter et al. suggests that colonic decompression is more effective than neostigmine as initial therapy of ACLO (30% vs 48% initial response). Both forms of therapy appear to be effective and relatively safe.

Recurrent colonic dilation occurs in a small percentage of patients after initial successful decompression, either with neostigmine or colonoscopy. Recurrent therapy with neostigmine or colonic decompression is successful in these patients, with overall good success.

A small randomized, blinded, placebo-controlled trial demonstrated a decreased incidence of relapses in patients treated with polyethylene glycol 29.5 g daily by mouth or via nasogastric tube compared with placebo (9% vs 53.9%). Polyethylene glycol therapy is initiated after successful decompression.

In patients not responding to neostigmine or endoscopic decompression, endoscopic cecostomies have been performed with good success and few complications. Studies have been extremely small, and experience limited.

Cecostomy can be performed via colonoscopy, interventional radiology, or less frequently, surgically. Experience is extremely limited; however, success rates appear to be high, and complications low.

Surgery is required in patients with ischemia or perforation. Mortality rates range from 30% to 60%. Surgical options include laparoscopic or open cecostomy or colectomy, subtotal or total colectomy, with or without ileostomy.

SUMMARY

Acute colonic pseudo-obstruction is a disorder of colonic motility leading to massive colonic dilation without obstruction. It occurs almost exclusively in hospital patients postoperatively and with comorbid conditions. Diagnosis is made with CT scan of the abdomen and pelvis. The patients are followed with daily abdominal radiographs.

All patients receive supportive care with bowel rest, IV hydration, and attempts to resolve precipitating abnormalities. If the patient does not respond to conservative therapy within 48 hours, therapy with neostigmine or colonic decompression should be initiated to prevent complications of ischemia and/or perforation. Repeat therapy may be necessary for partial or nonresponders. Further options, such as cecostomy or surgery, are rarely necessary.

MANAGEMENT OF COLONIC VOLVULUS

Victoria Needham, MD, Renee Huang, MD, and Rebecca Lavinia, MD, FACS

Volvulus refers to twisting of a segment of the intestine. It can occur at any site in the gastrointestinal tract that is both mobile and long enough to rotate on a narrow based base. The twist of intestinal volvulus produces a closed loop bowel obstruction. Colonic volvulus accounts for 2% to 4% of all bowel obstructions in the United States, and 10% to 15% of all large bowel obstructions, with higher incidence in Africa, the Middle East, and South America. It most commonly occurs in the cecum and sigmoid colon because they are the most mobile parts of the colon, but has also been reported in the transverse colon, splenic flexure, and as the rare pathology of floating mesenteric knotting. Sigmoid volvulus accounts for 30% to 60% of colonic volvulus in the literature, whereas cecal volvulus accounts for 30%, although it has been documented to be increasing in incidence over the past decade. In the United States, patients with colonic volvulus tend to be older and have medical conditions that predispose them to chronic constipation or colonic dysmotility. They present with classic obstructive symptoms in a range of intermittent, slowly progressive, or acute forms, and the diagnosis can be differentiated from other types of large bowel obstruction by imaging studies or via operative exploration. Although management differs based on site of volvulus and patient factors, there are three cornerstones of treatment: detorsion (operatively in most cases, endoscopically in select sigmoid cases), resection of any ischemic or compromised colon, and their diversion or anastomosis of the remaining lower gastrointestinal tract. Rarely do fixation procedures serve as definitive operative treatment.

CECAL VOLVULUS

Cecal volvulus is the second most common type of colonic volvulus and exists in two distinct forms. A true cecal volvulus is an axial rotation of the terminal ileum, cecum, and proximal right colon, usually clockwise, around its mesentery, whereas a cecal bascule is an anterosuperior folding of the cecum, accounting for 10% of cases.

Several factors are thought to predispose patients to develop cecal volvulus. Foremost, increased mobility of the cecum is a feature of all volvulus, which can be either congenital or acquired. Approximately 10% to 25% of the population has a cecum and ascending colon mobile enough to form a volvulus on autopsy studies, which is thought to result from failed fusion of the ascending colon mesentery to the posterior parietal peritoneum. Adhesions from prior surgery or other iatrogenic anatomic abnormalities can result in acquired cecal mobility, with 30% to 70% of patients with cecal volvulus having a history of abdominal surgery. Additional factors associated with cecal volvulus include a female predominance (1.4:1), younger age, pregnancy or other colonic upward displacement by abdominopelvic structures or masses, and chronic constipation or colonic motility disorders such as Hirschsprung's disease.

Patients with cecal volvulus may present clinically with an intermittent, recurrent obstructive process or with an acute obstruction. Patients generally present with classic obstructive symptoms and signs including nausea, vomiting, anorexia, abdominal distention, constipation, tympany, and tenderness. Because volvulus is a closed loop obstruction, vascular compromise ensues, which may lead to diffuse peritonitis and even perforation.

Once volvulus is clinically suspected, imaging studies can help to confirm the diagnosis, distinguish a volvulus from other types of bowel obstruction or intraabdominal pathology, and determine the severity at presentation. Patients who present with frank peritonitis should be sent to the operating room. Otherwise, a workup of severe abdominal pain should begin with upright and flat abdominal radiographs, although abdominopelvic computed tomography (CT) scan is also commonly used as a first line imaging modality. Specific plain film and CT scan findings for volvulus are a "coffee bean" sign, with the apex of the distended, volvulized segment of right colon located in the left upper quadrant (Fig. 1), an "X marks the spot" sign of two crossing transition points in neighboring imaging slices, a "split wall" sign showing cecal wall separation by mesenteric fat in incomplete twisting, and small bowel distention and air fluid levels proximal to the cecal obstruction with distal colonic decompression. In contrast, a cecal bascule may appear as a "kidney bean" on the right side of the abdomen. In addition, a "whirl sign" on CT is pathognomonic for true (axial) cecal volvulus when associated with an abnormally positioned cecum, representing the mesentery twisted around the ileocolic vessels. Contrast enema is more specific for cecal volvulus. Despite these classic radiographic signs, volvulus is first revealed at the time of surgical exploration in 17% to 50% of patients.

A treatment algorithm for cecal volvulus has been described based on the level of bowel compromise and takes into account the patient's hemodynamic status. Both axial cecal volvulus and cecal

In patients not responding to neostigmine or endoscopic decompression, endoscopic cecostomies have been performed with good success and few complications. Studies have been extremely small, and experience limited.

Cecostomy can be performed via colonoscopy, interventional radiology, or less frequently, surgically. Experience is extremely limited; however, success rates appear to be high, and complications low.

Surgery is required in patients with ischemia or perforation. Mortality rates range from 30% to 60%. Surgical options include laparoscopic or open cecostomy or colectomy, subtotal or total colectomy, with or without ileostomy.

MANAGEMENT OF COLONIC VOLVULUS

Victoria Needham, MD, Renee Huang, MD, and Rebecca Lavinia, MD, FACS

Volvulus refers to twisting of a segment of the intestine. It can occur at any site in the gastrointestinal tract that is both mobile and long enough to rotate on a narrow based base. The twist of intestinal volvulus produces a closed loop bowel obstruction. Colonic volvulus accounts for 2% to 4% of all bowel obstructions in the United States, and 10% to 15% of all large bowel obstructions, with higher incidence in Africa, the Middle East, and South America. It most commonly occurs in the cecum and sigmoid colon because they are the most mobile parts of the colon, but has also been reported in the transverse colon, splenic flexure, and as the rare pathology of floating mesenteric knotting. Sigmoid volvulus accounts for 30% to 60% of colonic volvulus in the literature, whereas cecal volvulus accounts for 30%, although it has been documented to be increasing in incidence over the past decade. In the United States, patients with colonic volvulus tend to be older and have medical conditions that predispose them to chronic constipation or colonic dysmotility. They present with classic obstructive symptoms in a range of intermittent, slowly progressive, or acute forms, and the diagnosis can be differentiated from other types of large bowel obstruction by imaging studies or via operative exploration. Although management differs based on site of volvulus and patient factors, there are three cornerstones of treatment: detorsion (operatively in most cases, endoscopically in select sigmoid cases), resection of any ischemic or compromised colon, and their diversion or anastomosis of the remaining lower gastrointestinal tract. Rarely do fixation procedures serve as definitive operative treatment.

CECAL VOLVULUS

Cecal volvulus is the second most common type of colonic volvulus and exists in two distinct forms. A true cecal volvulus is an axial rotation of the terminal ileum, cecum, and proximal right colon, usually clockwise, around its mesentery, whereas a cecal bascule is an anterosuperior folding of the cecum, accounting for 10% of cases.

Several factors are thought to predispose patients to develop cecal volvulus. Foremost, increased mobility of the cecum is a feature of all volvulus, which can be either congenital or acquired. Approximately 10% to 25% of the population has a cecum and ascending colon mobile enough to form a volvulus on autopsy studies, which is thought to result from failed fusion of the ascending colon mesentery to the posterior parietal peritoneum. Adhesions from prior surgery or other iatrogenic anatomic abnormalities can result in acquired cecal mobility, with 30% to 70% of patients with cecal volvulus having a history of abdominal surgery. Additional factors associated with cecal volvulus include a female predominance (1.4:1), younger age, pregnancy or other colonic upward displacement by abdominopelvic structures or masses, and chronic constipation or colonic motility disorders such as Hirschsprung's disease.

Patients with cecal volvulus may present clinically with an intermittent, recurrent obstructive process or with an acute obstruction. Patients generally present with classic obstructive symptoms and signs including nausea, vomiting, anorexia, abdominal distention, constipation, tympany, and tenderness. Because volvulus is a closed loop obstruction, vascular compromise ensues, which may lead to diffuse peritonitis and even perforation.

Once volvulus is clinically suspected, imaging studies can help to confirm the diagnosis, distinguish a volvulus from other types of bowel obstruction or intraabdominal pathology, and determine the severity at presentation. Patients who present with frank peritonitis should be sent to the operating room. Otherwise, a workup of severe abdominal pain should begin with upright and flat abdominal radiographs, although abdominopelvic computed tomography (CT) scan is also commonly used as a first line imaging modality. Specific plain film and CT scan findings for volvulus are a "coffee bean" sign, with the apex of the distended, volvulized segment of right colon located in the left upper quadrant (Fig. 1), an "X marks the spot" sign of two crossing transition points in neighboring imaging slices, a "split wall" sign showing cecal wall separation by mesenteric fat in incomplete twisting, and small bowel distention and air fluid levels proximal to the cecal obstruction with distal colonic decompression. In contrast, a cecal bascule may appear as a "kidney bean" on the right side of the abdomen. In addition, a "whirl sign" on CT is pathognomonic for true (axial) cecal volvulus when associated with an abnormally positioned cecum, representing the mesentery twisted around the ileocolic vessels. Contrast enema is more specific for cecal volvulus. Despite these classic radiographic signs, volvulus is first revealed at the time of surgical exploration in 17% to 50% of patients.

A treatment algorithm for cecal volvulus has been described based on the level of bowel compromise and takes into account the patient's hemodynamic status. Both axial cecal volvulus and cecal

FIG. 1 "Coffee bean" sign, classically observed on plain film of sigmoid volvulus, with the apex of the distended, redundant segment of right colon pointed to the left upper quadrant. *(From Hobler J. Colonic volvulus. In: The ASCRS Textbook of Colon and Rectal Surgery. 3rd ed. Springer International; 2016:[in press].)*

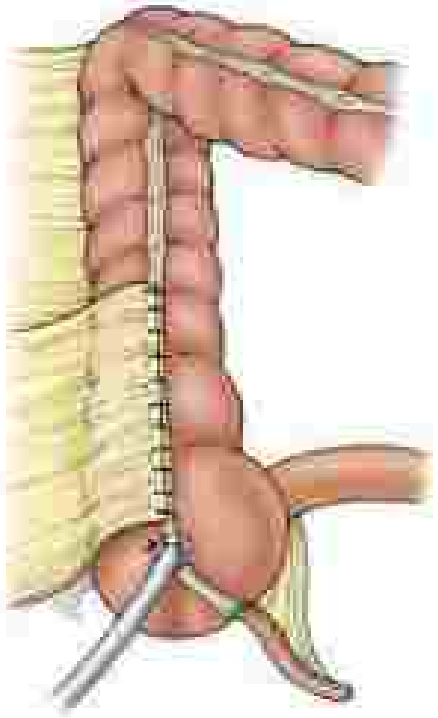

FIG. 2 *Colon fixation via cecopexy and percutaneous tube placement for treatment of cecal volvulus. (From Hobler J. Colonic volvulus. In: The ASCRS Textbook of Colon and Rectal Surgery. 3rd ed. Springer International; 2016:[in press].)*

fascicle are treated similarly. In contrast to select cases of sigmoid volvulus, endoscopic reduction of cecal volvulus, although described, is not a recommended treatment modality because of its technical difficulty, rate of missed ischemia, risk of perforation, and delay in more definitive surgical treatment. Surgical exploration with resection of the affected portion of intestine provides the lowest rate of recurrence. Both midline laparotomy and laparoscopic exploration have been described, with the latter having a lower mortality rate in a large retrospective dataset, but may be explained by a selection bias for patients with fewer medical comorbidities. On exploration, the bowel should first be examined for signs of compromise. If gangrene is evident, detorsion is not attempted because of the risk of bacteremia and sepsis from reperfusion. If the bowel appears viable, detorsion can be accomplished. In either case, the extent of resection is determined by the extent of bowel compromise plus the mobility of the ascending colon. Cases of nonviable or perforated bowel carry a higher rate of perioperative mortality and mandate resection. An ileocolectomy or a right colectomy are both appropriate operations if all compromised bowel is included. If redundancy of the right colon exists after ileocolic resection, literature has supported cecopexy of the right colon remnant to the posterior peritoneum to help prevent recurrent volvulus. For patients with significant perforation and soiling, extensive gangrene, hemodynamic instability, or severe underlying disease such as malnutrition or anemia, current guidelines support resection of the compromised portion with ileostomy (and or loop, and possible mucous fistula creation) if deemed necessary at the time of operation.

For patients with viable bowel, although definitive resection remains the most effective strategy for preventing recurrence, nonresectional operative techniques may be more appropriate in hemodynamically unstable patients and patients with risk factors for perioperative morbidity. Detorsion alone is associated with a recurrence rate of up to 23% and a high rate of perioperative mortality [138–139]; therefore, some studies have advocated against its use. Detorsion coupled with a fixation procedure is thought to reduce the risk of both recurrence and perioperative mortality in patients who would otherwise be poor candidates for operative resection. Fixation can be accomplished with either cecopexy, cecostomy tube placement, or both. A cecopexy is the suturing of the serosa of the distended, mobile segment of cecum (plus flexure and/or right colon), to a raised flap of adjacent retroperitoneal tissue, reducing colonic mobility. This can be done alone or in conjunction with cecostomy tube placement (Fig. 2). Recurrence rates approach that of detorsion alone, whereas mortality ranges from 0% to 14%. A cecostomy tube can be placed to decompress the distended colon and provide fixation. A tube, typically a Malecot drain, is placed via percutaneously along the anterior cecum, sutured in place with a purse-string suture, and then brought out to drain externally (Fig. 2). Although cecostomy tube placement can be faster and simpler than formal resection and therefore may be preferred in hemodynamically unstable patients, the potential perioperative complications are significant, including fecal spillage and cutaneous fistula, with a recurrence rate up to 10% and double the mortality of resection. The current literature provides no consensus regarding the best operation for this subset of patients; therefore, patients' perioperative risk should be weighed with their risk of recurrence and appropriate management chosen accordingly.

SIGMOID VOLVULUS

The sigmoid colon is the most common location for colonic volvulus. There is a male predominance of 2:1 and the age at presentation is often older (>70 years of age) than for cecal volvulus. Increased incidence of sigmoid volvulus is seen in regions where a high fiber diet predominates, such as Africa, India, and the Middle East. A high-residue diet is thought to lengthen the intestine and its mesentery, making it more prone to twisting. Other risk factors include black race, diabetes, pregnancy, colonic dysmotility, chronic constipation

FIG. 3. "Bent inner tube" or "coffee bean" appearance of a dilated sigmoid colon with the apex of the bend pointing toward the right upper quadrant. [From Kumar J, Kumar Abhishek M, Das Abhijit, Sreenivas V, Shukla R. Endoscopic management of sigmoid volvulus: a review of 30 cases. Dis Colon Rectum. 2010;53:1]

and megacolon. Higher rates are also seen in institutionalized patients and those with disability via neurologic and psychiatric disorders. Overall, patients with sigmoid volvulus have a higher degree of medical comorbidities compared with those with cecal volvulus and have an overall higher mortality rate (9.4% vs 6.7%).

Although the exact pathophysiology has not been fully described, these associated conditions all in some way predispose the sigmoid colon to become elongated and redundant, which leads to twisting on a narrow mesenteric attachment, most often in a counterclockwise direction. Once the colon twists 180 degrees, a clinically significant large bowel obstruction occurs and generally presents with a slow, insidious onset of abdominal pain, distention, nausea, and constipation, with vomiting following days after the initial symptoms. As the twisting persists or progresses, vascular compromise ensues, which can lead to necrosis and perforation. More acute presentations of severe pain with fulminant colonic gangrene have also been described, attributed to rapid colonic distention. Symptoms and signs may be less clinically apparent in the older population.

Participants on examination mandates operative exploration. Otherwise imaging studies can be obtained to further elucidate the diagnosis and cause of the obstruction. The classic radiographic finding of a "bent inner tube" or "coffee bean" appearance of a dilated sigmoid colon with the apex of the bend pointing toward the right upper quadrant confirms the diagnosis in 90% of cases (Fig. 3). If plain film is equivocal, either a CT scan or a contrast enema, which is a less common yet highly specific modality, should be performed. Similar to cecal volvulus, CT scan findings sensitive and specific for sigmoid volvulus include the coffee bean sign, the appropriately located X marks the spot sign, the split wall sign, and the whirl sign, along with the absence of rectal gas. In addition, the adjacent twisted colonic segments may show a "bird's beak" appearance, a sign that is also apparent on the afferent end of a volvulus in a water soluble contrast enema. Although some describe enema as both a diagnostic and therapeutic tool, its use for the latter is very infrequent (<1% in a cohort of >3 million cases in the United States over 10 years), and surgical expertise should be available at the time of the enema because of risk of perforation. Ogilvie's syndrome (colonic pseudo obstruction) is a common differential diagnosis for sigmoid volvulus because it often presents in a similar patient population and may appear similar on initial clinical presentation and plain film. CT scan should be able to differentiate between the two diagnoses, with the absence of whirled mesentery and distal transition point to pseudo obstruction.

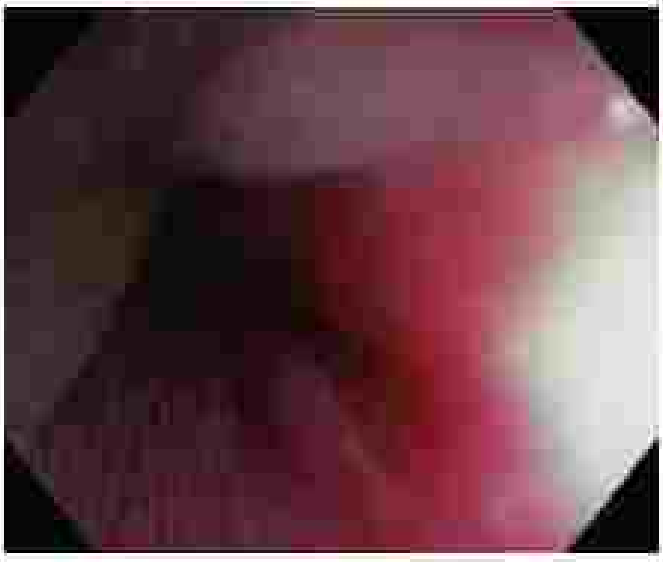

FIG. 4. Spiraling appearance of colonic mucosa in sigmoid volvulus at the site of obstruction. [From Ang S-J, Wu E-J. Endoscopic decompression, reduction and resection of sigmoid volvulus. Volvo J Hepatobiliary GI Oncol Sci. 2014;7:22]

As with any intestinal volvulus, the goals of treatment are to reduce the twisted bowel and prevent recurrence. In the presence of peritonitis or sepsis, or if gangrene or bowel perforation is suspected from laboratory findings and imaging studies or found on endoscopic evaluation, an emergent operation is required. Nonviable bowel should not be drawn. Voluminal, redundant, and any nonviable or suspected ischemic sigmoid colon should be resected. No statistically significant differences in perioperative morbidity and mortality have been observed in the literature between Hartmann's procedure and primary anastomosis with or without proximal diversion for resectable cases of sigmoid volvulus. Selective use of Hartmann's procedure may be appropriate and is described for patients with hemodynamic instability, coagulopathy, severe acidosis, hypothermia, or significant medical comorbidities (increased American Society of Anesthesiologists score). Patients with sigmoid volvulus in the setting of megacolon should undergo subtotal colectomy as sigmoid resection alone has been shown to have a higher rate of recurrence.

In the absence of emergent characteristics, current guidelines recommend proceeding in a stepwise fashion to achieve the lowest rate of recurrence with the lowest risk of perioperative mortality, first with endoscopic decompression and detorsion of the sigmoid volvulus and second by definitive sigmoid resection during the index admission. Endoscopy is both diagnostic and therapeutic because it offers an assessment of bowel viability and is successful in decompressing, detorting, and reducing the colon in 55% to 95% of patients. It is performed most commonly by flexible sigmoidoscopy, although both rigid sigmoidoscopy and colonoscopy can be used. First the distal colon is examined, maintaining low and low-pressure insufflation of air. The first, distal point of twisting should be recognized as a converging or spiraling of colonic mucosa, usually near the rectosigmoid junction (Fig. 4). If mucosal ischemia, gangrene,

or perforation are apparent on examination, reduction should not be attempted, and emergent surgical resection becomes necessary. If the colonic mucosa appears viable, the scope can be gently advanced into the dilated loop of sigmoid colon. Successful decompression is confirmed by the evacuation of copious flatus and stool with decreased abdominal distention. The endoscope can then be advanced toward the proximal point of the volvulus, again identifying and detorting the area of spiraling mucosa. The scope is then withdrawn to continue the reduction (shortening) of the bowel loop. A rectal tube can be placed for maintenance of decompression, prevention of recurrence, and facilitation of bowel preparation for definitive resection within the index admission. Endoscopic placement of the rectal tube over a guidewire has been described. A plain film is obtained post-procedure to evaluate for resolution of volvulus and to rule out free air. If reduction is unsuccessful, the patient requires urgent operative sigmoid resection.

Endoscopic decompression alone has a recurrence rate of 60% to 75%, with particularly high risk in the first 30 days postprocedure, and should therefore be followed by definitive sigmoid resection during the same admission. Elective resection after endoscopic decompression has a mortality rate less than 10% and a recurrence rate of nearly zero. Patients should undergo bowel preparation and preoperative optimization of comorbid medical conditions. A completion colonoscopy should be considered either at the first or subsequent endoscopy to evaluate for other colonic lesions that could alter the planned operation. Both open and laparoscopic approaches have been described, with use of the latter increasing over the past decade. Open resection can be approached via lower midline laparotomy. After mobilization, the colon can be exteriorized either through the laparotomy wound or through a wound protector in laparoscopic cases, the remainder of the field can be covered with towels to control contamination. Hartmann volvulus is most commonly presented by performing a sigmoid colectomy with colorectal anastomosis. Proximally, resection should include all redundant and ischemic sigmoid and descending colon, with the distal margin at the rectosigmoid junction. Ostomy creation (either Hartmann's procedure with end colostomy or a primary anastomosis with a diverting loop ileostomy) is less commonly performed in the nonemergent setting but may be necessary in the setting of a deteriorating clinical picture, significant colonic distension or fecal spillage, insufficient length, compromised blood supply, or significant comorbidities that could predispose a patient to anastomotic breakdown. Operative detorsion alone or combined with fixation procedures (extraperitoneal sigmoidopexy or peexy to the abdominal wall with prosthetic, parallel colopexy to transverse colon, and mesosigmoidoplasty) have been described for sigmoid volvulus, but are uncommonly performed and not recommended because they are associated with significant perioperative complications as well as high recurrence rates (at least 20%), and offer no benefit over formal resection particularly because morbidity for the latter has decreased substantially in recent years.

Endoscopic reduction and decompression convert an emergent pathology into an indication for elective surgery, ideally within the index admission after additional decompression and resuscitation for 24 to 72 hours. Endoscopic therapy alone has a high recurrence rate (Table 1). Although some have advocated for one-stage endoscopy and resection or an elective colonic lavage and resection, no randomized control trials exist to determine their efficacy and outcomes. Regardless, in the case of cecal or sigmoid volvulus, the operating room should be equipped with endoscopic equipment and expertise should the need arise.

Another procedure supported by increasing evidence is the percutaneous endoscopic colostomy technique for fixation of the sigmoid colon to the anterior abdominal wall following endoscopic detorsion and decompression. The procedure is indicated primarily for patients who are poor candidates for operative resection as a result of comorbid conditions because it can be done under minimal sedation. The colon is fixed to the abdominal wall either by tube colostomy or with T fasteners, at one or two points. From the available studies, recurrence rates for this procedure are low, and perioperative mortality is variable but potentially acceptable when weighed against these patients' comorbidities.

Overall, outcomes for sigmoid volvulus with necrotic are poor. Operation in the emergent setting carries a 20% mortality rate. Both peritonitis and gangrenous colon are strong predictors of perioperative complications and mortality, followed by the use of a stoma. In the literature, Hartmann's procedure is used in 15% of elective cases and 24% of emergent cases, and any stoma (end or diverting) is used in one half of all operations for sigmoid volvulus. Anastomotic complications occur in up to 15% of cases.

OTHER COLONIC VOLVULUS

Splenic flexure and transverse colon volvulus are rare, accounting for 1% to 3% and 1% to 4% of all colonic volvulus, respectively. These patients are generally younger than those with cecal or sigmoid

TABLE 1 Management and Outcomes of Endoscopy Therapy for Sigmoid Volvulus

volvulus, with a female predominance. Transverse colon volvulus has been associated with a higher comorbidity score than its cecal and sigmoid counterparts, despite resection at a younger mean age. As with other types of colonic volvulus, a history of chronic constipation, high fiber diets, and redundancy of the colonic segment are associated with their development, with the additional risk of prior abdominal surgery attributed to both splenic and transverse colonic volvulus. One half of cases present as acute and severe large bowel obstructions, whereas the other half have subacute or recurrent presentations. Plain films may show two air fluid levels. Similar to cecal volvulus, endoscopic decompression is not recommended, with resection of the involved segment necessary to relieve the twisted intestine and prevent recurrence. Transverse colon volvulus can be addressed via a transverse colectomy or an extended right colectomy, whereas a splenic flexure volvulus requires extended resection with theoretical anastomotic. Transverse colon volvulus has up to a threefold increase in mortality after resection compared to cecal and sigmoid volvulus.

Sinusgmoid knotting is a rare etiology of colonic volvulus in the United States, but is more commonly seen in Africa, Asia, and the Middle East. It involves wrapping of the ileum around itself or around the sigmoid colon, causing a double obstruction of both segments of intestine. Patients tend to be young, with a male predominance. These patients present with severe, acute bowel obstruction and require urgent operative exploration with detorsion (if possible) and resection of both segments. Hartmann's procedure, or en bloc resection of the knotting with ileocolic anastomosis. These cases carry a high mortality rate (10%–30%), which is increased if gangrene is present (up to 50%). Endoscopic reduction should not be attempted and has no documented success in the literature.

In addition, synchronous cecal and sigmoid volvulus has been documented (27 of 3,779 total cases of colonic volvulus over a 10-year period in the United States). In this cohort, patients had the highest level of medical comorbidities compared with other types of colonic volvulus, and a mortality rate of nearly 19%.

COLONIC VOLVULUS IN PREGNANCY

Pregnancy is an established risk factor for intestinal volvulus. Of all cases of bowel obstruction in pregnancy, although rare overall, 45% are caused by sigmoid volvulus. Ten percent of all patients with cecal volvulus are pregnant. This predisposition to volvulus likely occurs secondary to upward displacement of bowel loops by the gravid uterus, making them more mobile. The diagnosis has been shown to be delayed or made to the operating room after clinical deterioration, leading to a high mortality rate for volvulus in pregnancy. All available diagnostic options should be considered if there is clinical suspicion for volvulus up to and including safe radiologic techniques and diagnostic laparoscopy. In the absence of frank perforation or severe sepsis and peritonitis indicating emergent operation, treatment can be stratified by trimester for sigmoid volvulus. It is less well described for other types but in general warrants a careful analysis of the risks and benefits. In the first trimester, if the colon is deemed viable, endoscopic detorsion should be performed. Definitive resection can occur in the second trimester when peri-operative risks to the fetus are lessened. For sigmoid volvulus that occurs during the third trimester, nonoperative management including endoscopic decompression is preferred with definitive resection postpartum.

SUMMARY

Colonic volvulus accounts for approximately 13% of all large bowel obstructions in the United States, with sigmoid and cecal volvulus being the most common. It most frequently affects elderly patients with significant comorbidities, and therefore portends a poor outcome overall. Signs and symptoms of obstruction generally lead to an imaging diagnosis, whereas some cases can present as acute sepsis, peritonitis, or perforation and are diagnosed intraoperatively. Treatment method is determined by the viability of the involved bowel, the hemodynamic stability of the patient and the patient's overall perioperative risk. Endoscopic decompression can be achieved for sigmoid volvulus with viable bowel. Recurrence is best prevented by definitive operative resection of the involved colonic segment for all types of colonic volvulus, although fixation procedures have been described. Colonic volvulus is not uncommon in the setting of pregnancy and should be considered early in the differential for obstructive signs and symptoms, with treatment stratified by trimester.

Management of Rectal Prolapse

Katerina Wells, MD, MPH, and James Hashemari, MD

Rectal prolapse occurs when the rectal wall invaginates through the anus. This is a rare disorder that occurs in approximately 0.5% of the population. Typically, women in the fifth to eighth decades of life are affected; however, this disorder is also seen in a very different subset of younger patients, usually with psychiatric illness, developmental delay or autism, and severe constipation. Men with rectal prolapse tend to present earlier, in the third to fourth decades of life.

Historically, multiparity was thought to contribute to the pathogenesis of rectal prolapse. Yet, 30% of women with rectal prolapse are nulliparous, suggesting a different etiology compared to anterior (cystocele and uterine) prolapse.

PRESENTATION

The symptoms of rectal prolapse include rectal pressure or pain resulting from the prolapsing tissue through the anus and drainage of mucus and blood from the exposed friable mucosa. Patients may experience constipation (25%–50%) thought to be due to mechanical blockage of the rectum or associated pelvic dysfunction, fecal incontinence resulting from stretch-induced denervation, and subsequent atrophy of the external anal sphincter. In addition to the physical complications of prolapse, this can be an emotionally traumatic and socially isolating disease.

EVALUATION

Evaluation of a patient begins with a thorough evaluation for modifiable risk factors, exacerbating factors, and symptoms related to the prolapse. A surgical history must detail any prior abdominal surgery, rectal resection, or pelvic radiation that may influence surgical management. Physical examination includes digital rectal examination to assess sphincter tone and proctoscopy to evaluate for alternative diagnoses that can be confused with rectal prolapse, including prolapsing hemorrhoids or prolapsing masses. Full-thickness prolapse is distinguishable by the appearance of concentric circular folds, whereas prolapsing hemorrhoids will have radial grooves on either side of the hemorrhoidal columns. It is important to document the maximum extent of prolapse when the patient strains to distinguish between distal rectal mucosal prolapse and full-thickness rectal prolapse. A prolapse of less than 3 cm may be limited to the mucosa and is treated differently.

Patients with rectal prolapse frequently have a pudendal neuropathy with decreased resting tone. The prolapse will typically reduce to the prone jack-knife position but can be induced with Valsalva maneuvers. The best method for eliciting prolapse is to have the patient sit on the commode and bear down to simulate defecation. In some cases when the prolapse is more conditional, patients can be asked to photograph the prolapse in the comfort of their home. Anterior prolapse including cystocele or uterine prolapse may accompany the rectal prolapse up to 20% of the time. This combination of disease should be fully assessed with pelvic imaging (computed tomography, magnetic resonance imaging, cystography) because correction often requires a multidisciplinary approach. Additional diagnostic testing including defecography may be helpful in the case of occult prolapse or distal rectal mucosal prolapse.

TREATMENT

Rectal prolapse is a surgical disease. Nonoperative measures are used to temporize the surgical patient or provide palliation in the prohibitively morbid patient. In the case of acute prolapse without strangulation, the prolapse should be reduced. Topical application of table sugar to the incarcerated edematous rectum may decrease edema of the rectum and allow return of the rectum to the pelvis until surgery is planned. For those without a surgical option, attention to a bowel regimen and skin care can offer some improvement in quality of life.

Patients who are deemed fit for surgical intervention should proceed with surgery without delay to avoid irreversible fecal incontinence. Before the surgical procedure, oral antibiotic and mechanical bowel preparation should be prescribed as part of an enhanced recovery pathway. Standard prophylaxis for venous thromboembolism and surgical site infections are also administered.

Perineal vs Transabdominal Repair

There is no consensus on the best surgical approach for rectal prolapse and it remains a matter for debate. Traditionally, transabdominal repairs are preferred over perineal repairs in the fit patient because of the lower rate of recurrence and perineal repairs are recommended for comorbid patients because of a lower operative impact and morbidity. Recurrent prolapse has been reported after abdominal rectopexy in 7% to 9% of patients and after perineal procedures in 10% to 30% of patients. However, more recent evidence from the Prospective Study of Pneumatic in the Elderly at Risk randomized trial finds that functional outcomes and rates of recurrence (12%–21%) are similar between perineal and abdominal procedures, with a higher rate of recurrence for abdominal procedures than previously reported. The majority of patients reported significant functional improvements, suggesting that perineal proctectomy is an acceptable strategy even in the younger subset. The importance of recurrent prolapse may also be overemphasized in the comorbid population with a limited life expectancy. Minimally invasive techniques and advances in perioperative management have improved enough to mitigate the operative morbidity of a transabdominal repair. In a National Surgical Quality Improvement Program analysis of 2188 matched patients undergoing prolapse surgery by either a perineal or abdominal technique, no significant difference was found in the rate of any complication or mortality (0.9%). The hazard ratio for major morbidity after an abdominal approach relative to a perineal approach was only 1.30 (95% confidence interval, 0.92–2.10, $P = .15$). The authors concluded that many patients treated with perineal repair may have also done well if treated with a transabdominal repair. A 2012 Cochrane review included approximately 1000 patients, but the clinical data were found lacking to determine "clinically important differences between alternative surgical operations." Limitations of available data to direct choice of treatment mean that the approach for prolapse repair can be less motivated by outcomes of recurrence and more oriented to provide immediate reduction of the prolapse while addressing associated incontinence or bowel dysfunction.

Perineal Procedures

Prolapse procedures that employ a perineal approach are traditionally considered for those with short segment rectal prolapse (<3 cm) or for those with comorbidities precluding abdominal surgery. Anal encirclement (Thiersch wire) procedures that work by confining the prolapsed rectum within the anal canal are mostly mentioned for historical interest owing to associated high rates of fecal impaction and perineal sepsis. Currently, sleeve resection of the rectal mucosa (Delorme's procedure), Stapled Transanal Rectal Resection, and perineal rectosigmoidectomy with or without levatorplasty (Altemeier's procedure), are most commonly performed.

Mucosal Sleeve Resection (Delorme's Procedure)

First introduced in 1900, Delorme's procedure is safe and effective for the treatment of short segment (<5 cm) full thickness distal rectal prolapse or mucosal prolapse. The procedure is also an option for patients with previous rectal resection or pelvic radiation because no anastomotic resection or full thickness incision is required. This procedure consists of a circumferential resection of the prolapsing sleeve of mucosa to expose the distal muscularis propria. Placement of plicating stitches on at least three of the four quadrants to "accordion" and reduce the prolapsing muscularis propria to a thickened ring of muscle at the anal outlet.

Operative Technique

The patient can be positioned in either lithotomy, left lateral decubitus, or prone jackknife positions (Fig. 1A–F). A Lonestar retractor (Cooper Surgical), with hooks placed outside the anal verge, is used to expose the operative site. Using atraumatic clamps, the rectum is prolapsed as completely as possible to identify the proximal extent of planned mucosal resection. Tumescent solution of saline and epinephrine is injected circumferentially in the submucosa, creating a plane between the submucosa and muscularis propria and aiding in hemostasis. Using flush electrocautery, the mucosa is released from the circular muscles of the muscularis propria all the way to the anal transition zone above the dentate line. Plicating stitches are then placed in three or four quadrants from the proximal cut edge of the mucosa, in linear array serially through the muscularis (three to four bites), to the distal edge of the mucosa just proximal to the dentate line. Because quadrant plicating stitches are tied, the prolapse reduces into the anal canal to create a thickened rim of muscle that serves to create a barrier to prolapse and provides some continence support. The now adjacent cut edges of mucosa can be approximated as an anastomosis using a running or interrupted suture. Careful proctoscopy is performed at the end of the procedure to ensure patency of the rectum and completeness of the anal mucosal anastomosis.

Outcomes

Delorme's procedure is considered to be very safe with postoperative mortality approaching 0%. Complications occur in 0% to 12% of patients. The most common short-term complications include urinary retention, bleeding, infection, fecal impaction, fecal urgency, and tenesmus. In a manometric study of patients undergoing Delorme's procedure, increases in mean rest and squeeze pressures and rectal sensation were seen. Incontinence improved in 63% and constipation improved in 38%.

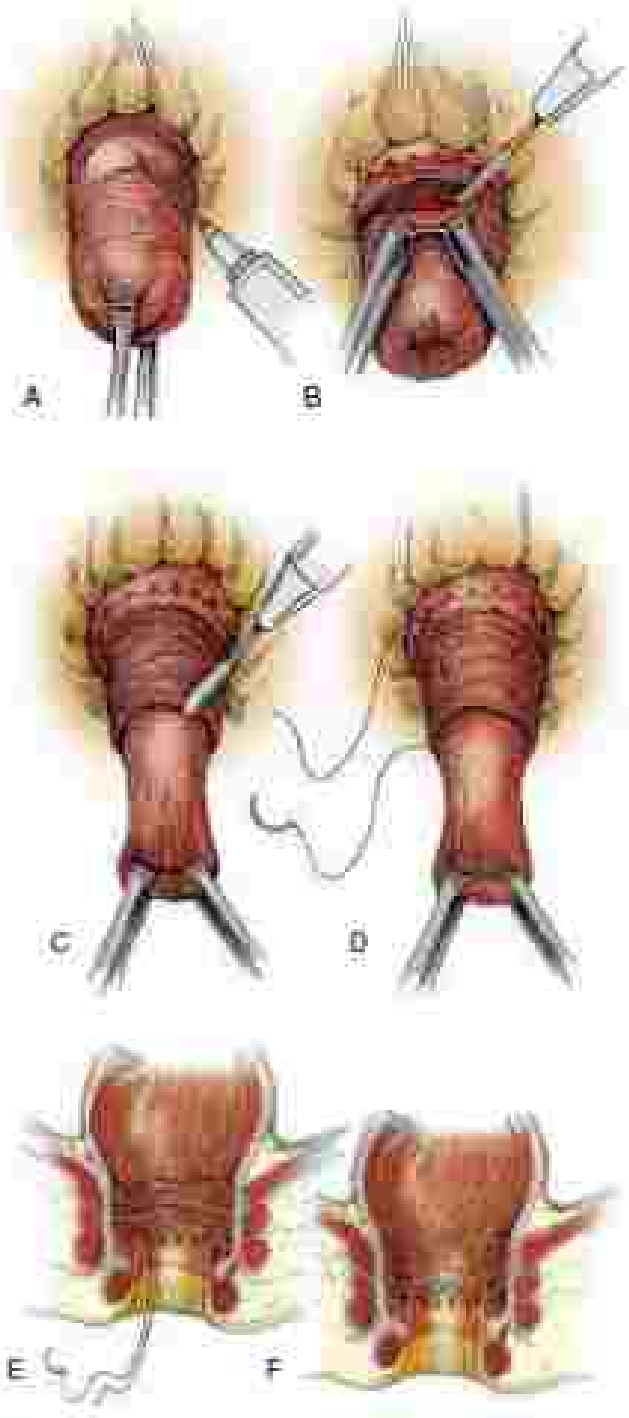

FIG. 1 Delorme's procedure. (A) Submucosal infiltration is carried out with saline or local anesthetic with epinephrine. (B) Partial-thickness circumferential incision is made 1–2 cm proximal to the dentate line. (C) The incision is carried through the mucosa, and the mucosa is dissected off the underlying muscularis. (D–E) Plication sutures is placed. (F) Mucosa is amputated and anastomosis is completed.

Perineal Rectosigmoidectomy (Altemeier's Procedure)

Perineal rectosigmoidectomy was first introduced by Miles in 1933 and then repopularized by Altemeier in the 1970s as a one stage repair for full thickness rectal prolapse.

Full thickness rectal prolapse greater than 5 cm is best treated with perineal rectosigmoidectomy and colorectal anastomosis. The approach can also be considered in the rare male patient with prolapse because it avoids dissection at the pelvic brim and potential postoperative sexual dysfunction. The procedure is essentially a transanal full thickness resection of the prolapsing portion of the rectum and entire sigmoid colon with a left colorectal anastomosis.

Operative Technique

The patient can be positioned in either lithotomy, left lateral (Sims'), or prone jackknife position (which we prefer) (Fig. 2A–F). A Lonestar retractor (Cooper Surgical), with hooks in the anal canal, is used to expose the operative site. The rectum is prolapsed, the tone of the anal sphincter inspected and estimated, and a full thickness circumferential incision in the rectal wall is created at a level 1 to 2 cm proximal to the dentate line. Anteriorly the cut is extended and the apex of the pelvic floor peritoneum marked with a suture. The lateral peritoneal attachments to the rectum are incised on both sides of the pelvis to expose the mesorectum. The lateral vascular attachments are divided with energy (monopolar or bipolar). The rectum is then progressively withdrawn from the body by incising the posterior attachments of the mesorectum in a cephalad direction.

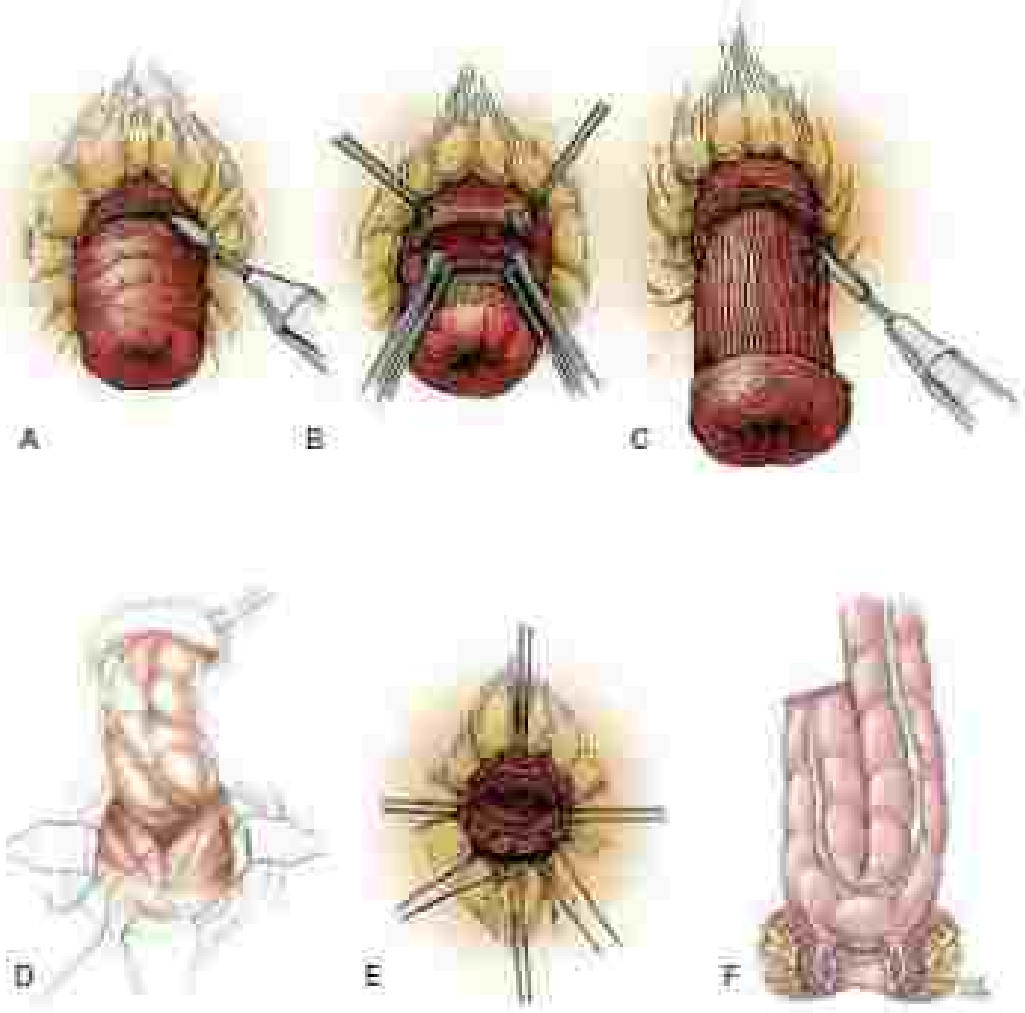

FIG. 1 Perineal rectosigmoidectomy. (A–C) Full-thickness excision of redundant bowel. (D) Levatoroplasty is performed with several figure-of-8 sutures. If possible, (E) excision of bowel at level of mucus anastomosis after redundancy is removed. (F) If adequate length is present, colonic J pouch is performed. (A–C, Modified from Corman ML: Rectal prolapse. In Corman ML, Nivatvongs S, eds: *Principles and Practice of Surgery for the Colon, Rectum, and Anus*. 3rd ed. New York: Informa Healthcare; 2007. p. 615–632. D–F, Modified from Wexner SD, Heitmann JM: Anal and Rectal Surgery. In Beckford RJ, ed: *Atlas of Operative Gynecologic Surgery*. Philadelphia: Lippincott Williams and Wilkins; 2011.)

Tethering vessels of the mesorectum are divided sequentially as the rectum is extracted. A finger through the anterior pubic opening can find the redundant sigmoid. The proximal rectum and distal sigmoid colon are released from the posterior vessels and drawn through the anus until no further redundancy of the colon occurs, yet a tension-free colorectal anastomosis can be created. The bowel and mesentery are then divided at this level, being mindful to preserve the mesenteric vessels supplying the left colon to prevent devascularization of the anastomosis. Using a laparoscopic-length bipolar sealing energy device is helpful to reach the distal vessels at the level of the sacral promontory as the dissection transitions to the sigmoid colon mesentery. A levatoroplasty is then performed by placing the levator ani muscle anteriorly and posteriorly to recreate the pelvic floor sutures with figure of 8 sutures of nonabsorbable material. Before creation of the colorectal anastomosis, the orientation of the mesentery and colon are checked to prevent torsion. Creation of the handsewn colorectal anastomosis is performed to either a straight or colonic J pouch configuration. A circular stapler technique can be applied by creating a purse-string closure of the top of the anal canal and securing the anvil to a purse-string in the cut end of the left colon. Removal of the entire rectum and sigmoid is essential to reduce bowel frequency and urgency. The sigmoid colon to anal anastomosis without a colonic pouch is almost intolerable.

Outcomes

As with Delorme procedure, mortality is low (0%–4%). Morbidity of the procedure is reported at 2% to 24% and largely secondary to patients' specific comorbidity. Technical complications are reported at 12% and include bleeding, anastomotic dehiscence, pelvic sepsis, and colorectal stricture. An oral antibiotic and complete mechanical bowel prep may reduce contamination, anastomotic leak, and pelvic sepsis.

Levatoroplasty is recommended in the case of preoperative fecal incontinence and a large pudendal canal with chronically stretched sphincter because it has been shown to afford greater gains in postoperative continence and a lower rate of recurrence compared to resection/rectopexy alone. In a prospective study by Kim et al., patients also gain an improved subjective state of health and quality of life in the areas of mobility, activity, pain and discomfort, and anxiety and depression at 49 month follow up.

Transabdominal Procedures

Many transabdominal procedures are described for the treatment of rectal prolapse. Ultimately, the goals of transabdominal rectal prolapse surgery are to completely mobilize the rectum to the pelvic floor with preservation of the lateral stalks and to reattach the rectum to

the rectum. Recurrence is eightfold higher among patients treated with mobilization alone compared with mobilization with fixation; however, limited evidence is available to support a benefit of fixation in the posterior or anterior structures.

In a 2015 Cochrane review, division of the lateral stalks to the low pelvis was associated with decreased rates of recurrence (0%–10%) but an increased rate of constipation (67% vs 0%).

Minimally invasive techniques have gained a foothold as the standard of care for most colorectal procedures. Laparoscopic techniques should be applied to transabdominal repairs of rectal prolapse whenever possible. Laparoscopic port sites are used for mobilization of the rectum with a small Pfannenstiel port extended to place fixation sutures. A minimally invasive approach offers similar rates of recurrence (4%–8%) and morbidity (10%–33%) with shorter length of stay, earlier return of bowel function, and better pain control compared with an open approach.

Abdominal Suture Rectopexy With or Without Resection

Abdominal rectopexy with sigmoid resection was first introduced by Frykman in 1963 as a composite of surgical procedures of the time for patients with massive prolapse requiring a "radical" and more permanent approach. The essential steps of this procedure included: (1) mobilization of the rectum; (2) elevation of the rectum as high as possible and suture fixation of the lateral stalks to the periosteum of the sacrum; (3) suture of the endopelvic fascia anterior to the rectum and obliteration of the cul de sac; and (4) sigmoidal resection of the excess sigmoid colon, without compromising the blood supply of the rectum, with end to end anastomosis. The suture rectopexy is performed on the anterior surface of S1 with a circle taper needle carrying permanent suture. The best point for suture placement is just off the midline on each side of the sacral promontory, just below the course of the common iliac vein. The peritoneal wings of rectum at the level of the peritoneal reflection are pulled up to the sacral promontory and the resulting stretch of the rectum eliminates the redundancy that starts rectal prolapse in the deep pelvis. The modern iteration of this procedure has omitted obliteration of the cul de sac.

Combined sigmoid resection carries minimal additional morbidity and is indicated for patients with constipation as it has been found in randomized controlled trials to reduce the rate of recurrence and improve constipation compared to rectopexy alone. Conversely, resection should be avoided in patients with preexisting incontinence. Resection should also be avoided in combination with mesh procedures due to the risk of superinfection of mesh and is absolutely contraindicated in the case of prior perineal rectosigmoidectomy since critical vascular supply has already been removed. A diverting ileostomy is only used if ongoing bleeding cannot be stopped.

Outcomes

Rectopexy carries acceptable morbidity; major complications of 6% to 21% and minor complications 10% to 20%. In a National Surgical Quality Improvement Program review of 560 patients, takeback to the operating room was 2.8%, and organ space infection was 2.3% (likely secondary to anastomotic leak). Minor complications included urinary tract infection and superficial site infection.

Functional outcomes are favorable with significant improvement in reported incontinence (67%–73%) and increased maximal anal resting pressures. Huber et al. showed a reduction of constipation from 81% to 26% postoperatively. However, other studies report de novo constipation as high as 41%, which may reflect lack of appropriate preoperative evaluation or failure to perform sigmoidectomy when indicated.

Ventral Rectopexy

Ventral rectopexy is an adaptation of the Orr Loygue mesh procedure as an alternative method for rectal prolapse repair that uses an anterior rectal dissection with only a limited posterior dissection to expose a site of fixation on the sacral promontory. An incision is made to the right lateral peritoneal wings all the way to the vagina. Following anterior dissection, separating rectum and vagina, to the pelvic floor, a synthetic or biological mesh is sutured as distally as possible to the anterior rectal wall and the proximal portion of the mesh is secured to the sacral promontory. The low anterior rectum is stretched and prevents intussusception. The pelvis is then reperitonealized and the mesh is covered by the peritoneum along the rectum to the right pelvic peritoneum. In doing so, the mesh is excluded from other intraperitoneal structures.

Outcomes

Morbidity (<7%), mortality, and rates of recurrence are similar to suture rectopexy; however, the fear of mesh related complications is the driver of criticism toward this technique in the United States. In a systematic review of 2856 patients (2517 synthetic/439 biologic), the mesh erosion rates were exceedingly low (3.87% synthetic/0.22% biologic), respectively, with mean ranging from 1.7 to 12.8 months. However, more long-term, controlled studies are needed to better understand the true effect of synthetic mesh material on rectum and the impact of the potentially devastating complication of erosion.

The main benefit of ventral rectopexy over traditional rectopexy is a significant and durable decrease in postoperative constipation due to avoidance of the posterior dissection that causes autonomic denervation. In a study of 45 consecutive patients by Boons et al., constipation was improved in 72% of patients at 3-month follow up, with a very low rate of de novo constipation (2%). In long-term follow up of 61 months, Williams et al. reports resolution of constipation in 64% (16 of 19) of patients without any cases of new onset constipation following this procedure. Continence is also improved in 82% of patients.

Recurrent Prolapse

In the case of recurrent prolapse, the choice of repair is dictated by the remaining blood supply to the rectum. Patients who have undergone a previous sigmoid resection risk ischemia to the remaining distal rectum if re resection is performed. It is imperative to review previous operative notes for history of resection. An algorithm for approaching repair of recurrence is provided in Fig. 3; however, the literature to fully inform decision making and outcomes is lacking.

Steele et al. reviewed 78 of 685 patients who underwent repeat prolapse surgery for recurrent prolapse by various approaches; recurrence occurred more often following a perineal approach (19 of 51) compared with a transabdominal approach (4 of 27), $P = .03$, at mean follow up of 9 (range, 1–82) months. This disparity is widened further following a third surgery with a recurrence rate of 50% following perineal repairs versus 8% following transabdominal repairs ($P = .07$). These findings support the general assertion from previous studies that second time recurrence is higher following perineal repair. However, selection bias may have affected this comparison. Ultimately, the choice of recurrence surgery must weigh these and other factors.

CONCLUSIONS

Rectal prolapse is a surgical disease that challenges the colorectal surgeon. The choice of surgery should address both the mechanical and functional disorders that underlie the diagnosis with an acceptable risk and recurrence profile in the typically comorbid patient. Outcomes of recurrence and function do not appear to differ largely between perineal and transabdominal approaches. The management of recurrent prolapse also lacks clear evidence to guide decision making. Perineal repair is associated with a higher rate of re recurrence. Despite limitations of available data, surgical decision making should ultimately provide the best treatment for reduction of the prolapse while addressing associated incontinence or bowel dysfunction.

Management of Solitary Rectal Ulcer Syndrome

Shlomo Yellinek, MD, FACS, FRCS, FRCS(Ed), and Steven D. Wexner, MD, PhD(Hon), FACS, FRCS(Eng), FRCS(Ed), FRCSI(Hon), FRCS, Glasg(Hon)

Solitary rectal ulcer syndrome (SRUS) is a rare and underdiagnosed benign rectal disorder that represents a spectrum of rectal wall abnormalities, ranging from ulcers to nodules or polypoid lesions. The term "solitary" is misleading because the ulcers can be multiple and can be anywhere between the rectum and the cecum. The prevalence of SRUS is less than 1 to 100,000 per year, with equal gender distribution and a median age of 50 years at time of diagnosis. The syndrome, characterized by Madigan and Morson in 1969, is a combination of clinical symptoms, endoscopic appearance, and histologic findings. The treatment is multidisciplinary and should be tailored to each patient.

PATHOPHYSIOLOGY

The underlying pathophysiology of SRUS is not fully understood and is probably multifactorial. There are several clinical pathologies associated with SRUS, including rectal prolapse, strenuous defecation, and paradoxical contraction of the pelvic floor muscles. In some individuals, these conditions may cause a chronic reduction in blood perfusion to the rectal mucosa and, over time, ischemia and ulceration. However, these conditions are probably only predisposing factors and most patients do not suffer from SRUS.

Chronic rectal mucosal prolapse is the most common pathology associated with SRUS. In a series of 58 patients with diagnosed SRUS, radiographic evidence of prolapse was present in 94%. Prolapse, either partial or full thickness, results in areas of focal ischemia in the rectal mucosa resulting from reduced blood flow and local inflammatory reaction.

Chronic local rectal trauma from strenuous defecation and hard stools may cause SRUS. The physical injury to the rectal mucosa may cause scarring and inflammation that eventually leads to local ischemia and ulceration. The high pressure in the rectum resulting from strenuous defecation may cause a reduction in mucosal perfusion. The uncoordinated contraction of the pelvic muscles in paradoxical puborectalis muscle syndrome and the resultant ineffective defecation can result in local ischemia and ulceration in the same mechanism.

DIAGNOSIS

The diagnosis of SRUS requires a high level of suspicion and is mainly based on clinical features, endoscopic findings, and typical histopathologic findings. Imaging studies can be useful in diagnosing the underlying pathology. It is imperative to exclude other causes of rectal ulcers such as malignancy, inflammatory bowel disease, HIV, syphilis, and stercoral ulcerations before making a diagnosis.

The clinical presentation of patients with SRUS is variable and reflects the symptoms of the ulcer and the symptoms of the underlying pathology. Frequent unproductive straining and incomplete evacuation are common and frustrating symptoms. Rectal bleeding and mucus discharge are also common symptoms. Other symptoms include prolapsed tissue, tenesmus, pelvic pain, and fecal incontinence.

External signs on physical examination are usually not present, unless there is a full thickness rectal prolapse. Digital rectal examination may reveal nodular and friable rectal mucosa and occasionally blood per rectum. It is possible to sense a lack of relaxation of the puborectalis muscle when the patient bears down.

Endoscopic findings may vary from hyperemic friable mucosa to mature ulcers covered by white or gray slough (Fig. 1). The

Management of Solitary Rectal Ulcer Syndrome

Shlomo Yellinek, MD, FACS, FRCS, FRCS(Ed), and Steven D. Wexner, MD, PhD(Hon), FACS, FRCS(Eng), FRCS(Ed), FRCSI(Hon), FRCSI(Glasg)(Hon)

Solitary rectal ulcer syndrome (SRUS) is a rare and underdiagnosed benign rectal disorder that represents a spectrum of rectal wall abnormalities, ranging from ulcers to nodules or polypoid lesions. The term "solitary" is misleading because the ulcers can be multiple and can be anywhere between the rectum and the cecum. The prevalence of SRUS is less than 1 to 100,000 per year, with equal gender distribution and a median age of 50 years at time of diagnosis. The syndrome, characterized by Madoff and Madigan in 1989, is a combination of clinical symptoms, endoscopic appearance, and histologic findings. The treatment is multidisciplinary and should be tailored to each patient.

PATHOPHYSIOLOGY

The underlying pathophysiology of SRUS is not fully understood and is probably multifactorial. There are several clinical pathologies associated with SRUS, including rectal prolapse, strenuous defecation, and paradoxical contraction of the pelvic floor muscles. In some individuals, these conditions may cause a chronic reduction in blood perfusion to the rectal mucosa and, over time, ischemia and ulceration. However, these conditions are probably only predisposing factors and most patients do not suffer from SRUS.

Chronic rectal mucosal prolapse is the most common pathology associated with SRUS. In a series of 58 patients with diagnosed SRUS, radiographic evidence of prolapse was present in 94%. Prolapse, either partial or full thickness, results in areas of focal ischemia in the rectal mucosa resulting from reduced blood flow and local inflammatory reaction.

Chronic local rectal trauma from strenuous defecation and hard stools may cause SRUS. The physical injury to the rectal mucosa may cause scarring and inflammation that eventually leads to local ischemia and ulceration. The high pressure in the rectum resulting from strenuous defecation may cause a reduction in mucosal perfusion. The uncoordinated contraction of the pelvic muscles in paradoxical puborectalis muscle syndrome and the resultant ineffective defecation can result in local ischemia and ulceration in the same mechanism.

DIAGNOSIS

The diagnosis of SRUS requires a high level of suspicion and is mainly based on clinical features, endoscopic findings, and typical histopathologic findings. Imaging studies can be useful in diagnosing the underlying pathology. It is imperative to exclude other causes of rectal ulcers such as malignancy, inflammatory bowel disease, HIV, syphilis, and stercoral ulcerations before making a diagnosis.

The clinical presentation of patients with SRUS is variable and reflects the symptoms of the ulcer and the symptoms of the underlying pathology. Frequent unproductive straining and incomplete evacuation are common and frustrating symptoms. Rectal bleeding and mucus discharge are also common symptoms. Other symptoms include prolapsed tissue, tenesmus, pelvic pain, and fecal incontinence.

External signs on physical examination are usually not present, unless there is a full thickness rectal prolapse. Digital rectal examination may reveal nodular and friable rectal mucosa and occasionally blood per rectum. It is possible to sense a lack of relaxation of the puborectalis muscle when the patient bears down.

Endoscopic findings may vary from hyperemic friable mucosa to mature ulcers covered by white or gray slough (Fig. 1). The

FIG. 1 Endoscopic imaging of a 17-year-old male with solitary rectal ulcer syndrome (SRUS). A polypoid lesion was found in the first rectal valve. Biopsy showed fragments of rectal mucosa with focal erosion, granulation tissue replacement, and glandular reactive changes consistent with SRUS.

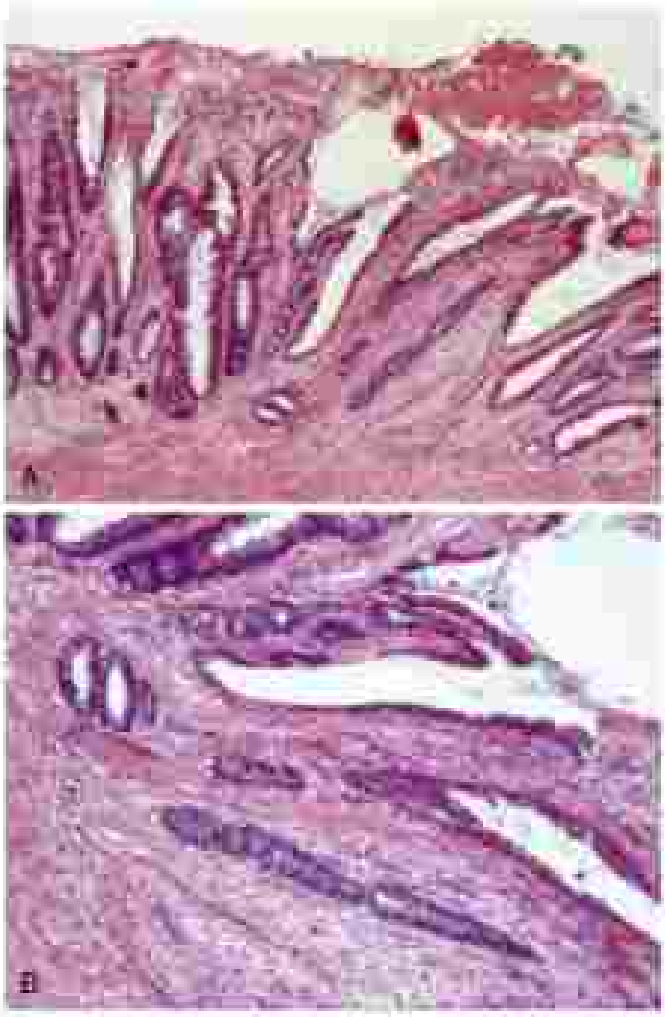

FIG. 2 Solitary rectal ulcer syndrome. (A) Erosion of the surface epithelium, vascular congestion, and irregularity of the glandular crypts. In addition, extra bundles of myofibroblasts projecting from the base to the upper areas of the lamina propria (hematoxylin and eosin, ×100). (B) Myofibroblastic hyperplasia was between the glandular crypts (hematoxylin and eosin, ×200).

macroscopic appearance of SRUS is often classified into three types: ulcerative (50%–60%), polypoid (25%), and flat (25%). The lesions are typically located 4 to 12 cm from the anal verge on the anterior rectal wall. It is important to obtain biopsies of the lesions and the surrounding area to make the diagnosis and exclude other pathologies as well as perform a full colonoscopy.

Morphologic findings in the pathology specimen include fibromuscular obliteration of the lamina propria, hypertrophied muscularis mucosa, and glandular crypt abnormalities. Secondary changes such as surface erosion, inflammation, hemorrhage, congested vessels, deep cyst formation, or misplaced glands in submucosa may be seen (Figs. 2 and 3).

Defecography and anorectal manometry may help in diagnosis the underlying pathology. Defecography is helpful in the diagnosis of rectal prolapse, intussusception, and paradoxical puborectalis syndrome. Manometry defines the pressure profiles, rectoanal inhibitory reflex, and sensory thresholds, and is helpful in the diagnosis of paradoxical puborectalis syndrome.

MANAGEMENT

Several options for treatment of SRUS are available. The decision must take into account the underlying pathology. Initially, a trial of conservative treatment is initiated and includes patient education, dietary modifications, topical agents, and biofeedback therapy. Patients should be educated to avoid straining and to regulate toilet habits. Dietary modifications should include a high fiber diet, fiber supplements, and stool softeners. Topical treatments with either anesthetic or mucosa occlude agents such as sucralfate, salicylates, steroids, salicylates, and mesalamine, with varying degrees of improvement. If symptoms fail to improve, especially in patients with documented paradoxical puborectalis syndrome, a trial of biofeedback therapy should follow. Biofeedback therapy focuses on reducing excessive straining and strenuous defecation by correcting abnormal pelvic floor behavior and by eliminating agitation and suppository use. In patients with paradoxical puborectalis syndrome who have failed to improve, botox injection to relax the sphincter muscle complex may be helpful.

The use of argon plasma coagulation (APC) has shown good results in with patients with SRUS who have failed medical and behavioral treatment. APC is especially useful in bleeding control, which can be significant in some patients and may manifest blood transfusion. In a series of 99 patients (41 treated with APC vs 58 treated conservatively), a significant difference in bleeding cessation in the APC group was noted, but there was no significant difference between the two groups in terms of pain relief.

If conservative treatment fails to improve the patient's symptoms, a surgical approach may be considered. Common indications for surgery include intractable pain, significant bleeding, and prolapse. There are various surgical procedures for repair of rectal prolapse that are mainly divided into two approaches: perineal and abdominal. Although the perineal approach is typically easier, it tends to be more difficult because of scarring and ulcerations in the setting of SRUS. The abdominal approach, which includes rectopexy with or without excessive sigmoid resection and with or without mesh placement, has higher success rates and is considered the gold standard given that there are no severe comorbidities. In patients without mucosal prolapse or intussusception who have failed conservative treatment and suffer from intractable pain or persistent bleeding, a proctectomy and/or fecal diversion may be warranted. Fig. 3 outlines a stepwise approach to the management of SRUS.

In a series from Cleveland Clinic Florida, 46 patients with SRUS underwent surgical procedures. There was a combined improvement

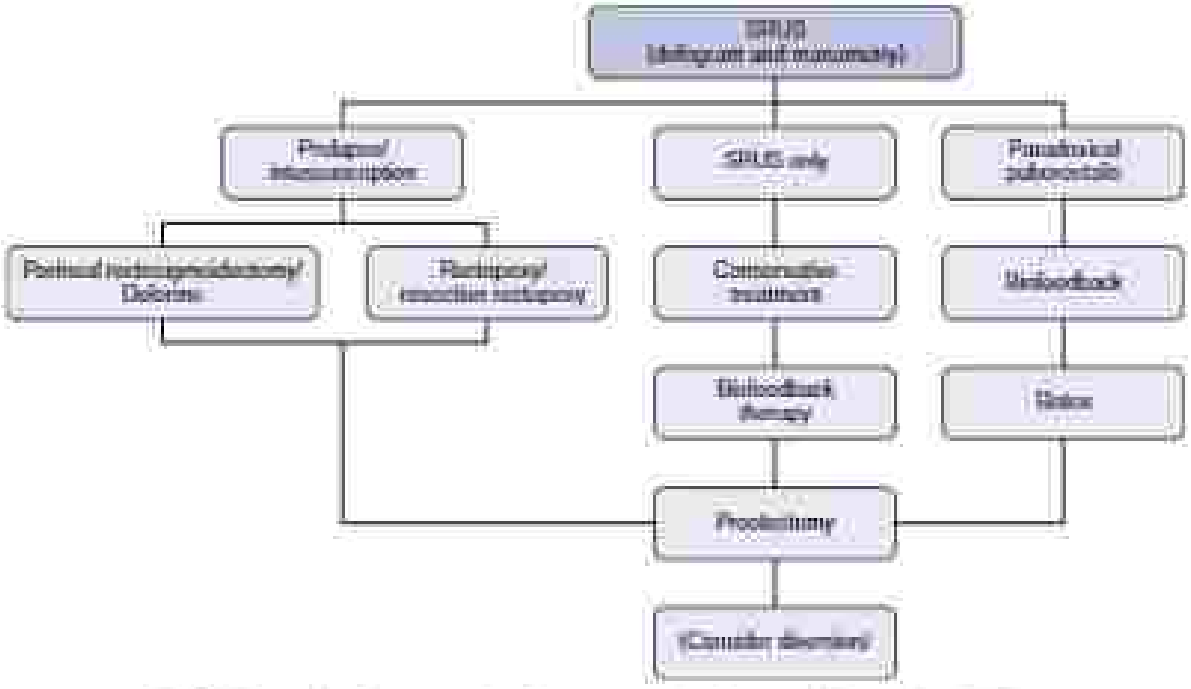

FIG. 3. Suggested stepwise approach for the management of solitary rectal ulcer syndrome (SRUS).

rate of 76% for all surgical procedures. The authors noted that, for SRUS without prolapse, a resection or local diversion was followed by a significantly higher improvement rate than local excision of the ulcer.

CONCLUSION

SRUS is a rare underdiagnosed condition with highly variable clinical presentation and can be the result of several underlying pathologies. The diagnosis of SRUS is challenging, mandating a high level of suspicion, and must be made only after excluding other pathologies such as malignancy or inflammatory bowel disease. The diagnosis is a combination of clinical presentation, endoscopic appearance, and pathologic findings. Treatment options depend on the underlying pathology and include conservative treatment, endoscopic treatment, and surgery. Surgical options include perineal repair procedures, proctectomy and/or fecal diversion. Local excision of SRUS is not recommended.

SURGICAL MANAGEMENT OF CONSTIPATION

Lisa Park, MD, and Jeremy M. Lipman, MD, MHPE, FACS, FASCRS

Constipation is a multifactorial and intricate diagnosis that remains one of the most common reasons for an office visit to a physician. It is a substantial clinical problem, affecting an estimated 3% to 11% of the population in Western countries, with an increased prevalence in women, children, and the elderly. In addition to leading to an estimated 2.5 million office visits, this common complaint has led to an increasing number of emergency department visits and hospitalizations. Between 2006 and 2011, the frequency of constipation-related emergency department visits increased by 41.5% and the aggregate national cost of constipation-related emergency department visits increased by 121.8%, making constipation among the top 10 digestive disorders in attributable costs of $1.4 billion annually.

ANATOMY AND PHYSIOLOGY

Defecation is a complex physiologic process that relies on the coordinated interplay between anatomic and neurologic features of an individual's colonic musculature, neurorectal reflex, and sphincter complex. As stool enters the rectum, the internal anal sphincter, comprising smooth muscle under autonomic control, involuntarily relaxes while the external anal sphincter simultaneously contracts, allowing rectal contents to reach the upper anal canal. Feedback from terminal sensory fibers in the anal canal, distinguishing liquids from solids and gas, allows the process of defecation to occur as the anal canal pressure increases. The puborectalis muscle, which is tonically contracted at rest but also under

BOX 1 Rome IV Criteria for Constipation

Requires Two or More of the Following:

- Straining with more than 25% of defecations
- Lumpy or hard stools (Bristol stool form scale 1 or 2) more than 25% of defecations
- Sensation of incomplete evacuation more than 25% of defecations
- Sensation of anorectal obstruction/blockage more than 25% of defecations
- Manual maneuvers to facilitate more than 25% of defecations (such as digital evacuation or support of the pelvic floor)
- Fewer than three spontaneous bowel movements per week

Plus:

- Loose stools are rarely present without the use of laxatives
- Insufficient criteria for irritable bowel syndrome
- Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis

From Lacy BE, Mearin F, Chang L, et al. Bowel disorders. Gastroenterology. 2016;150(6):1393–1407.

BOX 2 Rome IV Criteria for IBS-C

Recurrent abdominal pain, on average, at least 1 day per week in the past 3 months, associated with two or more of the following criteria:

- Related to defecation
- Associated with a change in frequency of stool
- Associated with a change in form (appearance) of stool
- Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis
- Patient reports that abnormal bowel movements are usually constipation (such as type 1 or 2 Bristol stool form scale)

From Lacy BE, Mearin F, Chang L, et al. Bowel disorders. Gastroenterology. 2016;150(6):1393–1407.

IBS-C, irritable bowel syndrome with predominant constipation.

voluntary control, relaxes to straighten the anorectal angle, and the striated external anal sphincter muscle also relaxes. Defecation occurs when the intrarectal pressure exceeds the anal canal pressure.

DIAGNOSIS

Constipation is generally defined by bowel symptoms such as difficulty passing stools, infrequent or hard stools, or a feeling of incomplete evacuation. Because of the subjectivity and variation of patient-reported symptoms, objective criteria to define this condition and more importantly, to distinguish and treat the underlying cause of constipation, have led to the creation of several scoring systems. The Rome Criteria for Gastrointestinal Disorders, introduced in 1988 and most recently updated to a fourth edition in 2016, is a commonly used tool to diagnose functional constipation as shown in Box 1. It is important to differentiate constipation from irritable bowel syndrome (IBS) as operative management is never recommended for IBS. Criteria for IBS with predominant constipation are shown in Box 2.

PREOPERATIVE EVALUATION

Once the diagnosis of constipation is made, it is critical to ensure it is functional and not from other causes. Structural and metabolic etiologies for constipation must be excluded because they will require therapy directed at these underlying causes. Thus, the evaluation of any patient with constipation should begin with a detailed history and physical examination to identify modifiable behavioral factors such as diet, medications, and contributing medical disorders such as hypothyroidism, electrolyte derangements, and diabetes, which can slow bowel function. Laboratory evaluations should only be done to assess for these conditions. Rectal bleeding, change in caliber of stools, unintentional weight loss, or a family history of colorectal cancer are red flags that should warrant further investigations to determine whether an underlying colorectal malignancy is the reason for associated constipation symptoms.

Functional constipation can be divided into two main categories based on the underlying pathophysiology: (1) disorders of colonic motility and (2) disorders of defecation. In terms of motility, constipation is categorized as either normal transit or slow transit constipation based on the rate of stool passage through the colon. Obstructed defecation syndrome, also referred to as dyssynergic defecation, is a generalized diagnosis used for various pathophysiologic disorders resulting in impaired defecation such as pelvic floor dysfunction. However, history and physical alone may be inadequate to clearly establish a diagnosis because overlap between the subtypes is not uncommon. In a study of more than 1000 patients with functional constipation who were evaluated at the Mayo Clinic, 19% were found to have normal transit constipation, 25% had defecatory disorders, 13% had slow transit constipation, and 3% had a combination of a defecatory disorder and slow transit constipation.

A careful anorectal examination is critical to evaluate for outlet obstruction constipation and should involve a digital evaluation of anal sphincter tone and coordination of function. Evaluation for pelvic floor dysfunction such as perineal descent, pelvic organ prolapse or the presence of rectal or cystoceles should also be performed.

Slow-Transit Constipation

The exact etiology of slow transit constipation is unknown but arises from disordered colonic motor function with neuronal and muscular factors implicated in its pathogenesis. As such, it is on the spectrum of disordered gut brain interactions. It is most common in young women and is characterized by infrequent bowel movements. Operative management should be reserved for patients whose symptoms are refractory to all available medical treatments. Because slow transit constipation can exist in concert with other functional gastrointestinal (GI) disorders, it is critically important to evaluate for these prior to considering an operation. This is particularly important with slow transit constipation because operative management may worsen coexistent motility disorders.

Preoperative evaluation for slow transit constipation should include a colonic transit study such as Sitzmark's study, Smart Pill study, or scintigraphy, to confirm the diagnosis. Also, amplification evaluation to exclude outlet obstruction and a colonoscopy should be performed to exclude luminal disease.

Sitzmark's Test (Radiopaque Marker Testing)

The Sitzmark's or radiopaque marker test can be used to measure colonic transit time by performing abdominal radiographs at predetermined times after the patient ingests radiopaque beads or rings. Patients are typically instructed to swallow the markers on a Sunday, and then undergo plain abdominal radiographs on Monday, Wednesday, and Friday to observe progression through the GI tract. The number and location of retained markers are used to assess overall GI transit time.

During the study, the patient should be maintained on a high-fiber diet and avoid laxatives, enemas, or medications that may affect bowel function. This can be problematic for some patients because of the severity of symptoms when off laxatives.

Retention of more than 20% of the ingested markers on day 5 suggests slow transit constipation. A typical positive test result for slow transit constipation would show more than 20% of ingested markers scattered throughout the colon on the fifth day of the test (Fig. 1). If all markers have not progressed to the colon by the first

FIG. 1 Stomach study suggesting slow-transit constipation.

FIG. 2 Stomach study suggesting outlet dysfunction.

day, this is suggestive of small bowel or gastric dysmotility and further investigation should be initiated. If, on the fifth day, all the test markers are retained exclusively in the sigmoid colon and rectum, this is suggestive of (but not diagnostic of) outlet dysfunction as an etiology for symptoms (Fig. 2).

Wireless Motility Capsule

The wireless recording capsule is a single use device used to distinguish normal from slow colonic transit. It can also be used in patients with a suspected motility disorder of the upper GI tract because it measures gastric emptying and small bowel transit in addition to colonic transit times. The capsule continuously sends temperature, pH, and pressure measurements as it moves along the GI tract. This is transmitted to a data receiver worn on the waist for 5 days. Patients also keep a log of daily activities, meals, sleep, and bowel movements. Normal colonic transit time using the wireless motility capsule is 10 to 59 hours, with delayed colonic transit considered greater than 44 hours in men and 59 hours in women. A typical study result is shown in Fig. 3. An advantage of the wireless motility capsule test is its use in patients being considered for a colectomy or diverting ileostomy as treatment for severe constipation when assessment of upper GI transit is also recommended. Moreover, the wireless motility capsule is well tolerated by most patients and is a more convenient ambulatory test than the Sitzmark's test because it does not require serial imaging. It is contraindicated in patients with pacemakers or defibrillators, swallowing disorders, or suspected strictures or fistulas.

Scintigraphy involves patients eating a radiolabeled meal and following its transit through the GI tract using a gamma camera. This provides an accurate assessment of GI motility but is more time intensive than other methods.

Outlet Obstruction Constipation

Defecatory disorders related to outlet dysfunction are primarily characterized by impaired rectal evacuation. As noted previously, defecatory disorders can occur in the presence of normal or delayed colonic transit times. Incomplete rectal evacuation results when there is an inadequate rectal propulsive force because of an inability to coordinate the abdominal, perineal, and pelvic floor muscles. In addition, an increased resistance to evacuation such as high anal resting pressures, incomplete relaxation, or paradoxical contraction of the pelvic floor can contribute to this. Less frequently, defecatory disorders are associated with structural abnormalities such as rectal intussusception, obstructing rectocele, megarectum, pelvic organ prolapse, or excessive perineal descent.

There is a significant coincidence of emotional, physical, and sexual trauma in patients with outlet obstruction constipation. A careful social history is important for identifying and treating this component of the disease.

A meticulous perineal and rectal examination is critical in diagnosing defecatory disorders. Patients may have high anal resting tone and increased resistance to insertion of the examining finger during a digital rectal examination. Findings may also include impaired relaxation or paradoxical contraction of the sphincter complex with reduced perineal descent (normal 2–4 cm descent) during a simulated evacuation test when they are instructed to "expel the examining finger." Other findings may include the quality of stool in the rectal vault, presence of fecal soiling, hemorrhoids, rectocele, or pudendal neuralgia tenderness. When a defecatory disorder is suspected, or before considering operative management for constipation, diagnostic testing may be used to supplement the history and physical examination in making the diagnosis. These include anorectal manometry, defecography, and electromyography (EMG).

Anorectal Manometry

Manometry is a functional test that can assess the resting and squeeze pressures of the anal sphincters, the neorectal inhibitory reflex, rectal sensation, and compliance. The results of anal manometry may be used to guide further testing or treatment. Although manometry findings may be supportive of a diagnosis of dyssynergic defecation,

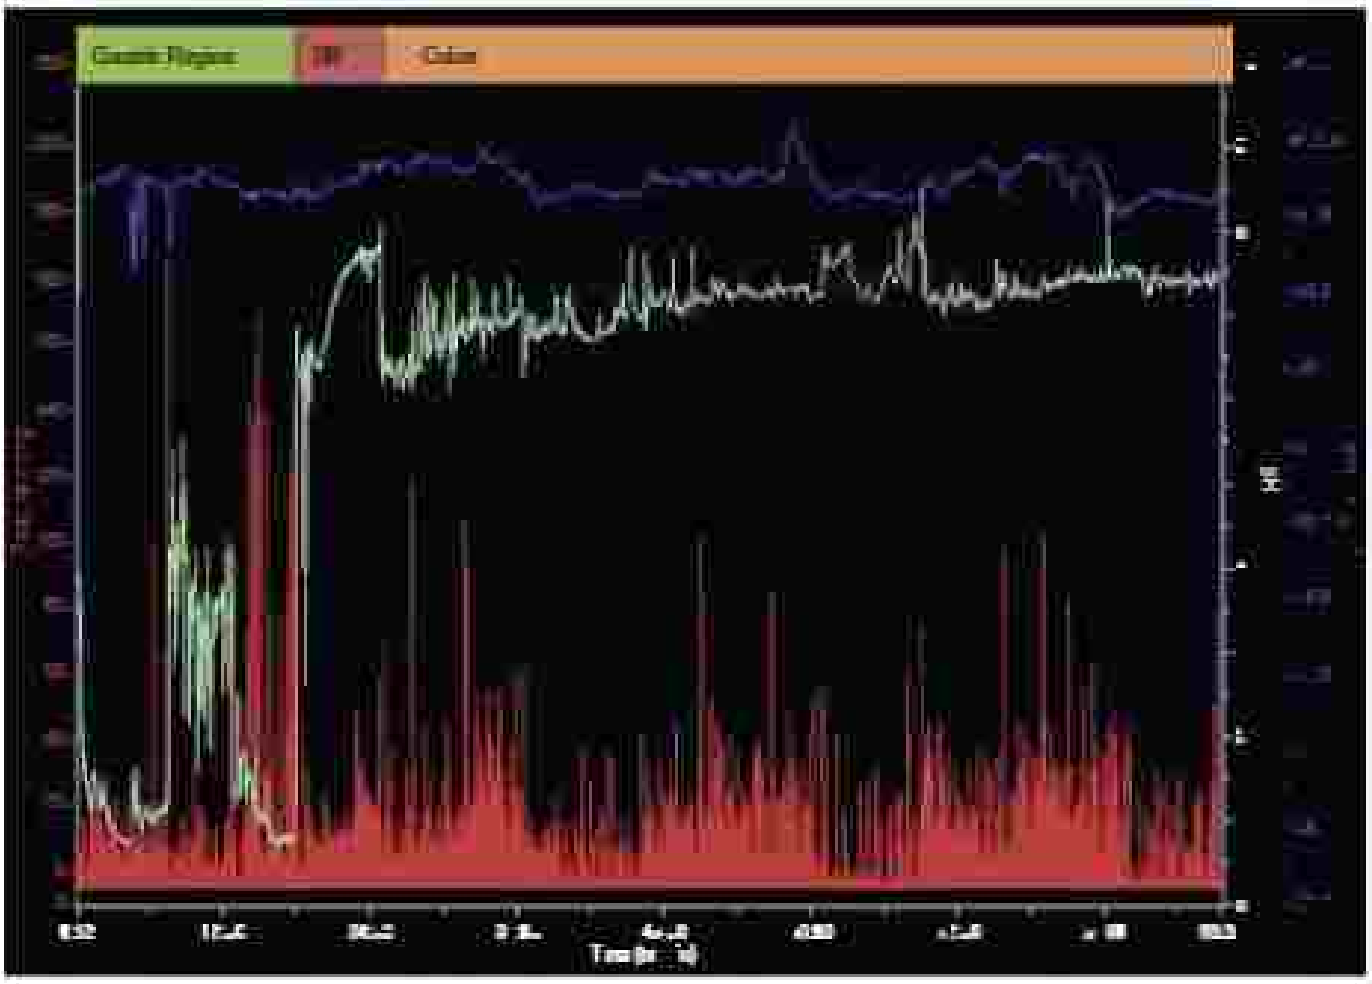

FIG. 3 ...colonic inertia transit study [illegible]

it is not conclusive by itself, and this result should be used in conjunction with other physiologic testing such as defecography as outlined below. A representative example of manometry findings is shown in Fig. 4.

Defecography

Defecography is a dynamic study that evaluates the rate and completeness of rectal emptying, anorectal angle, and length of perineal descent. Structural abnormalities that may contribute to outlet obstruction can also be seen such as rectocele, internal rectal prolapse and intussusception. Defecography can be performed as a fluoroscopic or magnetic resonance (MR) imaging study. MR defecography is advantageous in its ability to show the anatomy of the pelvic floor musculature including the puborectalis and external and internal sphincters. The disadvantages of MR imaging are the expense of the procedure, prolonged testing time, and the need for a dedicated radiologist with experience in reading dynamic MR imaging (Fig. 5).

EMG Testing of Striated Muscle Activity

EMG is used to assess the contraction of the external anal sphincter by measuring depolarization and the activity of both the external anal sphincter and puborectalis. Needle, surface, and anal plug EMG can be used based on indication and clinical preference. EMG activity may be recorded at rest and with squeeze and push efforts. During defecation, EMG activity should be absent now as the resting activity during defecation may point to a diagnosis of paradoxical puborectalis contraction causing difficult evacuation.

Management of Patients With Slow-Transit Constipation

Patients with refractory colonic slow transit constipation without coexisting outlet obstruction should first exhaust all medical options to treat the disease. This should include optimization of underlying metabolic derangements and trial of all appropriate laxative medications. Operative intervention should be reserved only for those who have no other options.

Operative management of slow transit constipation should be a total abdominal colectomy with ileorectal anastomosis (TAC IRA). The anastomosis should be performed at the level of the convergence of the taenia to the upper rectum to ensure an adequate resection.

A minimally invasive approach is preferred to reduce rates of postoperative complications, length of hospital stay, and time away from work. Port site placement is at the surgeon's preference but should consider the need for manipulation and visualization to all four quadrants of the abdomen. A high ligation of mesenteric vessels is not necessary, although some may find that plane of dissection easier. It is also not necessary to resect the omentum, and there may be some benefit to leaving it in place. At the level of the convergence of the taenia, the rectum is transected with an endoscopic stapler and the bowel is exteriorized through the preferred extraction site. Recent data suggest that extraction sites away from the midline have a lower

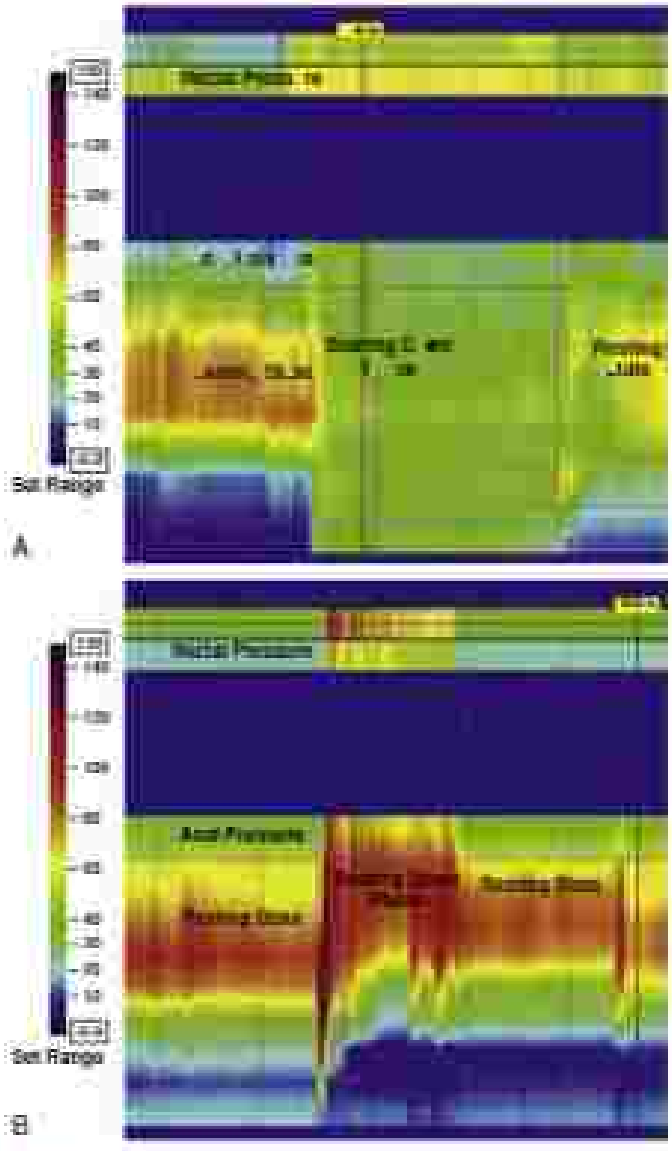

FIG. 4 Anorectal manometry (A) normal manometry (Sensor = 20 mm Hg pressure. (B) Dyssynergic defecation. Scale = 100 mm Hg pressure. (From Rao SS, Bharucha AE, Wald A, et al. American Gastroenterological Association medical position statement on anorectal testing techniques. Gastroenterology. 2019;144(1):211–217.)

incidence of hernia formation. The ileorectal anastomosis can be completed as an end to end, side to side, end to side, or side to end at the surgeon's preference. Proximal fecal diversion above the anastomosis is typically not indicated after this operation.

Recurrent constipation is uncommon. More often, patients will report diarrhea postoperatively, with some series reporting a rate as high as 46%. Diarrhea can often be managed with dietary modification, including a higher fiber diet. In some cases, patients may require the use of antimotility agents to control their bowel movements. Fecal incontinence is also reported, particularly in those with diarrhea. This can also usually be controlled by thickening the bowel movements through diet modification, fiber supplementation, and medications.

Alternative operative procedures have been proposed for the treatment of slow transit constipation, but data are lacking to support any resection other than TAC: IRA. Reports of experience with segmental colon resections in an attempt to preserve bowel have resulted in nearly universal failure to treat the underlying condition. This stands in sharp contrast to those who undergo TAC: IRA, in which 50% to 100% rates of clinical improvement are reported. Perhaps most important, more than 90% of patients state they would undergo the procedure again to treat their constipation. Subtotal colectomy with ileoproctostomy (ileorectal anastomosis) has been proposed because of the theoretical reduction of postoperative diarrhea due to preservation of the ileocecal valve. Sufficient data are lacking, however, to support this theoretical advantage.

As an alternative to resection, a diverting loop ileostomy (DLI) alone is another reasonable option to treat slow transit constipation. This may be recommended for patients who are poor operative candidates for a larger resection or for those whose symptoms cannot be definitively attributed to functional constipation. A DLI can prove to be both a therapeutic option as well as a diagnostic measure. It is important to communicate to the patient, however, that by performing a DLI alone the colon is still at risk for neoplasia and requires routine surveillance.

For patients who present with refractory slow transit constipation associated with outlet obstruction, constipation because of functional or structural abnormalities, treatment for the outlet obstruction is recommended before considering TAC: IRA. Resection in the presence of untreated outlet obstruction can result in significant worsening of symptoms because of the high stool burden coming from the small bowel. In addition, there is increased risk for anastomotic leak because of the functional obstruction distal to the anastomosis.

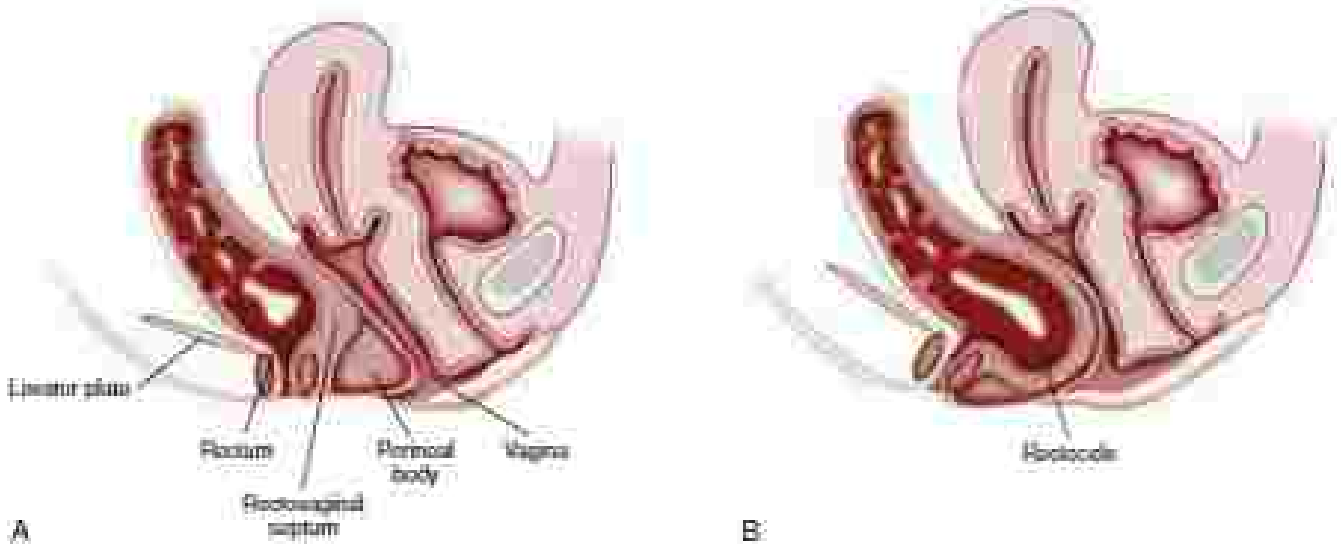
MANAGEMENT OF PATIENTS WITH NORMAL-TRANSIT CONSTIPATION AND OUTLET OBSTRUCTION

Functional disorders leading to outlet obstruction rely heavily on nonoperative treatments such as bowel retraining programs, pelvic floor physical therapy, and biofeedback. Structural abnormalities such as rectoceles, enteroceles, sigmoidocele, intussusception, and prolapse should be addressed with operative intervention as appropriate. These mechanical etiologies for outlet obstruction may occur concurrent with functional abnormalities; therefore, a thorough evaluation of the rectum and anus is valuable to aid decision making regarding a treatment plan.

Rectocele operations can be performed via transanal or transvaginal approaches. Equivalent complication rates have been shown for both approaches. According to the American Society of Colon and Rectal Surgeons' Clinical Practice Guideline (2016), transanal stapled repair of rectocele and rectal intussusception is not recommended because of the high rate of observed complications including proctalgia, urgency, incontinence, constipation, rectovaginal fistula formation, and bleeding. Rectopexy alone, resection rectopexy, and Delorme's procedure have been described for the successful management of rectal intussusception.

For patients with outlet obstruction constipation who have failed nonoperative therapy or are not candidates for other available treatment options, an ostomy can be considered. Patients with normal colonic transit can usually be treated with a descending colostomy. A loop colostomy is beneficial because it provides a means for proximal decompression of the distally obstructed, dysfunctional rectum/sigmoid remnant, but this comes at the cost of an increased risk for parastomal hernia. An end descending colostomy is also a reasonable alternative. Rarely, patients will continue to have pain or other ongoing symptoms related to the retained rectosigmoid colon. These very infrequent situations may benefit from an abdominoperineal resection of the rectum.

In patients who have both slow transit and outlet obstruction constipation refractory to nonoperative management, total proctocolectomy can be considered. It is reasonable, in these patients, to first offer a trial of a DLI alone to determine if their symptoms improve. This may also provide an improved quality of life while working to improve functional outlet constipation with nonoperative therapies. If effective, this could provide an option for restoration of intestinal continuity with an eventual ileorectal anastomosis. If amenable to ongoing endoscopic surveillance of the remaining, dysfunctional



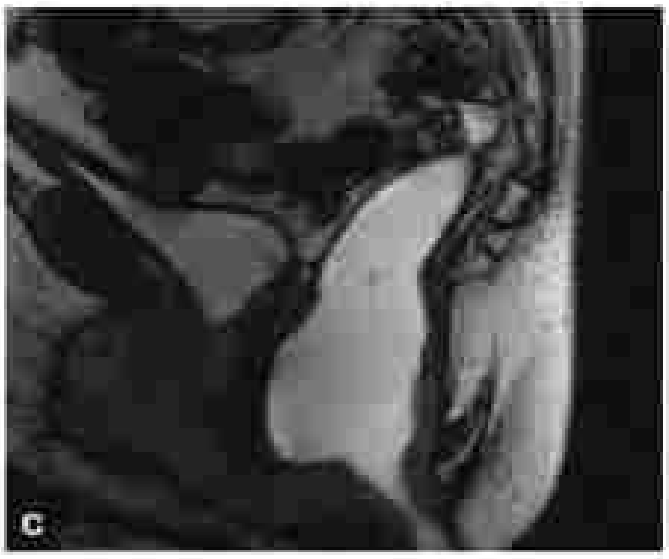


FIG 5. Rectocele. (A) Normal anatomy. (B) Rectocele. (C) Magnetic resonance defecography of rectocele. (A, B, from Hedrick M, Herman D, Shnaid D, Jackson and Hardiman Gastrointestinal and Liver Disease. Philadelphia: Elsevier; 2016. p. 796.)

colon, dressing alone can serve as definitive management. Some patients with fecal diversion alone will be troubled by mucous and stool production from the remaining colon. This can leave them with symptoms similar to those they experienced before fecal diversion. In these cases, total proctocolectomy is an appropriate option.

Total proctocolectomy with ileal pouch anal anastomosis has been described for patients with combination slow transit and outlet obstruction constipation. There are limited data on this approach, but some have reported as high as a 50% pouch failure rate after this procedure.

Malone Antegrade Continence Enema

Malone antegrade continence enema is another treatment modality, adapted from pediatric surgery, that involves the creation of a continent catheterizable appendicostomy or cecostomy through which antegrade enemas can be administered. This flush can overcome the dysmotility in the colon and in the anus. The Malone antegrade continence enema is an especially attractive option in patients who wish to avoid permanent external ostomy creation. This is a reasonable alternative to consider in those patients unfit for a colectomy. A retrospective study of 32 patients who underwent this procedure and were followed for a median of 36 months (range, 13–180 months) reported satisfactory long-term results in about 50% of the patients. Revisions were frequently required for complications such as leakage around the umbilicus site and stricturing, however.

Adult Hirschsprung's Disease

Adult Hirschsprung's disease is caused by the congenital absence of submucosal and myenteric ganglion cells in the internal anal sphincter. The length of proximal aganglionosis is variable but typically is a short segment in adults accounting for the delayed diagnosis. The resultant impaired rectoanal inhibitory reflex leads to stasis and distention in the more proximal bowel. The adult patient usually presents with a history of lifelong constipation. Anal manometry can be used as a diagnostic adjunct, but the diagnosis is confirmed with a full thickness rectal biopsy.

Posterior anorectal strip myectomy can be both diagnostic and therapeutic for those with short segment disease. This involves excising the rectal mucosa proximal to the dentate line to expose the underlying muscularis, which is excised for pathologic analysis of the ganglion cells. If myectomy is unsuccessful as a therapy, patients are usually recommended to undergo a bypass or resection of the dysfunctional rectum.

In a meta-analysis and review of adult Hirschsprung's disease from 2018, a total of 840 patients were identified in the literature. The most common surgical procedure performed in this cohort were Duhamel's (47%), Swenson's (19%), myectomy alone (9%), Soave's (8%), and low anterior resection (5%). There are no recently published comparative data to evaluate the relative success of these techniques in adults.

Duhamel's procedure is a retro-rectal transanal pull-through operation, in which the posterior wall of the rectum and anterior wall of the colon form a wide anastomosis. It has been adapted several times and has been simplified by surgical staplers. The main advantage of this approach is the avoidance of rectal mobilization and associated morbidity. The disadvantage is the preservation of a blind rectal stump with the diseased segment left in situ. In contrast, Swenson's procedure involves sequential biopsies along the anti-mesenteric border of the colon and rectum, until the most proximal aganglionic segment is identified. This then is mobilized fully, transected through the anus, and resected. The colon is pulled through for a colorectal anastomosis. Soave's procedure involves a rectal mucosectomy up to the level of the peritoneal reflection and retraction of the colon through the remnant sleeve of rectal muscle. The colon is anastomosed to the anal canal after confirming the presence of ganglion cells on frozen biopsy.

CONCLUSION

Constipation can be a disabling disease with multiple contributing etiologies. The majority of patients are effectively treated with non-operative therapies. A thorough diagnostic evaluation is critical to ensuring the correct management is prescribed. Careful patient selection is crucial to successful operative management, when indicated.

MANAGEMENT OF RADIATION INJURY TO THE LARGE AND SMALL BOWEL

Scott R. Kelly, MD, FACS, FASCRS, and Christopher L. Hallemeier, MD

Ionizing radiation is an important part of multimodal treatment for a variety of pelvic malignancies (anorectal, gynecologic, urogenital) and is administered in both electromagnetic (x-rays, gamma rays) and particulate (protons, neutrons, electrons, carbon ions, and alpha and beta particles) forms. Radiation directly affects cells and their microenvironments. Rapidly dividing cells such as those of the gastrointestinal tract are most sensitive, which is a major limiting factor affecting treatment tolerance. Cells of the mucosa are affected first, followed by the submucosal, muscularis, and serosa. Radiation-induced acute intestinal injury occurs during therapy and usually resolves weeks to months following cessation. Acute injury typically includes mucosal sloughing, glandular hypersecretion, and bowel wall inflammation and edema. Late or chronic tissue manifest months to years after treatment and are the result of occlusive endarteritis/obliterative endarteritis that leads to tissue ischemia/hypoxia, mucosal atrophy, transmural fibrosis, and impaired angiogenesis and tissue repair. Chronic changes are irreversible and can be challenging to treat.

Scoring systems for grading radiation toxicity have been developed by the Radiation Therapy Oncology Group and the European Organization for Research and Treatment of Cancer. Grading is separated into acute (up to 90 days) and late (after 90 days) and is summarized in Table 1. Other scoring systems available include the Late Effects Normal Tissue/Subjective Objective Management Analytic and the National Cancer Institute Common Terminology Criteria for Adverse Events.

It is imperative to have a thorough understanding of the radiation (duration of radiotherapy, target fields, dosing regimen, complications during therapy) and operative history before pursuing any surgical intervention. An inadequate understanding will result in unfavorable surgical outcomes. Patients need to understand before any procedure that surgery will not cure the disease, but rather palliate symptoms/complications of the disease process. Preoperative enterostomal therapy education and site marking is imperative. Placement of enteral stents should be considered. Patients with severe protein calorie malnutrition (weight loss >15% of ideal body weight or serum albumin <2.5 g/dL) should be nutritionally optimized and may require total parenteral nutrition prior to surgery.

RISK FACTORS

Both tumor and normal tissue have radiation dose response relationships. Increasing doses of radiation delivered to the tumor are

MANAGEMENT OF RADIATION INJURY TO THE LARGE AND SMALL BOWEL

Scott R. Kelley, MD, FACS, FASCRS, and Christopher L. Hallemeier, MD

Ionizing radiation is an important part of multimodal treatment for a variety of pelvic malignancies (anorectal, gynecologic, urogenital) and is administered in both electromagnetic (x-rays, gamma rays) and particulate (protons, neutrons, electrons, carbon ions, and alpha and beta particles) forms. Radiation directly affects cells and their microenvironments. Rapidly dividing cells such as those of the gastrointestinal tract are most sensitive, which is a major limiting factor affecting treatment tolerance. Cells of the mucosa are affected first, followed by the submucosal, muscularis, and serosa. Radiation-induced acute intestinal injury occurs during therapy and usually resolves weeks to months following cessation. Acute injury typically includes mucosal sloughing, glandular hypersecretion, and bowel wall inflammation and edema. Late or chronic tissue manifest months to years after treatment and are the result of occlusive endarteritis/obliterative endarteritis that leads to tissue ischemia/hypoxia, mucosal atrophy, transmural fibrosis, and impaired angiogenesis and tissue repair. Chronic changes are irreversible and can be challenging to treat.

Scoring systems for grading radiation toxicity have been developed by the Radiation Therapy Oncology Group and the European Organization for Research and Treatment of Cancer. Grading is separated into acute (up to 90 days) and late (after 90 days) and is summarized in Table 1. Other scoring systems available include the Late Effects Normal Tissue/Subjective Objective Management Analytic and the National Cancer Institute Common Terminology Criteria for Adverse Events.

It is imperative to have a thorough understanding of the radiation (duration of radiotherapy, target fields, dosing regimen, complications during therapy) and operative history before pursuing any surgical intervention. An inadequate understanding will result in unfavorable surgical outcomes. Patients need to understand before any procedure that surgery will not cure the disease, but rather palliate symptoms/complications of the disease process. Preoperative enterostomal therapy education and site marking is imperative. Placement of enteral stents should be considered. Patients with severe protein-calorie malnutrition (weight loss >15% of ideal body weight or serum albumin <2.5 g/dL) should be nutritionally optimized and may require total parenteral nutrition prior to surgery.

RISK FACTORS

Both tumor and normal tissue have radiation dose response relationships. Increasing doses of radiation delivered to the tumor are

TABLE 1 RTOG/EORTC Radiation Toxicity Grading

Grade	0	1	2	3	4	5
RTOG; acute radiation morbidity score[a]	None	Increased frequency or change in quality of bowel habits not requiring medication Rectal discomfort not requiring analgesics	Diarrhea requiring parasympatholytic drugs Mucus discharge not necessitating sanitary pads Rectal or abdominal pain requiring analgesics	Diarrhea requiring parenteral support Severe mucus or blood discharge necessitating sanitary pads Abdominal distension	Acute or subacute obstruction, fistula, or perforation GI bleeding requiring transfusion Abdominal pain or tenesmus requiring tube decompression or bowel diversion	NA
RTOG/EORTC late radiation morbidity score	None	Mild diarrhea and cramping Bowel movement <4 times daily Slight rectal discharge or bleeding	Moderate diarrhea and colic Bowel movement >4 times daily Excessive rectal mucus or intermittent bleeding	Obstruction or bleeding requiring surgery	Necrosis, perforation, or fistula	Death resulting from radiation late effects

[a]The acute morbidity criteria are used to scoregrade toxicity from radiation therapy. The criteria are relevant from day 1 through day 90, thereafter the RTOG/EORTC late radiation morbidity index is to be used.

GI, gastrointestinal; NA, not available; RTOG/EORTC, Radiation Therapy Oncology Group/European Organisation for Research and Treatment of Cancer.

typically associated with a greater degree of tumor cell kill and clinical response. However, increasing doses of radiation delivered to normal tissues are associated with increased likelihood and severity of toxicity. Higher doses administered in fewer fractions and/or over a shorter time interval are associated with increased rates of toxicity. Extended treatment areas (e.g., both abdomen and pelvis as pelvis or abdomen alone) result in higher rates of radiation-induced injury because more normal tissue is included in the treatment field. Those who have undergone pelvic and abdominal surgeries are at increased risk of intestinal injury as a result of visceral fixation and scarring. Factors that compound radiation-induced bowel injury include disease processes that affect vascularity and limit tissue perfusion/recovery genetics such as smoking, diabetes mellitus, hypertension, collagen vascular disorders, atherosclerosis, coronary artery disease, and vasculitis. A thin body habitus has also been associated with a higher rate of toxicity. Chemotherapeutic agents that potentiate the effects of radiation (radiosensitizers) are also culprit, such as fluoropyrimidines (5-fluorouracil and capecitabine), platinum agents (cisplatin and oxaliplatin), taxanes (docetaxel and paclitaxel), anthracyclin C, gemcitabine, methotrexate, actinomycin D, irinotecan, and dactinomycin.

CARCINOGENESIS

Ionizing radiation can increase the risk of subsequent cancer formation. Typically, there is a long latency period (>5 years) between treatment with ionizing radiation and the development of cancer, and different tissues have different rates of radiation-induced carcinogenesis. The most vulnerable is the hematopoietic cell line, followed by the thyroid, breast, lung, and salivary glands. The skin, bone, and gastrointestinal tract are less vulnerable. Multiple hypotheses have been postulated for radiation-induced carcinogenesis including mutation of tumor suppressor genes, activation of proto-oncogenes, genomic instability, and bystander effect (cells that have not been directly irradiated). A thorough evaluation for malignancy should always be part of the algorithm for patients with radiation-induced bowel injury.

SMALL BOWEL RADIATION INJURY

An undesirable side effect of treating abdominal and pelvic malignancies with ionizing radiation is injury to the small intestine. Acute radiation-induced small bowel disease, also known as radiation enteritis, is common if there is small intestine in the treatment field. It is typically transient and subsides following discontinuation of therapy. Common symptoms include nausea/emesis, diarrhea, bloating, and colicky abdominal pain. Late or chronic small bowel injury affects between 5% and 10%, of which 30% to 50% will require surgical intervention, and can result in malabsorption, unintended weight loss, stricture/obstruction, fistula formation, infection (abscess), perforation, and refractory bleeding/hemorrhage. Secondary to their fixed locations, the duodenum and terminal ileum are the most common areas of the small intestine affected.

Diagnosis

Acute radiation injury is typically diagnosed based on symptoms. For chronic issues, evaluation commonly includes imaging with computed tomographic or magnetic resonance enterography, which allows simultaneous evaluation of the small bowel and extraintestinal anatomy. Small intestine contrast studies (enteroclysis) are also an option, though rarely used. For suspected duodenal injury, upper endoscopy may be pursued. Lower endoscopy and barium or water soluble contrast enemas typically fail to reach the area of interest. Capsule endoscopy should be pursued with significant caution secondary to the risk of capsule obstruction at a right radiation stricture.

Medical Management

There is no proven effective medical treatment for radiation-induced small bowel disease. Symptoms can be controlled with a host of measures including dietary modifications (low residue, low fat, lactose free, elemental diet, hydration) and medications (antidiarrheals, antispasmodics, bile acid binding agents, antidiarrheals, antisecretory agents, analgesics).

Patients with chronic radiation enteritis often have disease that has been progressing for years and can present with infection (abscesses), fluid and electrolyte derangements, protein/calorie malnutrition, and debility. Optimization should occur prior to any elective surgery. Malnourished patients with fistulas often benefit from total parenteral nutrition, although spontaneous closure is unlikely.

Surgical Management

Secondary to increased morbidity (30%–50%) and mortality (10%), surgery for radiation–induced small bowel disease should be avoided other than for specific indications such as perforation, fistulae, obstruction, bleeding/hemorrhage, persistent abscess, and intractable pain.

Limited resection of the involved segment is the procedure of choice, although bypass and exclusion are options when dense adhesions or pelvic fixation make resection impossible. Secondary to diffuse adhesions and bowel fibrosis, it can be difficult to distinguish between normal and involved intestine and anastomosing irradiated segments of bowel is associated with leak rates upward of 50%. Incidence of nonirradiated bowel to the anastomosis or bypass is advisable. Ligation of the mesentery with vessel sealers or a clamp, cut, and tie technique is often inadequate secondary to mesenteric foreshortening, thickening, and friability. Oversewing the mesentery with heavy sutures between clamps is preferable.

Adhesiolysis during resection is associated with an increased risk of fistula formation and should only be performed if the area of resection can be resected if necessary. Injecting saline with a fine needle (50 g) into dense interloop adhesions (hydrodissection) can help delineate tissue planes and decrease the risk of serosal injuries.

Compared with bypass, resection will remove the affected segment, reduces the rate of reoperation, and is associated with increased survival. Bypass is more simplistic and decreases the risk of anastomosis or bowel injury but leaving an affected segment behind increases the risk of blind loop syndrome (bacterial overgrowth) and fistula formation. For dense adhesions and tethering in the pelvis, bypass is typically a better option.

Stricturoplasty can be considered in patients with strictures located within long segments of bowel where resection or bypass would exclude a large portion of the intestine and lead to metabolic and nutritional deficiencies.

Patients with enteric fistulas (e.g., enterovaginal, enterovesical, enterocutaneous) should be optimized before pursuing any surgical intervention. Time should be provided for fistula maturation while controlling output, enhancing nutrition, treating any underlying infection (abscesses), and restoring fluid and electrolyte balance. Fistulograms can help define the extent and area of intestine involved.

If unable to resect and anastomose the segment of bowel containing the fistula, it can be totally excluded by transecting proximally and distally leaving the short segment of well vascularized fistulating bowel attached to the bladder/vagina/skin for continued mucus decompression.

LARGE BOWEL RADIATION INJURY

Secondary to fixation, radiation induced injury affects the sigmoid colon more frequently than the small intestine but is less likely to require surgery and overall has a better prognosis.

Acute symptoms typically include diarrhea with or without bleeding, mucus discharge, abdominal cramping, and tenesmus. Chronic issues can result in obstruction, persistent bleeding/hemorrhage, intractable pain, fistulization, and perforation.

Diagnosis

As with the small intestine, acute colonic radiation injury is typically diagnosed based on symptoms alone. Endoscopy allows for the identification of edema, friability, ulcerations, telangiectasia, and strictures (Fig. 1). Barium and water–soluble contrast enemas can reveal shortening, narrowing, lack of distensibility, absence of haustral mucosal folds, and loss of normal curvature. Computed tomography or magnetic resonance enterography provide the ability to assess not only the colon and rectum, but also the small bowel and extraintestinal anatomy (Fig. 2). Identification of fistulas can require fistulograms, cystograms, and gynecologic examinations.

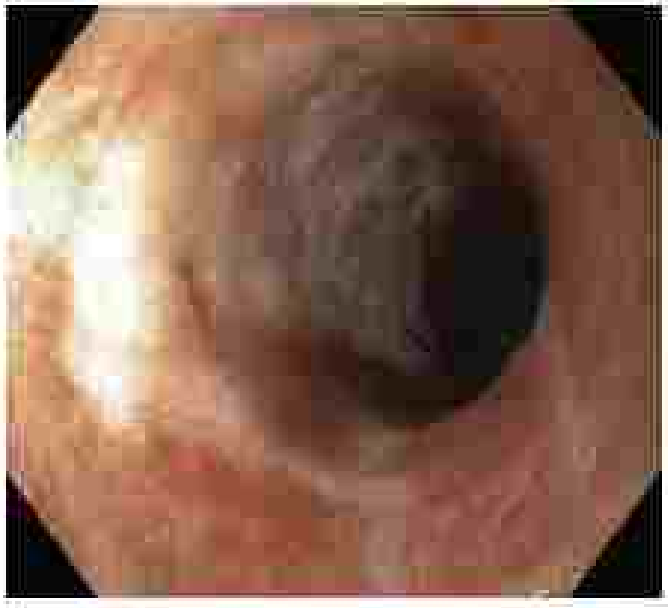

FIG. 1 Endoscopic view of sigmoid colon edema and erythema. (Courtesy Mayo Foundation for Medical Education and Research.)

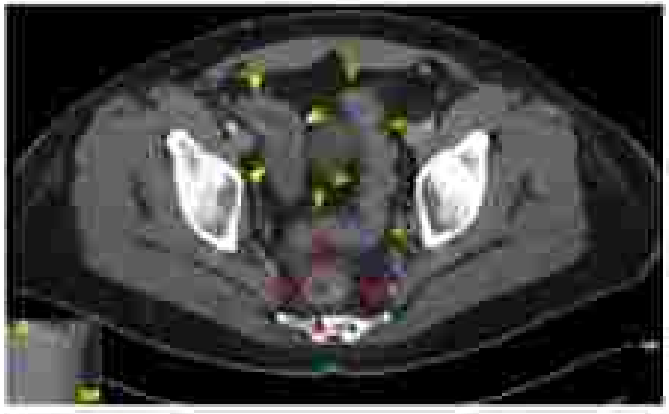

FIG. 2 Axial cassette of contrast filled gallbladder (yellow arrows), sigmoid colon (orange arrows), and rectum (red arrows). (Courtesy Mayo Foundation for Medical Education and Research.)

Medical Management

As with radiation induced small bowel disease there is no effective medical treatment for radiation induced colitis. Symptoms can be controlled with dietary modifications (low residue) and medications (anticholinergics, antispasmodics, antidiarrheals, stool softeners, sucralfate enemas, analgesics).

Surgical Management

Other than for specific indications (perforation, fistula, obstruction, persistent bleeding/hemorrhage, intractable pain, incontinence), the majority of patients with radiation induced colonic injury do not require operative intervention.

A segmental resection and anastomosis with a nonirradiated proximal colonic conduit, with or without temporary diversion, is effective in most cases. For those who are not surgical candidates, a permanent diverting ileostomy or colostomy is recommended. Using nonirradiated bowel is preferable to decrease issues with stoma structure, bleeding, and necrosis.

Fistulae involving the urinary tract (colovesical) or vagina (colovaginal) can be treated in a similar manner. Interposition of

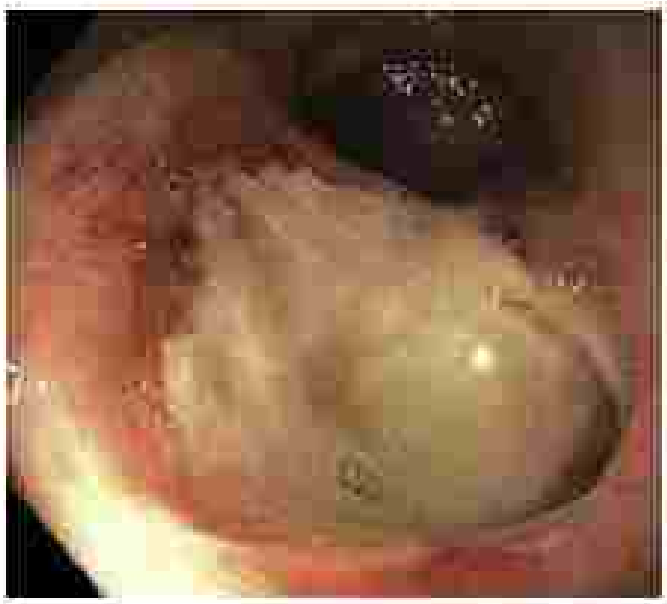

FIG. 3 Endoscopic view of rectal ulcer. (Courtesy Mayo Foundation for Medical Education and Research.)

FIG. 4 MRI of pelvis showing a low rectovaginal fistula. (Courtesy Mayo Foundation for Medical Education and Research.)

well vascularized nonirradiated tissue (omental or rectus pedicle flap) between the affected organs and instruments should be considered. A protective stoma should always be entertained. If unable to resect and reanastomose, the segment of bowel containing the fistula can be transected proximally and distally, leaving a short segment of well vascularized bowel attached to the offending organ, which may result in persistent mucous discharge.

RECTAL RADIATION INJURY

Rectal injury is unavoidable in most patients who receive pelvic radiation. With the increased use of radiation to treat pelvic malignancies, radiation proctopathy, also called radiation proctitis, has become more commonplace over the decades. The incidence of both acute and chronic radiation proctitis correlates with the dose and fractionation regimen and the volume of rectum receiving exposure. Acute self-limiting symptoms affect a majority of patients and typically include diarrhea with or without bleeding, urgency, tenesmus, mucus discharge, and abdominal cramping. A minority of patients will require temporary cessation of treatment or dose modification. Chronic radiation proctopathy, affecting up to 20%, can result in rectal bleeding from telangiectasias, bowel dysfunction (diarrhea, obstipation, urgency, frequency with or without incontinence, loss of compliance), pain, strictures, ulcerations, and fistulas (Fig. 3).

Diagnosis

Endoscopic findings alone are not directly correlative with symptoms because more than one half of asymptomatic patients will have mucosal congestion and telangiectasias, although it provides the ability to thoroughly evaluate the luminal integrity of the rectum. Unless there is concern for malignancy, deep biopsies should be avoided to decrease issues with bleeding, perforation, and fistulization. On imaging, the presacral space can appear wider than normal secondary to rectal scarring. Fistulous evaluation can require dedicated pelvic magnetic resonance imaging, cystograms, and gynecologic examinations (Fig. 4).

Medical Management

Minor to moderate rectal bleeding can be treated with a multitude of noninvasive modalities, including bowel regimens, enemas, topicals, and endoscopic treatments. For many patients, improving issues with constipation or diarrhea is all that is needed. Sucralfate (2 g in 20 mL tap water) administered as an enema twice daily has been shown in some studies to decrease issues with bleeding and promote healing.

For patients with moderate or severe bleeding symptoms, argon plasma coagulation (APC) is the primary treatment modality. APC uses inert argon gas at a flow rate from 1.2 to 2.1 L/min, an electrical power setting ranging from 45 to 50 W, and a probe size from 2.7 to 3.2 mm in diameter to treat bleeding by creating a superficial coagulation. Targeted pulse treatment is preferred to extensively painting the rectal mucosa to decrease the risk of postprocedure ulceration. Repeat treatments may be required and APC is less effective in sites with active bleeding. Bipolar or heater probes can also be used when a visible vessel is identified.

Dilute formalin (4% solution) prepared by mixing 200 mL of 10% buffered formalin with 300 mL water has been used to control sites of bleeding (chemical cauterization) using either gauze or direct instillation through a sigmoidoscope. Gauze soaked formalin sponges are placed through a rigid proctoscope and held in direct contact with bleeding areas for 2 to 3 minutes. Alternatively, aliquots of 30 to 50 mL can be instilled through a sigmoidoscope, allowing the solution to remain in contact with the rectal mucosa for 30 seconds. In addition, topical treatment with a 10% formalin soaked long jumbo tip (obstetrics/gynecology) cotton swabs placed through a rigid proctoscope can be used to treat spot areas of bleeding. Saline should be used liberally to irrigate the rectum between each treatment, and the perineum should be washed thoroughly if exposed because formalin is a severe irritant. Vaseline gauze can be used to protect the perineum, and the rectum can be packed with gauze proximal to the treatment area. Weekly/biweekly applications are typically necessary until cessation of bleeding. Worsening rectal strictures, ulcerations, and chronic pain can occur following treatment. Additional treatments that have been used for chronic radiation proctopathy include hyperbaric oxygen treatments, cryoablation, radiofrequency ablation, sunfinatrex, and probiotics.

Surgical Management

Surgical intervention is necessary in less than 1% of patients with radiation proctopathy and typically indicated for obstruction, stricture,

FIG. 5. Endoscopic view of urinary catheter visible through a low rectovaginal fistula. (Courtesy Mayo Foundation for Medical Education and Research.)

perforation, fistulization, intractable pain, persistent bleeding, and incontinence. In most cases, fecal diversion will improve pain, allow rectal mucosal edema to subside, and result in cessation of bleeding. In young patients with good sensation, function, and control, a proctectomy with coloanal anastomosis can be considered. To decrease issues with staple line ischemia, a handsewn coloanal anastomosis is preferred.

Mid- to upper rectal fistulas (rectovaginal, rectourethral) can be treated with resection and anastomosis of healthy colon to distal rectum or anus. Interposition of well-vascularized nonirradiated tissue (omental or rectus pedicle flap) between the affected organ and anastomosis should be considered.

Low rectal fistulas can be treated in a similar manner or managed in a perineal, transanal (Kraske) or transsphincteric (York Mason) approach (Fig. 5). Compared with using native tissue, interposition of well-vascularized healthy tissue (omentum, rectus, gracilis, bulbocavernosus) is associated with higher rates of healing.

For those with comorbidities precluding surgery, bowel diversion and placement of a suprapubic urinary catheter may be necessary. A loop ileostomy is easier to manage and does not interfere with the possibility of a future proctectomy and coloanal anastomosis. To decrease the risk of a Hartmann's stump disruption (blow out), an anal colostomy should be avoided.

Surgical Management of the Polyposis Syndromes

Erik R. Nelson, MD, MS, and Sang W. Lee, MD, FACS, FASCRS

Colorectal polyps can be classified as adenomatous, hamartomatous, hyperplastic, neoplastic, and inflammatory based on their morphology and histologic features. Several polyposis syndromes have been described, each with unique presentation, genetic basis, extracolonic manifestations, and malignancy risk. Most of the identified syndromes carry increased risk for development of colorectal cancer. Suspicion is the key to making the diagnosis of hereditary polyposis syndrome. A detailed family history and genetic evaluation are important to allow siblings and offspring the opportunity for genetic counseling and testing. Management options include strict surveillance for the early detection of cancer, chemopreventive medications, and surgery. Multidisciplinary care, including clinical services, support and counseling, as well as referral to a polyposis registry is recommended. This chapter discusses the most common polyposis syndromes with a focus on recommendations for management (Table 1).

ADENOMATOUS POLYPOSIS SYNDROMES

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant inherited disease resulting from a germline mutation to the adenomatous polyposis coli (APC) tumor suppressor gene located on chromosome 5q21. Most mutations are found between codons 1relt and 1640, with two of the most significant being 1061 and 1309. FAP is characterized by the endoscopic identification of greater than 100 synchronous adenomas. Severe cases often manifest thousands of adenomatous lesions, sparing little normal colon and rectal mucosa. Patients with fewer than 100 adenomatous polyps are considered to have attenuated FAP. Approximately 25% to 30% of APC mutations occur de novo and will not have a family history of FAP. Patients diagnosed with FAP should be referred to a polyposis registry and genetic counseling specialist to identify at-risk family members and coordinate testing.

Adenomatous polyps in FAP are found predominantly in the rectum and left colon. They develop in adolescence and are present in up to 15% of patients by 10 years of age and 75% by age 20. The risk of colorectal malignancy is nearly 100% by 40 years of age for patients with untreated FAP. Overall, FAP is estimated to account for just 1% of overall colorectal cancer diagnoses. The most common presenting symptoms are bleeding, diarrhea, abdominal pain, and mucous discharge. For those with a family history or identified APC mutation, a screening should be performed at 12 years of age and can be started with a flexible sigmoidoscopy. If polyps are detected, a full colonoscopy should be performed and repeated annually.

Extracolonic Intestinal Disease

Extracolonic intestinal disease is a common manifestation of FAP. More than 80% to 90% of patients will have gastric fundic gland hyperplastic polyps with very low malignant potential. Gastric adenomas are rare (10%), typically occur in the antrum, and are associated more commonly with Japanese and Korean heritage.

Duodenal adenomas, most commonly found around the ampulla of Vater and macroscopically different than colonic adenomas, are found in more than 90% of patients with FAP and develop approximately 15

FIG. 5. Endoscopic view of urinary catheter visible through a low rectovaginal fistula. (Courtesy Mayo Foundation for Medical Education and Research.)

perforation, fistulization, intractable pain, persistent bleeding, and incontinence. In most cases, fecal diversion will improve pain, allow rectal mucosal edema to subside, and result in cessation of bleeding. In young patients with good sensation, function, and control, a proctectomy with coloanal anastomosis can be considered. To decrease issues with staple line ischemia, a handsewn coloanal anastomosis is preferred.

Mid- to upper rectal fistulas (rectovaginal, rectourethral) can be treated with resection and anastomosis of healthy colon to distal rectum or anus. Interposition of well-vascularized nonirradiated tissue (omental or rectus pedicle flap) between the affected organ and anastomosis should be considered.

Low rectal fistulas can be treated in a similar manner or managed in a perineal, transanal (Kraske) or transsphincteric (York Mason) approach (Fig. 5). Compared with using native tissue, interposition of well-vascularized healthy tissue (omentum, rectus, gracilis, bulbocavernosus) is associated with higher rates of healing.

For those with comorbidities precluding surgery, bowel diversion and placement of a suprapubic urinary catheter may be necessary. A loop ileostomy is easier to manage and does not interfere with the possibility of a future proctectomy and coloanal anastomosis. To decrease the risk of a Hartmann's stump disruption (blow out), an anal colostomy should be avoided.

Surgical Management of the Polyposis Syndromes

Erik R. Nelson, MD, MS, and Sang W. Lee, MD, FACS, FASCRS

Colorectal polyps can be classified as adenomatous, hamartomatous, hyperplastic, neoplastic, and inflammatory based on their morphology and histologic features. Several polyposis syndromes have been described, each with unique presentation, genetic basis, extracolonic manifestations, and malignancy risk. Most of the identified syndromes carry increased risk for development of colorectal cancer. Suspicion is the key to making the diagnosis of hereditary polyposis syndrome. A detailed family history and genetic evaluation are important to allow siblings and offspring the opportunity for genetic counseling and testing. Management options include strict surveillance for the early detection of cancer, chemopreventive medications, and surgery. Multidisciplinary care, including clinical services, support and counseling, as well as referral to a polyposis registry is recommended. This chapter discusses the most common polyposis syndromes with a focus on recommendations for management (Table 1).

ADENOMATOUS POLYPOSIS SYNDROMES

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant inherited disease resulting from a germline mutation to the adenomatous polyposis coli (APC) tumor suppressor gene located on chromosome 5q21. Most mutations are found between codons 1relt and 1640, with two of the most significant being 1061 and 1309. FAP is characterized by the endoscopic identification of greater than 100 synchronous adenomas. Severe cases often manifest thousands of adenomatous lesions, sparing little normal colon and rectal mucosa. Patients with fewer than 100 adenomatous polyps are considered to have attenuated FAP. Approximately 25% to 30% of APC mutations occur de novo and will not have a family history of FAP. Patients diagnosed with FAP should be referred to a polyposis registry and genetic counseling specialist to identify at-risk family members and coordinate testing.

Adenomatous polyps in FAP are found predominantly in the rectum and left colon. They develop in adolescence and are present in up to 15% of patients by 10 years of age and 75% by age 20. The risk of colorectal malignancy is nearly 100% by 40 years of age for patients with untreated FAP. Overall, FAP is estimated to account for just 1% of overall colorectal cancer diagnoses. The most common presenting symptoms are bleeding, diarrhea, abdominal pain, and mucous discharge. For those with a family history or identified APC mutation, a screening should be performed at 12 years of age and can be started with a flexible sigmoidoscopy. If polyps are detected, a full colonoscopy should be performed and repeated annually.

Extracolonic Intestinal Disease

Extracolonic intestinal disease is a common manifestation of FAP. More than 80% to 90% of patients will have gastric fundic gland hyperplastic polyps with very low malignant potential. Gastric adenomas are rare (10%), typically occur in the antrum, and are associated more commonly with Japanese and Korean heritage.

Duodenal adenomas, most commonly found around the ampulla of Vater and macroscopically different than colonic adenomas, are found in more than 90% of patients with FAP and develop approximately 15

TABLE 1 Summary of CRC Polyposis Syndromes

Syndrome	Gene	Inheritance Pattern	Clinical Presentation	CRC Risk (%)
FAP	APC	Autosomal dominant	>100 adenomas Duodenal adenomas (90%) Fundic gland hyperplasia (90%) Desmoid tumors (30%) CHRPE (75%) Osteomas (80%)	100
Attenuated FAP	APC	Autosomal dominant	<100 adenomas Fundic gland hyperplasia Duodenal polyps	100

years later than colonic polyps. Duodenal cancer, typically diagnosed around 50 years of age, occurs in 5% to 10% of patients and is the second leading cause of death associated with FAP. A screening esophagogastroduodenoscopy (EGD) is recommended around 20 years of age, and the Spigelman severity score and staging system (Table 2) is used to determine surveillance intervals (Table 3). The risk of developing cancer after 10 years of follow up for stage I to II, stage II and III to IV, and 36% for stage IV. Small tubular adenomas, as well as those with low grade dysplasia, can undergo biopsies and be observed. High risk adenomas (villous, >1 cm), severe duodenal polyposis, high grade dysplasia, or stage IV disease should be offered a pancreas preserving duodenectomy, and those with cancer a pancreaticoduodenectomy. Chemoprevention with nonsteroidal antiinflammatory agents (sulindac, celecoxib) can result in polyp regression in those with a lower polyp burden, although overall the effect is minimal at best.

Extraintestinal Manifestations

The APC gene protein is expressed in organs throughout the body, but at lower levels than the colonic mucosa. Common extraintestinal manifestations of FAP include osteomas, congenital hypertrophy of the retinal pigment epithelium (CHRPE), epidermoid cysts, and desmoids. Benign osteomas of the mandible, skull, and tibia are the most common extraintestinal finding occurring in more than 80% of patients. Although CHRPE is not specific to FAP, having four or more areas of large, patchy fundic discoloration is pathognomonic and will be present in around 75% of individuals. Epidermoid cysts occur approximately 20% of the time.

TABLE 2 Spigelman Staging System for Upper Gastrointestinal Manifestations of FAP[a]

Points	1	2	3
Number of polyps	1–4	5–20	>20
Size of polyps	1–4 mm	5–10 mm	>10 mm
Histology	Tubular	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe

[a]Spigelman stage I, score 1–4; stage II, score 5–6; stage III, score 7–8; stage IV, score 9–12.

Other extraintestinal manifestations, although rare, include supernumerary teeth, cerebellar medulloblastoma, and cancers of the liver, biliary tree, adrenal glands, and thyroid. The risk for thyroid cancer for patients with FAP is approximately 2%, which is double that of the general population. Screening thyroid ultrasound is recommended annually, also starting at 20 years of age. Thyroid nodules larger than 1 cm warrant fine needle aspiration.

Desmoid Tumors

Desmoids are rare in the general population but develop in up to 30% of FAP patients. These locally invasive abdominal wall and intraabdominal/retroperitoneal myofibroblastic tumors typically develop 2

TABLE 3 Derivation of Spigelman Stage From Scores

Total Points	Spigelman Stage	Suggested Interval to Next Duodenoscopy
0	0	5 y
1–4	I	3–5 y
5–6	II	3 y
7–8	III	1 y
9–12	IV	Consider duodenectomy vs endoscopy in 6 mo

to 3 years after surgery and occur around 30 years of age. Etiology and pathogenesis are not well understood. Desmoids can develop spontaneously, are the third most common cause of death associated with FAP and have been noted to be associated with trauma. Risk factors associated with the development of desmoids are mutations in the 3′ end of the APC gene, female gender, extraintestinal manifestations, and a family history of desmoid disease. Of desmoids, 30% grow rapidly, 10% resolve spontaneously, 30% oscillate between cycles of growth and regression, and 50% remain stable or grow very slowly.

Extraabdominal desmoids are best treated with surgical extirpation with a 1-cm margin, although recurrence is high with documented rates of 20% to 50%. Early excision is recommended to decrease the size of the resultant abdominal wall defect.

Intraabdominal/intraperitoneal desmoids can invade the mesentery and surrounding structures resulting in obstruction, hemorrhage, ischemia, and perforation. The primary treatment is medical and includes nonsteroidal antiinflammatory agents (sulindac, celecoxib), estrogen antagonists (tamoxifen, toremifene, raloxifene), and chemotherapy (vinblastine, methotrexate, doxorubicin, dacarbazine). Surgical removal is difficult and often impossible if the root of the mesentery is involved. Resection with completely uninvolved margins (R0) will result in recurrence 50% of the time. If possible, noninvasive procedures such as dilatation and bypass are preferable for palliation. Ureteral obstruction is best treated with stenting.

There is not a defined screening regimen for desmoid tumors, although computed tomography and magnetic resonance imaging can be used, especially for patients with an increased risk of developing desmoids.

Attenuated FAP

In contrast to classic FAP, attenuated FAP (aFAP) occurs at a later age (30s and 40s), with fewer than 100 polyps, found predominantly in the right colon. If untreated, the risk of colorectal malignancy is 70% and cancer develops later in life (58 years of age on average). Fundic gland polyps and duodenal adenomas occur frequently, but other extracolonic and extraintestinal manifestations, including gastric adenomas, desmoids, and CHRPE, typically are not seen in aFAP.

For those with a family history or identified APC mutation suggestive of aFAP, screening colonoscopy should begin at 20 years of age and be repeated every 1 to 2 years. With the predilection for polyp development in the right colon, a formal colonoscopy is recommended.

Mutation Y-Homolog–Associated Polyposis

Mutation Y homolog (MYH) associated polyposis (MAP) is the only polyposis syndrome with an autosomal recessive inheritance pattern. It results from a biallelic mutation in the MYH gene located on chromosome 1p34. The number of polyps associated with MAP is variable from to hundreds with a median around 50. Polyps are found most commonly in the left colon and occur at a median age of 48 years. Polyposis is not required for the diagnosis of MAP. Up to 30% of such patients present with colorectal cancer without history of synchronous polyps. If untreated, the risk of colorectal malignancy is around 75% for males and 72% for females by 70 years of age. Extraintestinal manifestations can be associated with MAP, although these are exceedingly rare.

Because of the phenotypic overlap with FAP, genetic testing for the MYH mutation is typically performed when no APC mutation is detected. There are fewer than 100 adenomatous polyps, and the family history is irrelevant or does not reveal a dominant mode of inheritance.

Although there are no defined endoscopic screening criteria for MAP, an initial endoscopic (colonoscopy and EGD) evaluation should be performed starting around 25 to 30 years of age. If no polyps are appreciated, endoscopy should be repeated every 3 to 5 years and more frequently if present. As in the case of FAP, patients have an increased risk for developing thyroid malignancy, and annual screening ultrasound of the thyroid is recommended.

CHEMOPREVENTION

Although clinic trials have shown that nonsteroidal antiinflammatory drugs (sulindac, celecoxib) and aspirin can reduce the size and number of adenomas in the colon and rectum, there was not an appreciable reduction in cancer. Chemoprevention is not recommended as a primary therapy for polyposis syndromes and is not an appropriate alternative to prophylactic surgery. Situations in which chemoprevention can be entertained include treating ileal pouch and anastomosis polyps, a high family risk of desmoid tumors, delayed surgery, and unwillingness or inability to tolerate polypectomy or completion proctectomy.

SURGERY

The goal of prophylactic surgery for polyposis syndromes is to prevent colorectal cancer. The timing and type of surgery offered depends on a multitude of factors, including clinical presentation, family history, and, if known, the site of the chromosomal mutation. Severe polyposis (more than 1000 colonic or 20 rectal polyps) and APC mutations between codons 1250 and 1464 carry a higher risk of cancer, and surgery should be offered as early as possible. Surgery also should be pursued early for symptomatic disease. For those with a high risk of desmoid disease (family history, mutation in the 3′ end of the APC gene, female gender, extracolonic manifestations), surgery should be delayed as long as possible to decrease the chance of desmoid tumors developing. Young patients should have surgery delayed, if possible, to allow for adequate physical, rectal, and intellectual maturity. For patients with classic FAP, surgery typically occurs around 16 to 20 years of age.

Surgical options include open or minimally invasive total proctocolectomy with creation of an end or continent ileostomy, total abdominal colectomy with creation of an ileorectal anastomosis (IRA), and a total proctocolectomy with creation of an ileal pouch anal anastomosis (IPAA). A thorough preoperative discussion of the advantages and drawbacks to each approach is necessary to achieve the best patient outcome.

PROCTOCOLECTOMY WITH END-ILEOSTOMY

A proctocolectomy with end ileostomy has a low rate of complications. Most patients do not elect for creation of an incontinent stoma if they are candidates for other continence restoring approaches. Indications for this approach are patient preference, low rectal cancer requiring an abdominoperineal resection, rectal cancer requiring postoperative pelvic radiation, inability to create an IPAA (inadequate mesenteric length), and poor sphincter function. In

some cases, patients with chronic pouch dysfunction may elect for conversion to an end ileostomy.

The procedure is carried out in an oncologic approach secondary to the risk of a preoperatively unrecognized cancer. A perineal intersphincteric dissection is carried out preserving the external sphincter and levator ani muscles. The perineum is closed in layers and the greater omentum, if present, is mobilized and placed in the pelvis to prevent future bowel obstructions. After closure of the abdomen the ileostomy is matured to a standard end-stoma fashion.

Proctocolectomy With Continent Ileostomy

The continent ileostomy was initially described by Nils Kock (Kock's pouch) in 1969; it allows patients an option for an ileostomy without need for a cumbersome bag. Modifications and revisions to the original Kock's continent ileostomy have been described (Barnett continent intestinal reservoir and T-pouch). Each features an ileal pouch reservoir and valve mechanism to prevent leakage of accumulating stool. Although the technique lost favor when IPAA was established as the first choice technique, continent ileostomy remains an option for select patients undergoing proctocolectomy for FAP, including those with inadequate sphincter function, insufficient small bowel mesentery, a history of low rectal or anal cancer, failed existing IPAA, and/or in whom traditional ileostomy is undesirable. Contraindications to construction of a continent ileostomy include Crohn's disease, morbid obesity, marginal small bowel length, and a psychologic or physical disability that would preclude understanding or being able to perform daily stoma catheterization.

Total Abdominal Colectomy With IRA

Colectomy with IRA should be considered only in cases of attenuated or mild polyposis (fewer than 20 rectal or 1000 colonic adenomas), rectal polyps smaller than 3 cm, no colorectal dysplasia or cancer, a distensible and compliant rectum, and in patients with an intact sphincter mechanism that are willing to adhere to strict follow up. This rectal sparing approach is an appealing alternative to younger patients of reproductive age to decrease the risk of impotence and reduced fecundity. Strict rectal surveillance (every 6–12 months) must be adhered to because of the increased risk of future neoplastic changes. The risk of rectal carcinoma can reach up to 40% by 30 years, although this is based on literature from the pre-1980s era. In patients who require a completion proctectomy, an end ileostomy, restorative IPAA, or continent ileostomy remain viable options.

Restorative Proctocolectomy With IPAA

Initially described in 1978 by Parks and Nicholls, the restorative proctocolectomy has become the most common continence preserving procedure performed in patients who are appropriate candidates. Indications include severe polyposis (>20 rectal or >1000 colon adenomas), rectal polyps larger than 3 cm in size, colonic dysplasia or cancer, dysplastic rectal polyps, and in patients with an intact sphincter mechanism willing to adhere to strict follow up. The restorative pouch can be fashioned in two limbs (J), three limbs, four limbs, or isoperistaltic configurations. The J pouch, because of its ease of construction and excellent functional outcomes, has become the most common choice for surgeons.

A total colectomy is performed in an oncologic fashion, and the ileum is transected flush with the cecum. To provide adequate perfusion to the pouch, it is imperative to preserve the ileal branches of the ileocolic and distal mesenteric arteries. Evaluation for adequacy of reach of the small bowel to the deep pelvis should be undertaken before creation of the pouch. If the proposed apex of the pouch and mesentery can be advanced 3 to 4 cm below the inferior edge of the pubis, one can feel confident of successful reach for anastomosis. Strategies to decrease tension at the anastomosis include complete mobilization of the small bowel mesentery to the root of the superior mesenteric artery cephalad to the head of the pancreas, proximal division of the ileocolic artery, and relaxing incisions of the mesentery over tension points along the superior mesenteric artery. Rectal dissection to completion in the total mesorectal excision plane, and transection of the rectum with a 30 mm transverse stapler should occur 2 to 3 cm above the dentate line in the anal transition zone. After reach has been verified, a J configuration is fashioned with each limb measuring between 12 and 15 cm in length. The limbs are parted in an antimesenteric fashion and are held in orientation with interrupted stay sutures. For those without evidence of adenomas in the anal transition zone, or dysplasia in the lower rectum, a double stapled IPAA can be fashioned; otherwise, an anal mucosectomy and handsewn IPAA is recommended. After creation of the IPAA, an air insufflation leak test is performed and, if necessary, a protective loop ileostomy fashioned, which should be created as close to the pouch as possible to decrease issues with high output. In selected patients, the operation can be completed with good results without the creation of a diverting loop ileostomy.

Double-Stapled Technique

An enterotomy is made to the antimesenteric apex of the pouch, and a linear cutting stapler is used to divide the walls of the two limbs, creating a common channel (Fig. 1). A pursestring suture then is fashioned around the enterotomy, and the anvil from a circular stapler is placed inside the pouch, where it is held in place by tightening the purse string (Fig. 2). The circular stapler then is placed transanally. After appropriate orientation, the circular stapler cartridge spike is advanced either above or below the transverse rectal staple line and attached to the anvil. The stapler then is closed, approximating the pouch and anus (Fig. 3).

Handsewn Technique

An anal mucosectomy is performed starting at the dentate line. Raising the mucosa with a submucosal injection (Fig. 4) of dilute saline and epinephrine (1:200,000) facilitates dissection of the mucosa away from the internal sphincter muscle (Fig. 5), which can be completed sharply or with electrocautery. After the mucosa and

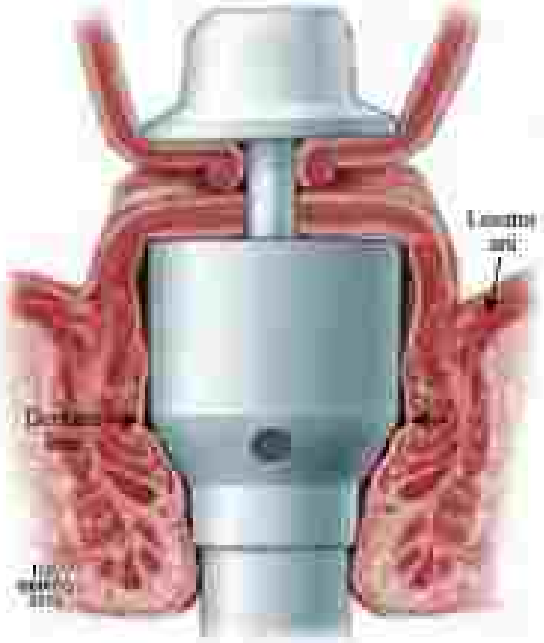

FIG. 3 **Stapled ileal pouch anal anastomosis.** (Courtesy Mayo Foundation for Medical Education and Research.)

proximal rectum have been removed circumferentially, the pouch is brought down gently to the level of the dentate line. An enterotomy is made in the apex of the pouch, if not already created, and anchored in position by placing a suture in each of the four quadrants, incorporating a full thickness bite of the pouch, internal sphincter muscle, and mucosa. Sutures are placed between the anchoring stitches to complete the anastomosis (Fig. 4).

FIG. 5 **Ileal transection.** (From Kelly SB, Thekkinkattil D, Cahill RA, et al. Colorectal surgery: A companion to specialist surgical practice. 5th ed. Edinburgh: Elsevier; 2014. p. 141.)

Postoperative Surveillance

After creation of an ileal J pouch, IPAA, or IRA, annual surveillance with flexible endoscopy facilitates early detection and removal of adenomas, dysplasia, and carcinoma. The patient must understand the need for a lifelong surveillance regimen. Histologic evaluation of random biopsies and polyps should be performed to exclude dysplasia and cancer, particularly in any areas of chronic scarring. More frequent surveillance is performed for increased numbers or size of polyps. Severe dysplasia and villous adenomas more than 1 cm in size should prompt a completion proctectomy in those with an IRA.

HAMARTOMATOUS POLYPOSIS SYNDROMES

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is an autosomal dominant inherited disease resulting most commonly from a mutation in the *LKB1* (*STK11*) tumor suppressor gene located on chromosome 19p13. Approximately 30% to 80% will occur de novo. Hamartomatous polyps are found throughout the gastrointestinal tract, although most

FIG. 8 Giant cow fetal pouch and anencephaly. (Courtesy Allegra Foundation for Health & Education and Research.)

commonly in the small intestine. Polyps vary in size and tend to become pedunculated as they grow larger. Extraintestinal manifestations are common, with the hallmark phenotypic feature in adolescence being mucocutaneous hyperpigmentation that can affect the perioral and buccal region, eyes, nostrils, perianal region, fingers and toes, and hands and feet. Hyperpigmentation dissipates as a patient ages. Hamartomatous polyps and mucocutaneous pigmentation confirms a diagnosis of Peutz-Jeghers syndrome. Although the overall number of polyps tend to be small (<20), the large polyp size tends to cause abdominal pain, alteration in bowel habits, weight loss, bowel intussusception, anemia, hematochezia and melanotic stools, and small bowel obstruction. The risk of malignancy is substantially higher than the general population and increases with age. The most common cancers are colorectal, breast, pancreatic, and genitourinary.

Colonoscopy and UGD should be initiated around 10 years of age. If polyps are detected, endoscopic evaluation should continue every 2 to 3 years. If no polyps are found, repeat endoscopy and small bowel follow through or capsule enteroscopy should be initiated by 20 years of age and repeated every 2 to 3 years. Other surveillance recommendations with low levels of evidence include an annual clinical examination, annual testicular examination starting at birth with ultrasound for abnormalities detected, monthly breast examination starting at age 18, and annual breast magnetic resonance imaging and cervical smear starting at age 25 years.

Gastrointestinal surgery is reserved for symptomatic disease, endoscopically uncontrollable polyp burden, high grade dysplasia, or cancer. Any polyp larger than 1.5 cm should be removed, if possible, at the time of surgery. Intraoperative on table endoscopy can be used to evaluate the entire gastrointestinal tract. Laparoscopic total abdominal colectomy and IRA is the operation of choice for management of colonic disease.

Juvenile Polyposis Syndrome

Juvenile polyposis syndrome is an autosomal dominant inherited disease resulting most commonly from mutations in the *SMAD4* and *BMPR1A* genes, which are located, respectively, on chromosomes 18q21 and 10q22. Polyps can be found throughout the gastrointestinal system, the colon is affected 100% of the time and gastric polyps found in approximately 50%. Extraintestinal manifestations occur around 15% of the time and can include cleft lip and palate, polydactyly, genitourinary anomalies, intestinal malrotation, hydrocephalus, and congenital heart disease. Hereditary hemorrhagic telangiectasia and bleeding arteriovenous malformations in the gastrointestinal, pulmonary tracts, brain, and mediastinum are associated with some *SMAD4* mutations. Diagnosis of juvenile polyposis syndrome is confirmed when five or more juvenile polyps are found in the colon or rectum, multiple polyps are appreciated in other regions of the gastrointestinal tract, or after identification of polyps with a positive family history. Presenting symptoms can include hematochezia and melanotic stools, anemia, intussusception, obstructing, and passage of autoamputated or prolapsed polyps. Colorectal cancer is the most common associated malignancy with lifetime rates as high as 50%. Other malignancies include gastric, duodenal, and pancreatic.

Asymptomatic patients should begin with screening colonoscopy by 15 years of age, and earlier for those with symptoms. If no polyps are detected, evaluation can be repeated every 2 to 3 years, otherwise annually. UGD is recommended by age 25 years. Those with an *SMAD4* mutation should have periodic screening for arteriovenous malformations.

Colorectal surgery is reserved for symptomatic disease, dysplasia, cancer, or polyp burden not amenable to endoscopic management alone. For those with a relatively spared rectum, a total abdominal colectomy with IRA can be pursued. Patients must be cautioned about the need for lifelong surveillance of the remaining rectum. If the rectum is significantly involved, a total proctocolectomy with IPAA is advisable. Surgeries to the remaining gastrointestinal tract may also be warranted.

Cowden's Syndrome

Cowden's syndrome is an autosomal dominant disorder resulting from a mutation to the *PTEN* tumor suppressor gene located on chromosome 10q23. Ninety five percent of patients will manifest colon polyps, most commonly hamartomas, though fibromas, adenomas, lipomas, and neurofibromas are also found. Extraintestinal manifestations include pathognomonic trichilemmomas, macrocephaly, and a wide variety of tumors and hamartomas of various organ systems (oral mucosa, small bowel, breast, thyroid, uterus).

The risk of developing colon and rectal cancer is thought to be no greater than the general population, although the risk for thyroid and breast cancer is noted to be around 10% and 50%, respectively. Screening recommendations are not standardized, but some recommend colonoscopy, mammography, and thyroid ultrasound beginning around 30 years of age. Treatment is based on symptoms. Polyp burden unable to be controlled endoscopically is an indication for prophylactic colectomy.

Bannayan-Riley-Ruvalcaba Syndrome

Bannayan-Riley-Ruvalcaba syndrome is an autosomal dominant disorder resulting from a mutation in the *PTEN* tumor suppressor gene located on chromosome 10q23. Hamartomatous polyps of the colon and ileum are characteristic of the disorder. Other common findings associated with Bannayan-Riley-Ruvalcaba syndrome include pigmented penile macules, macrocephaly, hemangiomas, and mental retardation in more than 10% of patients.

The risk of developing colon and rectal cancer is thought to be no greater than the general population. Treatment is focused on symptom reduction and supportive care.

Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome is a nonhereditary disorder resulting from a mutation to the *PTEN* tumor suppressor gene located on

chromosome 10q23. Hamartomatous gastrointestinal polyps in addition to alopecia, macrocephaly, myxolipoma, and cutaneous pigmentation are common findings. Diffuse gastrointestinal inflammation resulting in malabsorption, diarrhea, and protein losing enteropathy can occur.

The risk of developing colon and rectal cancer is thought to be no greater than the general population. Treatment is focused on symptom reduction and supportive care.

OTHER POLYPOSIS SYNDROMES

Serrated Polyposis Syndrome

Serrated polyposis syndrome is characterized by the presence of multiple or large serrated or hyperplastic polyps throughout the colon. Sessile serrated polyps are premalignant lesions that progress to cancer via a pathway of *BRAF* mutation and DNA hypermethylation. A heritability pattern and causative germline mutation have not been identified. The World Health Organization has proposed three criteria for diagnosing serrated polyposis syndrome. Fulfillment of any one of the criteria is sufficient for diagnosis. The criteria include the following:

- Twenty or more serrated polyps of any size distributed throughout the colon.
- More than five serrated polyps proximal to the sigmoid colon, at least two of which are larger than 10 mm in diameter.
- Any number of serrated polyps occurring proximal to the sigmoid colon in an individual who has a first-degree relative with serrated polyposis.

The risk of developing colorectal cancer is increased with rates of up to 50% documented in those with synchronous serrated polyps. The average age for developing colon and rectal cancer is 48 to 60 years.

Strict surveillance with colonoscopy every 1 to 2 years is advisable. First-degree relatives are at a fivefold increased risk of developing colon and rectal cancer and should be offered surveillance starting at 40 years of age or 10 years younger than the earliest age that a relative was diagnosed with a neoplastic lesion.

Treatment is focused on decreasing the patient's risk for developing colorectal cancer by removing premalignant polyps before they progress to cancer. Endoscopic removal and histologic evaluation of all polyps 5 mm in size or larger is recommended. Histologic diagnosis of carcinoma, dysplasia identified within a lesion that cannot be completely removed endoscopically or cases of extensive polyp burden that cannot be eradicated endoscopically are indications for surgical resection. Traditionally, any patient with a complex polyp not amenable to simple endoscopic removal, even those with a benign appearance, was recommended to undergo colon resection. Development and utilization of advanced endoscopic techniques and combined endoscopic and laparoscopic surgery now allows many such patients with ultimately benign polyps to avoid colectomy.

Hereditary Mixed Polyposis Syndrome

Hereditary mixed polyposis syndrome (HMPS3) is an autosomal dominant inherited syndrome associated with mutation in the *GREM1* gene. Patients with HMPS manifest multiple different colon and rectal polyps including adenomatous, hamartomatous, hyperplastic, and serrated lesions.

HMPS is most frequently described in patients of Ashkenazi Jewish descent and genetic screening is recommended for members of affected families as the risk of developing colorectal cancer is thought to be greater than the general population.

SURGICAL MANAGEMENT OF COLON CANCER

Winson Jiantong Tan, MBBS(Hons), MRCS(Ed), MMed(Surg), FRCS(Ed), and José G. Guillem, MD, MPH

Colorectal cancer is the fourth most commonly diagnosed cancer in the United States. An estimated 4.3% of the US population will be diagnosed with the disease in their lifetime. Fortunately, the disease-associated mortality has been declining over the years. While much of the improvement in outcomes can be attributed to the increase adoption of screening, advancement in colorectal cancer treatment also plays a major role. The colonic adenocarcinomas approximately 70% of all colorectal cancer cases. In the management of colon cancer, surgery remains the mainstay of treatment for patients with resectable and nonmetastatic disease. In this chapter, we outline the major principles behind the surgical management of adenocarcinoma of the colon. Since most of our primary colon cancer resections are performed using the enhanced recovery after surgery (ERAS) approach and the robotic minimally invasive surgery (MIS) platform, we highlight these modifications.

PREOPERATIVE EVALUATION AND STAGING

The evaluation of patients referred with a diagnosis of colon cancer begins with a complete history and physical examination. While the presenting symptoms can usually shed light on the location of the cancer, it is the severity of those symptoms that offer practical information and dictates the urgency of surgical intervention necessary to prevent the development of complications. In addition, a detailed family history is also critical and this should encompass both colorectal malignancies and extracolonic malignancies of endometrial and urothelial origin that can be associated with Lynch syndrome. This potentially influences the surgical plan, as extended resections can be offered as a treatment option for patients with Lynch syndrome since the rate of metachronous colorectal cancer ranges from 22% to 30%. In addition, these individuals may benefit from referral to a clinical genetic service to facilitate counseling and genetic testing for the patient and the family.

Physical examination is usually normal in patients with early stage colon cancer. In advanced disease, an abdominal mass may be palpable and fixation may indicate invasion into the abdominal wall and the need for an en bloc abdominal wall resection. The presence of hepatomegaly, ascites, Virchow's node enlargement, Blumer's shelf, and Sister Mary Joseph nodule, and so forth may also indicate metastatic disease and alter the therapeutic intent and treatment plan.

chromosome 10q23. Hamartomatous gastrointestinal polyps in addition to alopecia, macrocephaly, myxofibroma, and cutaneous pigmentation are common findings. Diffuse gastrointestinal inflammation resulting in malabsorption, diarrhea, and protein losing enteropathy can occur.

The risk of developing colon and rectal cancer is thought to be no greater than the general population. Treatment is focused on symptom reduction and supportive care.

OTHER POLYPOSIS SYNDROMES

Serrated Polyposis Syndrome

Serrated polyposis syndrome is characterized by the presence of multiple or large serrated or hyperplastic polyps throughout the colon. Sessile serrated polyps are premalignant lesions that progress to cancer via a pathway of *BRAF* mutation and DNA hypermethylation. A heritability pattern and causative germline mutation have not been identified. The World Health Organization has proposed three criteria for diagnosing serrated polyposis syndrome. Fulfillment of any one of the criteria is sufficient for diagnosis. The criteria include the following:

- Twenty or more serrated polyps of any size distributed throughout the colon.
- More than five serrated polyps proximal to the sigmoid colon, at least two of which are larger than 10 mm in diameter.
- Any number of serrated polyps occurring proximal to the sigmoid colon in an individual who has a first-degree relative with serrated polyposis.

The risk of developing colorectal cancer is increased with rates of up to 50% documented in those with synchronous serrated polyps. The average age for developing colon and rectal cancer is 48 to 60 years.

Strict surveillance with colonoscopy every 1 to 2 years is advisable. First-degree relatives are at a fivefold increased risk of developing colon and rectal cancer and should be offered surveillance starting at 40 years of age or 10 years younger than the earliest age that a relative was diagnosed with a neoplastic lesion.

Treatment is focused on decreasing the patient's risk for developing colorectal cancer by removing premalignant polyps before they progress to cancer. Endoscopic removal and histologic evaluation of all polyps 5 mm in size or larger is recommended. Histologic diagnosis of carcinoma, dysplasia identified within a lesion that cannot be completely removed endoscopically or cases of extensive polyp burden that cannot be eradicated endoscopically are indications for surgical resection. Traditionally, any patient with a complex polyp not amenable to simple endoscopic removal, even those with a benign appearance, was recommended to undergo colon resection. Development and utilization of advanced endoscopic techniques and combined endoscopic and laparoscopic surgery now allows many such patients with ultimately benign polyps to avoid colectomy.

Hereditary Mixed Polyposis Syndrome

Hereditary mixed polyposis syndrome (HMPS3) is an autosomal dominant inherited syndrome associated with mutation in the *GREM1* gene. Patients with HMPS3 manifest multiple different colon and rectal polyps including adenomatous, hamartomatous, hyperplastic, and serrated lesions.

HMPS3 is most frequently described in patients of Ashkenazi Jewish descent and genetic screening is recommended for members of affected families as the risk of developing colorectal cancer is thought to be greater than the general population.

Surgical Management of Colon Cancer

Wimon Jiantong Tan, MBBS(Hons), MRCS(Ed), MMed(Surg), FRCS(Ed), and José G. Guillem, MD, MPH

Colorectal cancer is the fourth most commonly diagnosed cancer in the United States. An estimated 4.5% of the US population will be diagnosed with the disease in their lifetime. Fortunately, the disease-associated mortality has been declining over the years. While much of the improvement in outcomes can be attributed to the increase adoption of screening, advancement in colorectal cancer treatment also plays a major role. The colonic adenocarcinoma approximately 70% of all colorectal cancer cases. In the management of colon cancer, surgery remains the mainstay of treatment for patients with resectable and nonmetastatic disease. In this chapter, we outline the major principles behind the surgical management of adenocarcinoma of the colon. Since most of our primary colon cancer resections are performed using the enhanced recovery after surgery (ERAS) approach and the robotic minimally invasive surgery (MIS) platform, we highlight these modifications.

PREOPERATIVE EVALUATION AND STAGING

The evaluation of patients referred with a diagnosis of colon cancer begins with a complete history and physical examination. While the presenting symptoms can usually shed light on the location of the cancer, it is the severity of those symptoms that offer practical information and dictates the urgency of surgical intervention necessary to prevent the development of complications. In addition, a detailed family history is also critical and this should encompass both colorectal malignancies and extracolonic malignancies of endometrial and urothelial origin that can be associated with Lynch syndrome. This potentially influences the surgical plan, as extended resections can be offered as a treatment option for patients with Lynch syndrome since the rate of metachronous colorectal cancer ranges from 22% to 30%. In addition, these individuals may benefit from referral to a clinical genetic service to facilitate counseling and genetic testing for the patient and the family.

Physical examination is usually normal in patients with early stage colon cancer. In advanced disease, an abdominal mass may be palpable and fixation may indicate invasion into the abdominal wall and the need for an en bloc abdominal wall resection. The presence of hepatomegaly, ascites, Virchow's node enlargement, Blumer's shelf, and Sister Mary Joseph nodule, and so forth may also indicate metastatic disease and alter the therapeutic intent and treatment plan.

A colonoscopy with complete visualization of the entire colon to the cecum should be performed in all patients not only to exclude the presence of synchronous colon lesions but also to ratify the location of the cancer, which is helpful for localization during an MIS approach. Synchronous colon benign polyps have been reported in 17% to 62% of cases, whereas synchronous cancers have been reported in 2% to 8% of cases. In a scenario where a stenotic tumor precludes passage of an endoscope, computed tomography (CT) colonography can be utilized to exclude synchronous lesions in the proximal colon.

Staging of colon cancer is performed using CT of the chest, abdomen, and pelvis. CT of the chest assesses for pulmonary metastasis, while the abdominal and pelvic scans provide information on the local extent of the tumor and the presence of lymphatic and liver metastases. In the presence of liver lesions deemed indeterminate for metastases, magnetic resonance imaging (MRI) of the liver can be utilized to better characterize the lesions. Positron emission tomography scans do not appear to provide additional information compared to CT scans. Carcinoembryonic antigen (CEA) levels should be included, when possible, in the preoperative evaluation, as it has prognostic significance and baseline values provide a useful adjunct for surveillance after curative resection.

STAGING OF COLON CANCER

The tumor node metastasis (TNM) system as described by the American Joint Committee on Cancer is currently used to stage colon cancer (Table 1).

TABLE 1 Tumor-Node-Metastasis Staging for Colon Cancer

Definition of Primary Tumor (T)

T Category	T Criteria
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ, intramucosal carcinoma (involvement of lamina propria with no extension through muscularis mucosae)
T1	Tumor invades the submucosa (through the muscularis mucosa but not into the muscularis propria)
T2	Tumor invades the muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organs or structures
T4a	Tumor invades through the visceral peritoneum (including gross perforation of the bowel through tumor and continuous invasion of tumor through areas of inflammation to the surface of the visceral peritoneum)
T4b	Tumor directly invades or adheres to adjacent organs or structures

Definition of Regional Lymph Node (N)

N Category	N Criteria
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One to three regional lymph nodes are positive (tumor in lymph nodes measuring ≥0.2 mm), or any number of tumor deposits are present and all identifiable lymph nodes are negative
N1a	One regional lymph node is positive
N1b	Two or three regional lymph nodes are positive
N1c	No regional lymph nodes are positive, but there are tumor deposits in the • Subserosa • Mesentery • Or nonperitonealized pericolic, or perirectal/mesorectal tissues
N2	Four or more regional lymph nodes are positive
N2a	Four to six regional lymph nodes are positive
N2b	Seven or more regional lymph nodes are positive

Definition of Distant Metastasis (M)

M Category	M Criteria
M0	No distant metastasis by imaging, etc; no evidence of tumor in distant sites or organs (this category is not assigned by pathologists)
M1	Metastasis to one or more distant sites or organs or peritoneal metastasis is identified
M1a	Metastasis to one site or organ is identified without peritoneal metastasis
M1b	Metastasis to two or more sites or organs is identified without peritoneal metastasis
M1c	Metastasis to the peritoneal surface is identified alone or with other site or organ metastases

SURGICAL MANAGEMENT

General Principles

Preparation

We use a mechanical and antibiotic bowel preparation prior to elective colon resection. Mechanical bowel preparation involves a clear liquid diet and the administration of polyethylene glycol on the evening prior to surgery. Oral neomycin and metronidazole are administered concurrently with the bowel prep. In malignant polyps and small lesions, it is important to ensure that the tumor location has been marked with an endoscopic tattoo to facilitate intraoperative identification. This is particularly pertinent if the MIS approach is intended.

All suitable patients are currently managed perioperatively via an enhanced recovery protocol. Most patients undergoing elective colorectal surgery are included, unless the operation is a major tumor debulking or complex multivisceral resection (e.g., pelvic exenteration, primary tumor resection with synchronous liver metastasectomy), or if the patient's physiologic status precludes safe inclusion in an enhanced recovery protocol. Protocols vary between institutions, but our program focuses on goal-directed fluid administration, enhanced pain management while minimizing narcotic use, and early postoperative feeding and mobilization. Specific interventions include preoperative carbohydrate loading 2 hours prior to admission and administration of gabapentin, and a peripheral acting μ receptor opioid antagonist (alvimopan) prior to surgery. Opioid sparing strategies are employed, using preoperative epidurals or transversus abdominis plane blocks with liposomal bupivacaine, intraoperative nonopioid infusions (e.g., ketamine or dexmedetomidine), and maximizing antiinflammatories and nonopioid adjuncts throughout the perioperative period, as clinically appropriate.

On the day of surgery, patients are given an intravenous dose of a second generation cephalosporin prior to skin incision. Sequential compression devices are placed prior to induction of anesthesia for deep venous thrombosis prophylaxis. For left sided resections, the modified lithotomy position using Lloyd-Davies stirrups is preferred. This position provides versatility for the surgeon to stand between the legs during open procedures for mobilization of the splenic flexure and facilitates intraoperative colonoscopy or the use of circular stapling devices during both open and MIS procedures. For right sided resections, supine positioning is usually adequate. For distal colon and sigmoid lesions, the rectum is irrigated with saline solution until clear in the operating room prior to skin preparation. An orogastric tube and Foley catheter are placed after induction of anesthesia.

Operative Approach

Both open and MIS (laparoscopic or robotic) approaches can be employed for colon cancer resection. Multiple randomized trials (COST, COLOR, and CLASICC) have demonstrated that long term oncologic outcome of the MIS approach is not inferior to that of open surgery. In addition, MIS confers benefits of a shorter length of stay with reduced analgesia requirements and postoperative ileus. However, it is important to emphasize that the oncologic adequacy of a laparoscopic resection should be identical to that of open surgery, and in instances whereby this may not be possible (e.g., locally advanced tumor necessitating multivisceral resection), an open approach may be more prudent.

Surgery for colon cancer should begin with a thorough abdominal exploration to assess the extent of local involvement and to detect any occult metastatic disease. This includes inspection of the liver, peritoneal surfaces, omentum, retroperitoneum, and ovaries. When feasible, metastatic disease should be documented histologically.

Lymphadenectomy

An adequate lymph node dissection entails the removal of the tumor en bloc with the mesentery up to the origin of the primary feeding vessel. Suspicious apical lymph nodes should be marked for pathologic analysis, as involvement is a negative prognostic indicator. Efforts should be made by the pathologist to examine a minimum

of 12 lymph nodes to ensure adequate nodal sampling. In recent years, some surgeons are advocating an extended lymphadenectomy, whereby nodes beyond the primary feeding vessel and associated central lymph node basins are removed as well. This is commonly performed as part of "complete mesocolic excision," which in right-sided colon cancer involves ligation of the mesenteric vessels at the base of the superior mesenteric artery and vein with dissection and removal of any overlying lymphatic tissue. However, the oncologic benefit of such extended lymphadenectomy is not widely accepted by the surgical community.

Tumor Handling

Excessive manipulation of the tumor during resection should be avoided. Adjacent organs that are adherent or grossly involved should be resected en bloc with the tumor to minimize cancer spillage. Proximal and distal margins of resection should be at least 5 cm in cancer at risk pericolonic lymph nodes are resected with the specimen. The actual margins are usually greater as an adequate vascular ligation often defines a larger devascularized segment.

Anastomoses

During creation of a colonic anastomosis, two key principles ought to be emphasized. The anastomosed bowel ends should be well vascularized, and the anastomosis should be created without tension. The alignment of the resultant small and large bowel should be checked prior to anastomosis to ensure there is no internal herniation or torsion around the bowel mesentery. This is of particular concern when using the MIS approach. Both hand-sewn and stapled anastomoses can be performed with randomized studies showing no difference in outcomes between the 2 modalities. For handsewn, we commonly perform a two-layer anastomosis (interrupted inner seromuscular rows and an outer row of running full-thickness sutures) in a side-to-side or end-to-end fashion. In MIS extracorporeal anastomosis, we use a two-layer closure (inner full-thickness and outer serosal running V-lock stitch). Single layer handsewn colon anastomoses have been shown to be effective as well. When we perform stapled colon anastomoses, we most commonly perform either an end-to-end anastomosis or a side-to-side anastomosis using the GIA-80 stapler (anastomosis to antimesenteric border) to create the anastomosis and a TA-90 stapler to close the defect.

Drains

We do not use drains (open or closed) following an elective colon resection. Temporary surgical drains may be utilized in select cases whereby significant intraperitoneal spillage was encountered.

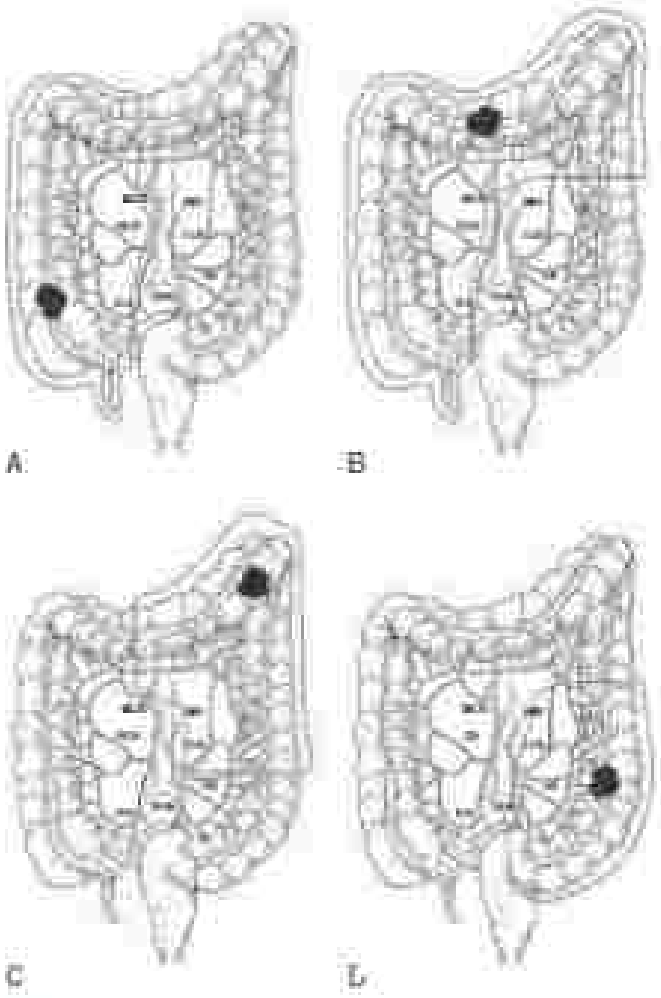

FIG. 1 Extent of resection for colon carcinoma. (A) Cecal or ascending colon cancer; (B) transverse colon cancer; (C) splenic flexure colon cancer; (D) sigmoid colon cancer. ICA, ileocolic artery; IMA, inferior mesenteric artery; LCA, left colic artery; MCA, middle colic artery; RCA, right colic artery; SA, sigmoidal arteries; SHA, superior hemorrhoidal artery. (From Nelson H, Gallinger JL. Cancer of the colon. In: Niederhuber JE, Armitage JO, Kastan MB, Doroshow JH, Tepper JE, eds. Abeloff's Clinical Oncology. 5th ed. Philadelphia: Churchill Livingstone Elsevier; 2014.)

Right-Sided Colon Cancers

Cancers of the right colon account for up to 15% of primary colorectal cancers. Patients with adenocarcinoma involving the cecum or ascending colon who do not have hereditary nonpolyposis colorectal cancer or other synchronous lesions should be treated with a right hemicolectomy (Fig. 1A). The ileocolic, right colic, and right branch of the middle colic arteries and veins should be ligated near their origin in order to ensure an adequate lymphadenectomy. Approximately 7.5 to 10 cm of distal small intestine should be resected in continuity with the right colon to ensure well-vascularized small bowel is available for the ileocolic anastomosis.

Transverse Colon Cancers

Transverse colon cancers are relatively uncommon, accounting for only 8% of colorectal primaries. Lesions of the proximal and midtransverse colon are usually best managed with an extended right hemicolectomy involving ligation of the ileocolic, right colic, and middle colic vessels (Fig. 1B). The cecum, ascending colon, hepatic flexure, transverse colon, and splenic flexure are removed with anastomosis of the ileum to the descending colon. Blood supply to the colon is based on the ascending branch of the left colic artery. We generally avoid an anastomosis at the hepatic or splenic flexure because of concerns over its vascularity and tension at the anastomosis, as the ascending and descending colon tend to migrate to and lie in their anatomic position within the lateral gutters.

Left-Sided Colon Cancers

Lesions of the splenic flexure and descending colon are also uncommon, accounting for less than 9% of colorectal primaries. Splenic flexure cancers may be managed with an extended right or left hemicolectomy (Fig. 1C). Cancers in the descending colon may be managed with a left hemicolectomy involving division of the left colic artery, preservation of the left branch of the middle colic artery, and anastomosis of the distal transverse colon to the sigmoid following a full splenic flexure mobilization. Alternatively, a left hemicolectomy may be performed with ligation of the inferior mesenteric vessels and an anastomosis between the transverse colon and the upper rectum.

Sigmoid Cancers

Tumors of the sigmoid colon are the most common. These tumors are usually removed by means of an anterior sigmoid colectomy, which usually involves division of the inferior mesenteric artery and vein with anastomosis of the descending colon to the upper rectum (Fig. 111). Large, bulky sigmoid cancers located above the peritoneal reflection but at the level of the pelvic inlet as defined by a sagittal MRI view present a unique challenge. Anteriorly they can invade the bladder and form a colovesical fistula. Posteriorly they abut important structures such as the ureters, hypogastric nerves, and iliac vessels. Proper preoperative planning based on optimal imaging (CT scan and/or MRI) is essential. In carefully selected cases, preoperative chemoradiation has proven helpful by down-staging the tumor to facilitate negative resection margins while preserving vital structures.

Postoperative Care

Antibiotics are not routinely continued for more than 24 hours postoperatively, and appropriate thromboembolism prophylaxis should be maintained until the patient is ambulating sufficiently. Postoperative course is largely governed by an ERAS protocol, as mentioned previously, which encourages early feeding and ambulation, removal of the Foley within the first 24 hours after surgery and early discontinuation of intravenous fluids. Patients on the ERAS protocol are usually discharged within 3 to 5 days.

SPECIAL SCENARIOS

Malignant Polyp

With the implementation of colonoscopic screening, colon cancers are increasingly being detected as malignant polyps. This often happens when a polyp, initially thought to be benign, is resected endoscopically only to be found to contain a focus of invasive adenocarcinoma after pathology review. The propensity for lymph node metastasis is related to several histopathologic features. Adverse risk factors include deep invasion of the submucosa, high tumor grade, poor degree of differentiation and the presence of perineural or lymphovascular invasion. Classification systems for pedunculated and sessile polyps are available to quantify the depth of invasion in malignant polyps.

The Haggitt classification system is used to quantify the depth of invasion for a malignant pedunculated polyp (Fig. 28). The risk of lymph node metastasis in Haggitt level 0, 1, and 2 lesions is less than 1% in the absence of the other adverse prognostic factors mentioned previously. Endoscopic removal is deemed to be sufficient if the lesion was removed en bloc and with clear margins of at least 2 mm, even though in recent years many regard margins 1 mm or greater as adequate. Haggitt level 4 malignant polyps should be offered oncologic segmental resection, as the risk of lymph node metastases is estimated to be close to 30%.

The Kikuchi classification divides the extent of submucosal invasion into thirds and is used to quantify the depth of invasion for a sessile malignant polyp (Fig. 28). The risks of lymphatic metastases increase with the depth of submucosal invasion and range from: 2% for Sm_1 lesions to 23% for Sm_2 lesions. In general, only Sm_1 and select Sm_2 lesions can be adequately treated with complete endoscopic removal. Sessile malignant polyps that are Sm_2 or with other adverse prognostic factors should be offered oncologic segmental resection. The practical implementation of the Kikuchi classification may be difficult, as the muscularis propria layer is usually not included in the resected polyp, which limits the accurate division of the submucosal layer into thirds. Hence, some have used the depth of invasion beneath the muscularis mucosae as an alternative measure of submucosal involvement. A malignant sessile polyp with depth of submucosal invasion 1 mm or greater is considered low risk for lymphatic metastases in the absence of other adverse features and can be managed with endoscopic resection.

Patients with malignant polyps who opt for nonsurgical management should, however, be adequately counseled that even though the risk of lymph node metastasis is low, it is not zero, and close surveillance for cancer local recurrence/persistence or distant metastases would still be required.

Locally Advanced Colon Cancers

Approximately 5% to 10% of colon cancers will present as locally advanced lesions with invasion of contiguous organs. The most commonly involved organs include the small bowel, spleen, pancreas, duodenum, and stomach. In these situations, an en bloc multivisceral resection of contiguous structures with histologically negative margins should be attempted whenever feasible.

Unlike the rectum, which is confined to the pelvis, the location of the colon within the abdominal cavity precludes the use of radiation as a modality for neoadjuvant treatment due to concerns regarding collateral damage to the surrounding viscera. Neoadjuvant chemotherapy is an option for tumor downstaging and has been shown in a randomized study (FOxTROT Collaborative Group) to be effective in downstaging the primary tumor with acceptable morbidity and toxicity. However, improvement in long-term oncologic outcomes is yet to be established.

Synchronous Colon Cancers

Synchronous colon cancers are estimated to occur in 4% of patients, with incidence ranging from 0.3% to 11% in various studies. For synchronous cancers located in different segments of the colon, both extended resections and two separate resections are viable options. Extended resection offers the benefit of a single anastomosis with the trade-off for possible increased daily bowel movements associated with inferior functional outcomes and quality of life in patients with underlying colonic disease predisposing to cancer formation such as ulcerative colitis or Lynch syndrome–associated colon cancer, an extended resection may be preferred to address the underlying diseased at risk colon.

Stage IV Colon Cancer

Approximately 20% of colorectal cancer patients present with stage IV disease at the point of diagnosis. Patients with colon cancer and limited metastatic disease confined to one organ (liver or lung) can be surgically resected with curative intent if adequate residual organ function is preserved after metastasectomy. These patients can experience 5-year survival rates ranging from 40% to 60% after curative surgery and systemic chemotherapy. Hence, stage IV colon cancer patients with resectable single-site metastases in the lung and liver should be recommended curative surgical resection if they are suitable surgical candidates. The management of stage IV colon cancer patients with isolated peritoneal metastases remains controversial. Cytoreductive surgery with intraperitoneal chemotherapy is performed in some centers, but it remains unknown if outcomes are superior compared to modern systemic chemotherapy and biologic agents. Hence, it is not recommended as a routine treatment option in the current National Comprehensive Cancer Network guidelines.

The management of stage IV colon cancer with unresectable metastases must be individualized. Factors such as the patient's fitness for surgery, extent of symptoms from the primary, and the life expectancy ought to be considered during decision-making regarding resection of the primary colon tumor. Surgical resection may not be indicated in patients with an asymptomatic colon lesion. This is most commonly encountered in right-sided lesions where an obstruction is less likely. In patients with symptomatic lesions, palliative resection of the primary can provide symptom relief and quality of life improvement. In patients with limited life expectancy, the surgical approach should be tailored toward the least invasive procedure to achieve symptom relief (e.g., diverting ileostomy instead of resection in a patient with obstructive symptoms).

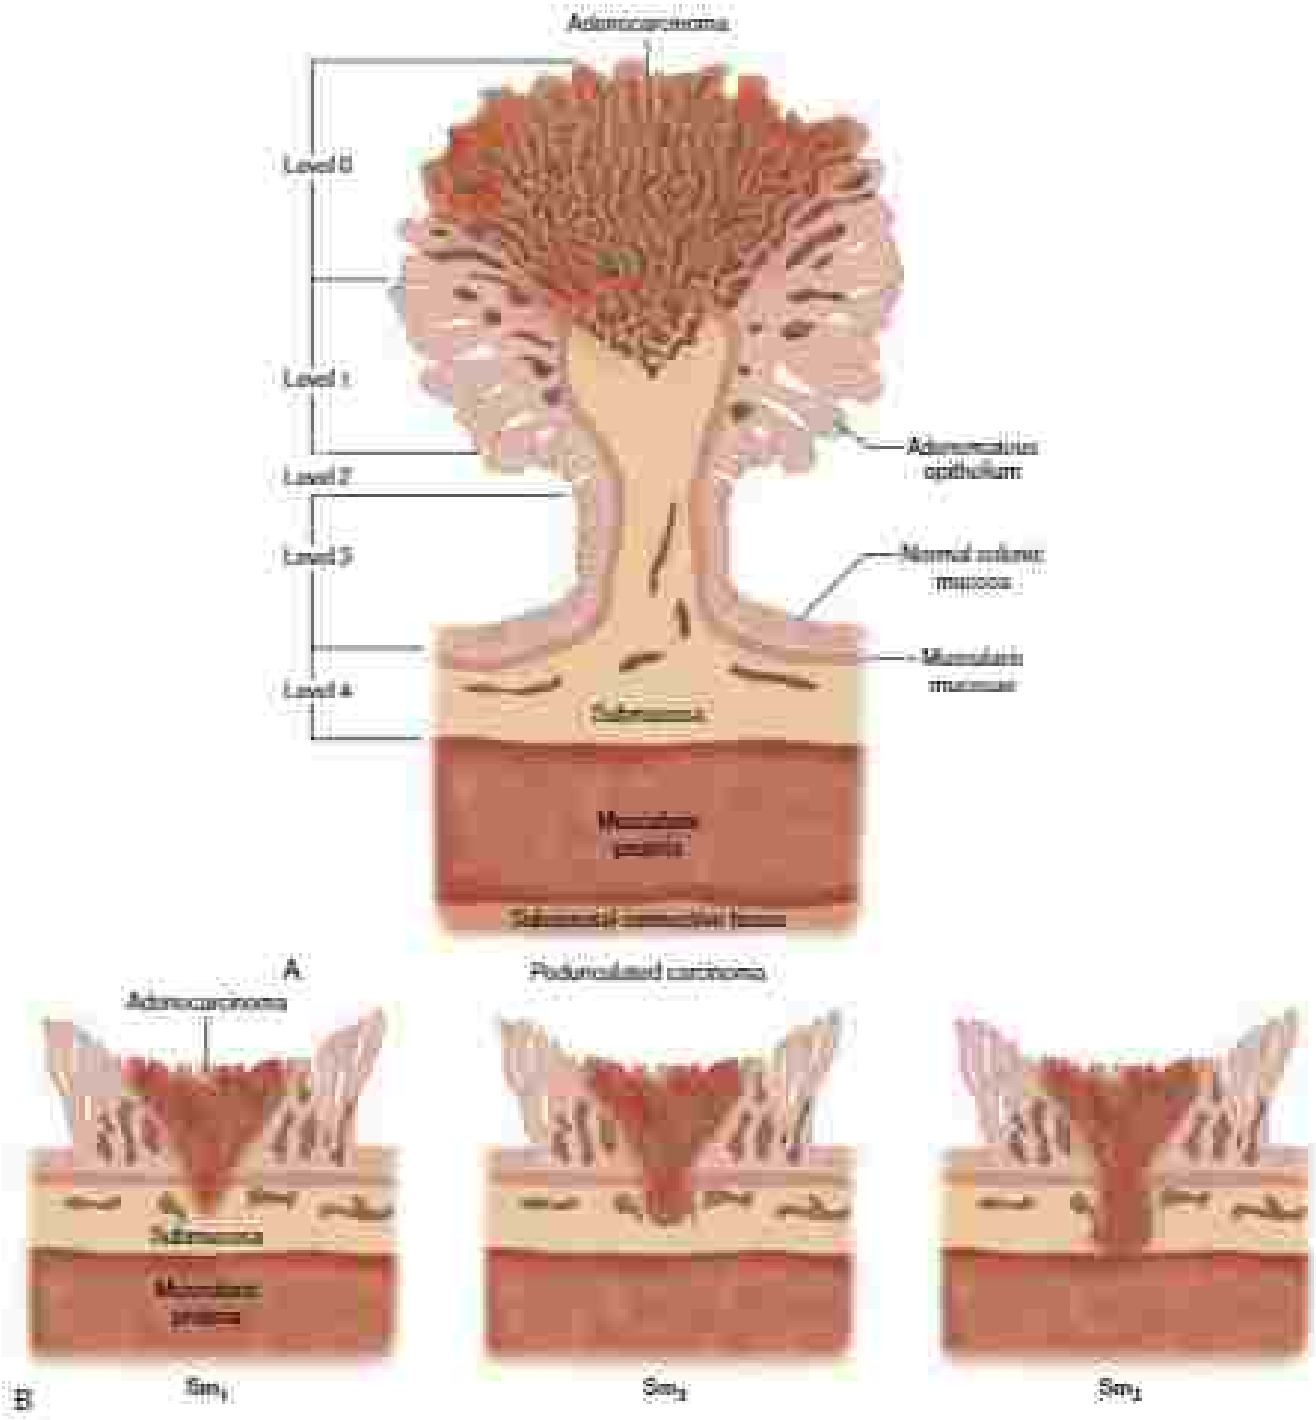

FIG. 2 Depth of invasion of malignant polyps. (A) Haggitt's classification for pedunculated polyps. (B) Kikuchi classification for sessile polyps. [illegible]

Emergency Presentation of Colon Cancer

Perforated Colon Cancers

Perforated colon cancers pose a management conundrum for the colorectal surgeon. Patients often present with peritonitis and hemodynamic instability, and the emergent nature of the surgery may preclude adherence to surgical oncology principles since the priority may be damage control in these potentially unstable patients. The resection should adhere to established oncologic principles whenever possible.

The goals of surgical management are to remove the diseased segment of colon and prevent ongoing peritoneal contamination. Following resection and thorough irrigation of the peritoneal cavity, options for subsequent management include proximal diversion with creation of a mucous fistula/Hartmann pouch or primary anastomosis with proximal diversion via loop ileostomy. Perforated colon cancer is associated with a high rate of local recurrence and poor overall survival.

Obstructing Colon Cancers

Bowel obstruction can be the presenting symptom in up to 30% of newly diagnosed colon cancer. Obstructing lesions tend to be more common in the left colon, although lesions in the cecum can sometimes also cause small bowel obstruction by occluding the ileocecal valve.

Obstructing right and transverse colon cancers can generally be managed with a right hemicolectomy or an extended right hemicolectomy and primary anastomosis. In frail and malnourished patients or those with hemodynamic instability requiring inotropic support, a defunctioning or end stoma may be indicated with intestinal continuity reestablished in a separate elective setting.

The surgical approach for obstructed left sided tumors can be an either single stage or two stage approach. Factors influencing a single stage or two stage approach include the patients' nutritional status, clinical stability, and life expectancy.

Single stage management usually includes subtotal colectomy with ileosigmoid or ileorectal anastomosis. This has the benefit of incorporating well vascularized small bowel in the anastomosis and removes the uncertainty of retained synchronous tumors in the proximal colon. However, bowel function may be compromised after surgery. Segmental resection with a colocolonic anastomosis is another option but it entails anastomosis of dilated and edematous proximal colon to the distal colon, which may increase the risk of anastomotic dehiscence. In addition, synchronous lesions in the proximal colon may be left in situ.

A two stage procedure involves resection of the primary tumor with proximal diversion and creation of a mucous fistula (Hartmann's pouch or a sigmoid resection with primary anastomosis and proximal ileal diversion with a loop ileostomy). Bowel continuity is reestablished at a separate elective setting.

In recent years, colonic stenting has emerged as a viable option for patients who present emergently with a malignant colon obstruction. Stenting can be used as a bridge to surgery by converting an emergent situation to an elective one. Successful deployment of a colonic stent allows bowel decompression and medical or nutritional optimization prior to elective resection, which can be performed via the minimally invasive approach. It also allows evaluation of the proximal colon for synchronous lesions prior to resection. Clinical success rates of approximately 80% have been demonstrated in various reviews and meta analysis. However, stenting does have its complications and perforation can occur in 6% to 7% of cases. There are also concerns regarding inferior long-term oncologic outcomes after stenting, although this has not been consistently demonstrated.

CHEMOTHERAPY FOR COLON ADENOCARCINOMA

The need for adjuvant therapy following resection of a colon cancer is best determined in a multidisciplinary manner with a member of the medical oncology service. In general, adjuvant chemotherapy is indicated in stage III colon cancer, as disease recurrence is reduced by 30% and mortality by 20% to 30% with treatment. Adjuvant chemotherapy generally utilizes a fluoropyrimidine backbone (intravenous 5-fluorouracil with leucovorin or oral capecitabine) with oxaliplatin given for 3 to 6 months duration. In frail or elderly patients, oxaliplatin may occasionally be omitted due to concerns regarding toxicity.

In stage II colon cancer, adjuvant chemotherapy is generally not indicated unless adverse risk factors for recurrence are present. These factors include poorly differentiated histology, T4 stage, perforated or obstructed tumors, perineural or lymphovascular invasion, close margins, or less than 12 lymph nodes examined at pathology. In these patients, chemotherapy may be indicated to reduce the risks of recurrence, and therapy usually involves fluoropyrimidine monotherapy.

In stage IV disease, advancements in chemotherapy have markedly improved survival. A fluoropyrimidine backbone with oxaliplatin (FOLFOX) or irinotecan (FOLFIRI) are the usual first line choices. Targeted therapies such as bevacizumab (monoclonal antibody targeting vascular endothelial growth factor) and cetuximab/panitumumab (monoclonal antibody targeting epidermal growth factor) are also part of the current treatment armamentarium in stage IV disease. The response to treatment of these targeted agents can be predicted with tumor mutational status and whenever possible should be determined for all metastatic colon cancers. Tumors with *KRAS* or *BRAF V600E* mutations respond poorly to monoclonal antibodies targeting epidermal growth factor (cetuximab/panitumumab).

SURVEILLANCE FOLLOWING RESECTION OF COLON ADENOCARCINOMA

The goal of postoperative surveillance following resection of colon adenocarcinoma is the early identification of asymptomatic recurrences to allow early treatment and improvement in survival. While many studies on intensive surveillance have shown benefits in terms of the rate of curative resection of the recurrence, survival benefit has not been consistently demonstrated.

The current American Society of Clinical Oncology recommend history and physical examination with CEA monitoring every 3 to 6 months for 5 years, CT chest, abdomen, and pelvis annually for 3 years and surveillance colonoscopy within 1 year after curative resection of stage II and III colon cancers. Surveillance for stage I colon cancer is currently not recommended, although this may be of value in high risk cases such as those with poor prognostic factors like lymphovascular invasion, positive margins, poor tumor differentiation, and T2 disease. While these recommendations serve as a reference, the surveillance strategy for each patient should be individualized. Factors such as the patient's preference, functional status, comorbidity profile, and lifetime to tolerating resection of any detected recurrent disease might to be considered when deciding the optimal surveillance strategy.

Management of Rectal Cancer

Junior Salgado Pagacnik, MD, and Michael A. Choti, MD, MBA, FACS

The complexity of care and treatment choices facing the clinician managing rectal cancer is more than with most surgical diseases. Surgical treatment options can vary from radical transabdominal operations to local excision. Newer techniques are being applied to reduce the necessity for permanent colostomy, improve functional results, and reduce local recurrence. Multimodality treatment strategies, including expanded use of preoperative therapy, are being advocated more commonly. Changing treatment algorithms in this disease make evidence based management particularly important.

Approximately 40,000 new cases of rectal cancer are diagnosed annually in the United States accounting for about 30% of large bowel malignancies. While colon cancer is nearly equal in men and women, more men are diagnosed with rectal cancer. Deaths from colorectal cancer in the United States number approximately 50,000 per year. Unfortunately, reliable data on deaths specifically from rectal cancers are not known, as almost 40% of deaths from rectal cancer are misclassified as colon cancer.

Surgeons generally consider the rectum to begin at the level of the sacral promontory. It descends along the curvature of the sacrum and coccyx and ends by passing through the levator ani muscles, turning downward and backward to become the anal canal. It differs from the colon in that the outer layer is entirely longitudinal muscle. It measures 12 to 15 cm in length and lacks a mesentery, sacculations, and appendices epiploicae.

This chapter reviews the preoperative evaluation and clinical staging of patients with rectal cancer and management options based on stage of disease, highlighting a multidisciplinary approach, careful preoperative planning, and sequential multimodal therapy when indicated.

PREOPERATIVE PLANNING

The evaluation of a patient with rectal cancer should be performed in a multidisciplinary, integrated approach, addressing the medical, surgical, and psychosocial needs of the patient. Determination of an ideal treatment plan in a patient with rectal cancer is a complex process. Guidelines must be followed, focusing on the diagnosis, pathologic staging, neoadjuvant therapy, surgical management, adjuvant management, management of recurrent metastatic disease, and patient surveillance. Multimodality (MDT) approach includes integrating primary care physicians, gastroenterologists, surgeons, radiation and medical oncologists, radiologists, interventional therapy nurses, pain specialists, and social workers. In European countries, MDT approach has resulted in lower rates of permanent stoma, reduced rates of local recurrence, greater delivery of evidence based care, and improved overall survival.

CLINICAL EVALUATION AND PREOPERATIVE STAGING

The general physical examination is crucial for determining the extent of local disease, unveiling distant metastases, and evaluating the operative risk of the patient regarding nutritional, cardiovascular, pulmonary, and renal status. A thorough digital rectal examination allows the surgeon to identify the extent and location of the mass, mobility or fixity, size, and macroscopic configuration, involvement in relation to the anorectal ring, extension to adjacent viscera or fixation to the sacrum. These are all key features in establishing the nature of the problem and target the appropriate testing and therapy.

A full colonoscopic evaluation should be done in rectal cancer patients in order to rule out synchronous lesions and other associated pathologic conditions of the colon and rectum. These patients may also require rigid or flexible proctoscopy by the surgeon in selected cases in order to assess and confirm macroscopic characteristics of the tumor, including size, location, and extent of circumference of the tumor affected.

Biopsy with histopathologic examination is important to confirm adenocarcinoma and determine any unique histologic features that may be of value prior to therapy, such as microsatellite status. Endoscopic biopsies obtained at an outside institution should be confirmed and reviewed when possible. Additional testing should include routine serum laboratory studies, including liver function tests and carcinoembryonic antigen.

Preoperative imaging for rectal cancer is essential to adequately stage the disease and plan the treatment approach. Computed tomographic (CT) scan of the chest, abdomen, and pelvis is recommended to determine absence or presence of regional or distant metastatic disease. Transrectal endoscopic sonography (EUS) was considered important for staging, specifically to delineate the depth of tumor penetration through the rectal wall and determine whether local regional lymph nodes are involved. Pelvic high resolution magnetic resonance imaging (MRI) has largely replaced EUS as the preferred locoregional staging modality. MRI has similar accuracy to EUS with regard to T and N staging accuracy but with less operator dependency. In addition, MRI is better at accurately assessing the circumferential resection margin and identifying other prognostic features such as extramural venous invasion. EUS also has limited utility in high rectal cancer or stricturing lesions.

Fluorodeoxyglucose positron emission tomography (PET)-CT can be considered in some cases when evaluating a patient with rectal cancer, but its routine use for staging is controversial. Several studies have shown an overall accuracy in detecting distant disease in excess of 90%. However, reports challenge the value of PET in changing surgical management. Most guidelines recommend the use of PET/CT selectively to evaluate an equivocal finding on CT or in patients with contraindication to intravenous contrast.

RADICAL RESECTION WITH TOTAL MESORECTAL EXCISION

Most patients with intermediate stage rectal cancer will require radical resection. This is defined as resection of the tumor and rectum en bloc with its blood and lymphatic supply and surrounding mesorectum. Traditionally during transabdominal resections, much of the pelvic dissection below the peritoneal reflection was performed in a blind fashion. In 1982, Heald et al. published the first description of dissection of the mesorectum in a sharp fashion. This technique, called total mesorectal excision (TME), involves the sharp dissection between the parietal and visceral planes of the endopelvic fascia (Figs. 1 through 4). Such a technique minimizes the risk of a positive circumferential margin, a factor of strong prognostic significance for local recurrence. Along with the TME, the other tenets of adequate surgical resection include achieving negative distal and circumferential resection margins, preservation of autonomic nerves, and restoration of gastrointestinal continuity if possible.

In the early 2000s, the laparoscopic minimally invasive technique emerged as an acceptable surgical approach for the treatment of rectal cancer. In recent years, newer surgical techniques such as robot assisted procedures and transanal TME have been developed as part of our surgical armamentarium. Robotic assisted surgery can reduce some of the limitations of conventional laparoscopy with improved visualization and better maneuverability. In some reports, robotic techniques were associated with comparable short term oncologic outcomes, but operative times and costs are higher compared with laparoscopic colorectal surgery. The role of robotics in rectal surgery remains to be defined.

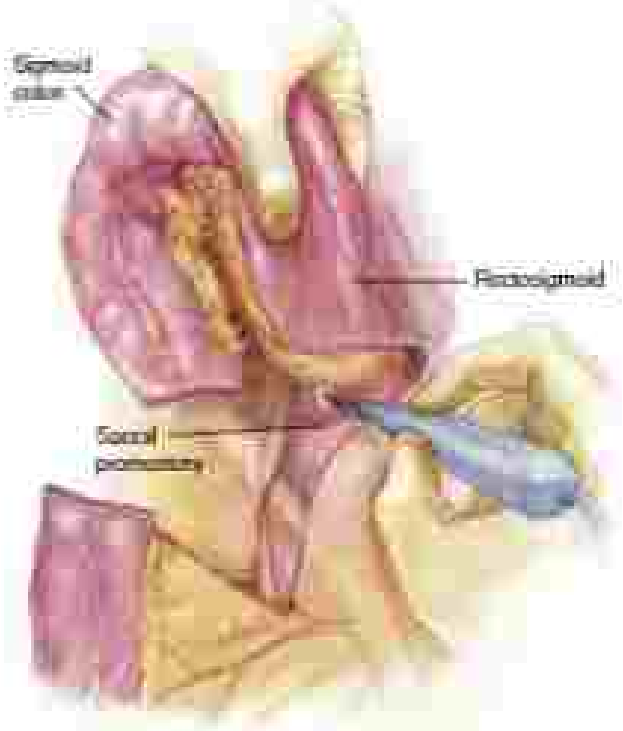

FIG. 1 Total mesorectal excision is between parietal fascia and fascia propria. (Courtesy Cleveland Clinic Foundation, Department of Colorectal Surgery.)

FIG. 2 Total mesorectal excision plane. Posterior rectal dissection. (Courtesy Cleveland Clinic Foundation, Department of Colorectal Surgery.)

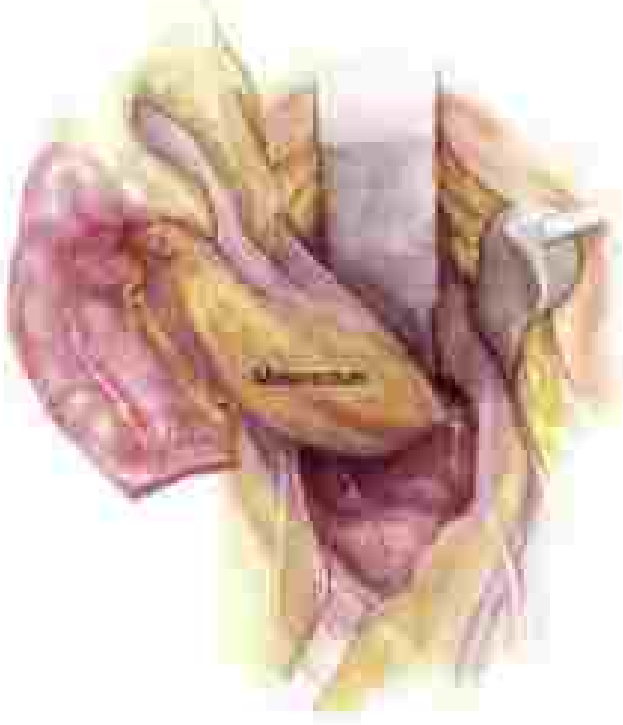

FIG. 3 Lateral peritoneal reflections divided. (Courtesy Cleveland Clinic Foundation, Department of Colorectal Surgery.)

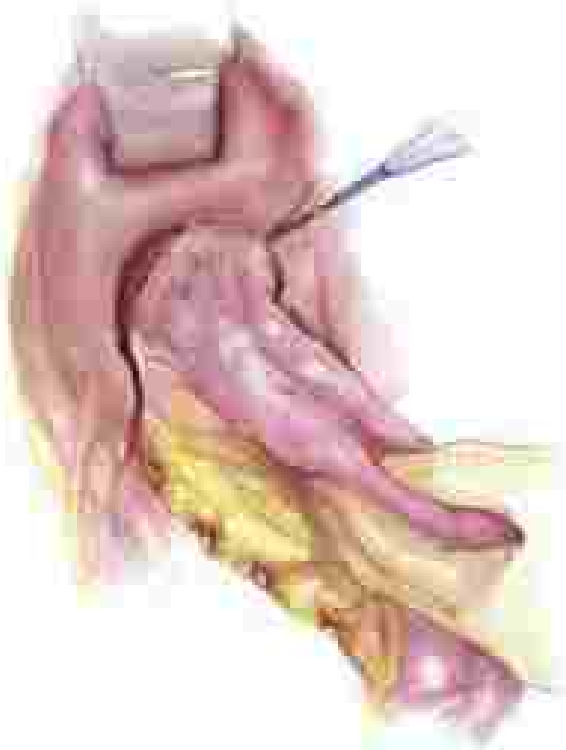

FIG. 4 Anterior peritoneal attachments divided. (Courtesy Cleveland Clinic Foundation, Department of Colorectal Surgery.)

In rectal cancer surgery, achieving a negative distal resection margin is the principal factor when deciding between a sphincter-preserving procedure and an abdominoperineal resection (APR). Historically, margins of greater than 2 cm were considered oncologically adequate. More recent studies have challenged the need for such a wide margin. However, reports comparing distal margin distance find that narrow margins of 0 to 10 mm are associated with higher risk of local recurrence. Therefore, a distal margin of greater than 1 cm is recommended when possible.

NEOADJUVANT THERAPY

Over the last 30 years, treatment of clinical stage II or III locally advanced rectal cancer has moved to an almost universal use of neoadjuvant therapy, with demonstration of reduced local recurrence rates improved sphincter preservation, even among those patients undergoing transabdominal TME surgery. Most neoadjuvant regimens include combined chemotherapy and radiation. The Swedish Rectal Cancer Trial, when comparing preoperative radiation therapy versus surgery alone, found a significant reduction in local recurrence (11% vs 27%) and an increase in 5-year survival (58% vs 48%). In another large randomized trial from the Netherlands, investigators found the long-term incidence of local recurrence was 5% in those patients receiving preoperative short-course chemoradiation therapy compared with 11% in the TME surgery alone group. Based on these and other randomized trials, treatment for clinical stage II or III should include preoperative chemoradiotherapy followed by transabdominal resection with TME.

The standard of care in patients who have undergone resection following neoadjuvant chemoradiation therapy is additional postoperative adjuvant chemotherapy with oxaliplatin-based regimen. More recently, the concept of total neoadjuvant therapy (TNT) has gained some appeal, with the administration of systemic chemotherapy and chemoradiation prior to surgery. This approach has been particularly encouraged in locally advanced rectal cancer. In most reports, induction chemotherapy is oxaliplatin based for 2 to 3 months prior to chemoradiation. Findings suggest that those patients undergoing TNT were more likely to receive the planned chemotherapy, had higher rates of complete pathologic response, and were more likely to have early reversal of the temporary ileostomy.

ROLE OF LOCAL EXCISION OF RECTAL CANCER

In treating rectal cancer, the surgeon's goal is curative resection of the tumor with minimal morbidity and mortality. Sometimes, the best operation for this is a local excision, most commonly through a transanal approach. Proper selection of patients is the key factor here. Ideal rectal tumors for this approach are below the peritoneal reflection, less than 4 cm in diameter, take up less than 40% of the rectal circumference, have no palpable or radiologically visible perirectal nodes, are mobile on digital exam, and have a well differentiated histology. Transanal excision is most commonly utilized to manage early stage rectal cancer (Tis, T1 N0) with the objective of performing a full-thickness excision of the lesion with negative margins without the intent to remove regional lymph nodes. It can be achieved with a number of surgical techniques, including the traditional Parks transanal excision, transanal endoscopic microsurgery, transanal minimally invasive surgery and, more recently, transanal robotic surgery utilizing different robotic platforms including Da Vinci surgical system and a Flex Robotic System.

RESTORATION OF GASTROINTESTINAL CONTINUITY

The emphasis of surgery for low rectal cancers is to achieve adequate oncologic outcomes in addition to obtaining good functional result and the importance of maintaining quality of life. Different surgical techniques have been described to restore intestinal continuity in patients undergoing a sphincter preserving operation (low anterior resection). These techniques include a straight colorectal anastomosis, the creation of a colonic J-pouch, or coloplasty. Evidence suggests that the J-pouch is associated with improved bowel function, particularly in the first year after surgery.

Fecal diversion by the creation of a temporary ileostomy is generally performed when performing proctectomy, particularly in patients following neoadjuvant radiation therapy. It is believed to protect or mitigate the risk of an anastomotic leak after a colorectal anastomosis. It is most beneficial when used selectively in high-risk patients with low pelvic anastomoses that are at an increased risk for leak. As some have challenged its routine use, better methods are needed to identify patients at high risk for anastomotic failure after low anterior resection. When performed, the timing of reversal or closure is also controversial. In some recent randomized trials, early closure (8–12 days) may be associated with less suffering and improved satisfaction compared with late closure (after 12 weeks).

In spite of significantly increased success of sphincter-preserving approaches, complete resection of the rectum and anus with permanent colostomy, the APR, is still required for many patients with low rectal cancers. As with restorative proctectomy, the APR must also be performed with a total mesorectal excision.

NONOPERATIVE TREATMENT

As discussed, the standard treatment for rectal cancer is neoadjuvant chemoradiotherapy followed by major resection surgery. However, there has been increasing interest in whether a nonoperative or watch and wait strategy instead of routine surgery is an option in selected patients with complete clinical response following chemoradiation therapy. Recent reports from Brazil and the Netherlands provide some support for this approach. Preoperative chemoradiation results in pathologic complete response rates of about 10% to 20% in rectal cancer, potentially avoiding the need for surgery in these patients. However, questions remain regarding the potential for increased salvage in those who have regrowth. Even with an apparent complete tumor response within the bowel wall, up to 17% can still have disease in the mesorectal lymph nodes. Moreover, the ability to adequately determine complete response clinically in most centers, as well as the challenges associated with aggressive posttreatment surveillance, limit the recommended use of this approach outside of a clinical protocol.

CONCLUSIONS

Improved imaging techniques and increased use of multidisciplinary treatment strategies have led to improved outcomes of those patients with rectal cancer. Neoadjuvant chemoradiation therapy has clearly been associated with significantly decreased local recurrence and the addition of induction combination chemotherapy, total neoadjuvant therapy, will likely be used with increased frequency. A nonoperative watch and wait strategy in selected patients with complete response after neoadjuvant therapy has been proposed, but this bold approach awaits long-term results. Improved operative results have been achieved with TME as the standard technique, with an expanding use of laparoscopic and robotic assisted techniques. Most importantly, management of rectal cancer can be challenging and is best managed when approached in a coordinated way by an experienced multidisciplinary cancer treatment team.

Management of Tumors of the Anal Region

Miriam W. Tsao, MD, and David Shibata, MD

OVERVIEW AND ANATOMY

Appreciation of the anatomic landmarks and histologic features of the anorectal region is essential to understanding management of tumors of the anal region. The anal canal measures approximately 4 cm in length and extends proximally from the dentate line (anorectal canal) or the anorectal ring (surgical anal canal) to the anal margin located at the intersphincteric groove (Fig. 1). The dentate line can be identified macroscopically by the anal valves and bases of the anal columns, while the anal margin coincides histologically with the mucocutaneous junction between nonkeratinizing squamous mucosa and keratinizing squamous epithelium with hair follicles, sebaceous glands, and sweat glands. The anal canal itself can be microscopically separated into three zones: an upper zone proximal to the dentate line featuring columnar and cuboidal cells similar to colorectal mucosa, a middle anal transition zone (ATZ) near the level of the dentate line/valves of Morgagni comprised of transitional epithelium, and finally, a distal zone containing squamous epithelium (Fig. 2). The ATZ can also contain reactive, endocrine, and melanocytic cells. This variation in cell histology throughout the three zones accounts for the array of neoplasms that may arise from the anal canal.

The proximal anal canal is supplied by the superior rectal artery and venous drainage occurs via the superior rectal veins (tributaries of the inferior mesenteric vein), as well as the middle rectal veins (into the internal iliac veins). The distal anal canal is supplied by the inferior rectal branch of the pudendal artery, and venous drainage occurs to the inferior hemorrhoidal vessels then to the internal iliac veins. Lymphatic drainage from the proximal anal canal (above the dentate line) is into the mesorectal, internal iliac and inferior mesenteric lymph nodes. In contrast, the lower anal canal drains to the inguinal lymph nodes. This is particularly important when considering regional spread of anal lesions.

Although anal cancer is rare, its incidence is increasing and it now accounts for 2.4% of all newly diagnosed gastrointestinal malignancies within the United States. Most (80%) anal canal malignancies are of squamous origin, 10% are adenocarcinomas, and 5% are other types, such as melanoma and small cell. Although patients with anal tumors may present with symptoms such as bleeding, pain, and discharge, they are frequently asymptomatic and lesions are diagnosed incidentally.

SQUAMOUS NEOPLASMS

Human Papillomavirus and Anal Squamous Neoplasia

Human papillomavirus (HPV) is the most common sexually transmitted infection, with a prevalence of 42% among all adults within the United States and up to 93% among human immunodeficiency virus (HIV)–positive men who have sex with men (MSM). Over 100 HPV types have been identified, with over one third affecting the anogenital region; however, only a few types have been associated with anal carcinoma, mainly HPV 16 and 18. Additionally, HPV infection is associated with squamous cell carcinoma (SCC) of other areas of the genital tract but also of the oropharynx. Epidemiologic studies worldwide have identified the presence of HPV in up to 94% of anal carcinomas and up to 100% of premalignant anal lesions. The development of HPV vaccines targeting oncogenic HPV types has subsequently been associated with decreased rates of anogenital malignancy. The Centers for Disease Control and Prevention (CDC) currently recommends a two dose HPV vaccination schedule for all children at age 11 to 12 and a three dose vaccination schedule for women up to age 26, men up to age 21, and for high risk patients, such as patients with HIV. Within the United States, however, vaccine uptake remains suboptimal, and therefore anogenital malignancies will likely continue to be a relevant issue in the foreseeable future.

Condylomata Acuminatum (Anal Warts)

Condylomata acuminata, or anal warts, occur when a patient is infected by certain types of HPV, with nononcogenic types 6 and 11 accounting for approximately 90% of lesions. Lesions typically appear as flat or raised flesh-colored papules or plaques associated with discomfort or pruritus. The lag time between HPV infection and the appearance of condylomata can range from weeks to months, and spontaneous regression, mediated by the patient's own immune system is common, even in the setting of HIV/AIDS (acquired immunodeficiency syndrome).

Management of condylomata can include medical and surgical approaches; however, there are limited data to guide optimal therapy. Evaluation should always include a thorough anogenital examination, including anoscopy to examine the anal canal, and women should be referred for a Papanicolaou (Pap) smear. Biopsy should be considered if lesions are pigmented, indurated, bleed spontaneously, or ulcerated, or if there is no response to standard therapy.

Treatment of condylomata consists of topical patient administered treatments and provider administered treatments. Topical therapies include imiquimod cream, podophyllotoxin, 5-fluorouracil (5-FU) and sinecatechins, all of which have moderate efficacy, with clearance rates of 40% to 60%. Their use for larger lesions is limited, however, due to significant local irritation and systemic toxicity. Current CDC recommendations for provider administered treatment include 80% to 90% trichloroacetic acid (TCA) cryotherapy, or surgical fulguration/excision and are typically employed when other medical therapy fails. Surgical excision for condylomata is typically reserved for giant condylomas. Recurrence rates for all provider administered treatment, however, remain between 20% and 40%, likely as a result of persistent HPV infection.

The Buschke-Lowenstein tumor (BLT), verrucous carcinoma or giant condyloma acuminatum is a rare, slow growing lesion characterized by exophytic, ulcerative, and cauliflower like tumors most commonly in the anogenital region with a tendency for local invasion and frequent fistula or abscess formation (Fig. 3). It differs from SCC in that it lacks lymphatic involvement and is unlikely to metastasize, but rather spreads laterally. As with condylomata acuminatum, BLT is thought to be caused by HPV infection, most commonly types 6 and 11. Wide local excision (WLE) remains the mainstay of treatment, with abdominoperineal resection and pelvic exenteration reserved for extensive disease. Unfortunately, even with optimal management recurrence rates are from 40% to 70% with a 30% to 50% rate of malignant transformation.

Management of Tumors of the Anal Region

Miriam W. Tsao, MD, and David Shibata, MD

OVERVIEW AND ANATOMY

Appreciation of the anatomic landmarks and histologic features of the anorectal region is essential to understanding management of tumors of the anal region. The anal canal measures approximately 4 cm in length and extends proximally from the dentate line (anorectal canal) or the anorectal ring (surgical anal canal) to the anal margin located at the intersphincteric groove (Fig. 1). The dentate line can be identified macroscopically by the anal valves and bases of the anal columns, while the anal margin coincides histologically with the mucocutaneous junction between nonkeratinizing squamous mucosa and keratinizing squamous epithelium with hair follicles, sebaceous glands, and sweat glands. The anal canal itself can be microscopically separated into three zones: an upper zone proximal to the dentate line featuring columnar and cuboidal cells similar to colorectal mucosa, a middle anal transition zone (ATZ) near the level of the dentate line/valves of Morgagni comprised of transitional epithelium, and finally, a distal zone containing squamous epithelium (Fig. 2). The ATZ can also contain reactive, endocrine, and melanocytic cells. This variation in cell histology throughout the three zones accounts for the array of neoplasms that may arise from the anal canal.

The proximal anal canal is supplied by the superior rectal artery and venous drainage occurs via the superior rectal veins (tributaries of the inferior mesenteric vein), as well as the middle rectal veins (into the internal iliac veins). The distal anal canal is supplied by the inferior rectal branch of the pudendal artery, and venous drainage occurs to the inferior hemorrhoidal vessels then to the internal iliac veins. Lymphatic drainage from the proximal anal canal (above the dentate line) is into the mesorectal, internal iliac and inferior mesenteric lymph nodes. In contrast, the lower anal canal drains to the inguinal lymph nodes. This is particularly important when considering regional spread of anal lesions.

Although anal cancer is rare, its incidence is increasing and it now accounts for 2.4% of all newly diagnosed gastrointestinal malignancies within the United States. Most (80%) anal canal malignancies are of squamous origin, 10% are adenocarcinomas, and 5% are other types, such as melanoma and small cell. Although patients with anal tumors may present with symptoms such as bleeding, pain, and discharge, they are frequently asymptomatic and lesions are diagnosed incidentally.

SQUAMOUS NEOPLASMS

Human Papillomavirus and Anal Squamous Neoplasia

Human papillomavirus (HPV) is the most common sexually transmitted infection, with a prevalence of 42% among all adults within the United States and up to 93% among human immunodeficiency virus (HIV)–positive men who have sex with men (MSM). Over 100 HPV types have been identified, with over one third affecting the anogenital region; however, only a few types have been associated with anal carcinoma, mainly HPV 16 and 18. Additionally, HPV infection is associated with squamous cell carcinoma (SCC) of other areas of the genital tract but also of the oropharynx. Epidemiologic studies worldwide have identified the presence of HPV in up to 94% of anal carcinomas and up to 100% of premalignant anal lesions. The development of HPV vaccines targeting oncogenic HPV types has subsequently been associated with decreased rates of anogenital malignancy. The Centers for Disease Control and Prevention (CDC) currently recommends a two dose HPV vaccination schedule for all children at age 11 to 12 and a three dose vaccination schedule for women up to age 26, men up to age 21, and for high risk patients, such as patients with HIV. Within the United States, however, vaccine uptake remains suboptimal, and therefore anogenital malignancies will likely continue to be a relevant issue in the foreseeable future.

Condylomata Acuminatum (Anal Warts)

Condylomata acuminata, or anal warts, occur when a patient is infected by certain types of HPV, with nononcogenic types 6 and 11 accounting for approximately 90% of lesions. Lesions typically appear as flat or raised flesh-colored papules or plaques associated with discomfort or pruritus. The lag time between HPV infection and the appearance of condylomata can range from weeks to months, and spontaneous regression, mediated by the patient's own immune system is common, even in the setting of HIV/AIDS (acquired immunodeficiency syndrome).

Management of condylomata can include medical and surgical approaches; however, there are limited data to guide optimal therapy. Evaluation should always include a thorough anogenital examination, including anoscopy to examine the anal canal, and women should be referred for a Papanicolaou (Pap) smear. Biopsy should be considered if lesions are pigmented, indurated, bleed spontaneously, or ulcerated, or if there is no response to standard therapy.

Treatment of condylomata consists of topical patient administered treatments and provider administered treatments. Topical therapies include imiquimod cream, podophyllotoxin, 5-fluorouracil (5-FU) and sinecatechins, all of which have moderate efficacy, with clearance rates of 40% to 60%. Their use for larger lesions is limited, however, due to significant local irritation and systemic toxicity. Current CDC recommendations for provider administered treatment include 80% to 90% trichloroacetic acid (TCA) cryotherapy, or surgical fulguration/excision and are typically employed when other medical therapy fails. Surgical excision for condylomata is typically reserved for giant condylomas. Recurrence rates for all provider administered treatment, however, remain between 20% and 40%, likely as a result of persistent HPV infection.

The Buschke-Lowenstein tumor (BLT), verrucous carcinoma or giant condyloma acuminatum is a rare, slow growing lesion characterized by exophytic, ulcerative, and cauliflower like tumors most commonly in the anogenital region with a tendency for local invasion and frequent fistula or abscess formation (Fig. 3). It differs from SCC in that it lacks lymphatic involvement and is unlikely to metastasize, but rather spreads laterally. As with condylomata acuminatum, BLT is thought to be caused by HPV infection, most commonly types 6 and 11. Wide local excision (WLE) remains the mainstay of treatment, with abdominoperineal resection and pelvic exenteration reserved for extensive disease. Unfortunately, even with optimal management recurrence rates are from 40% to 70% with a 30% to 50% rate of malignant transformation.

Anal Intraepithelial Neoplasia

Epidemiology and Histologic Features

As with cervical intraepithelial neoplasia and the development of cervical cancer, anal intraepithelial neoplasia (AIN) is considered a precursor to SCC of the anus and has historically been graded according to the degree of dysplasia: AIN I (low grade), AIN II (moderate grade) and AIN III (high grade or SCC in situ). These lesions can involve the perianal skin, anal canal, and are strongly associated with HPV types 16 and 18 for high grade lesions and types 6 and 11 for low grade lesions. In 2012, however, the Lower Anogenital Squamous Terminology Standardization project attempted to unify nomenclature across all HPV-related lesions. This consolidated the three categories into two, with low grade squamous intraepithelial lesion (LSIL) corresponding to AIN I and high grade squamous intraepithelial lesion (HSIL) corresponding to AIN II/III. The use of the term *flowerik disease*, which has traditionally referred to squamous cell carcinoma in situ, has been discouraged by the same coalition. This classification is intended to reduce interobserver variability and is currently the most commonly used terminology. Cytologic specimens collected by anal Pap smear utilize the Bethesda classification system, which classifies cells as atypical squamous cells of undetermined significance (ASCUS), LSIL, HSIL, and atypical squamous cells cannot exclude HSIL.

Histologically squamous intraepithelial lesions (SIL) are characterized by cellular and nuclear abnormalities in squamous epithelial cells, not extending into the basement membrane. SIL abnormalities include loss of epithelial stratification and nuclear polarity with development of nuclear polymorphism, hyperchromasia, mitosis, and increased mitotic activity. SIL may also demonstrate koilocytes—enlarged cells with a cytoplasmic halo surrounding the nucleus indicating active HPV replication. LSIL is defined as the replacement of the lower third of the

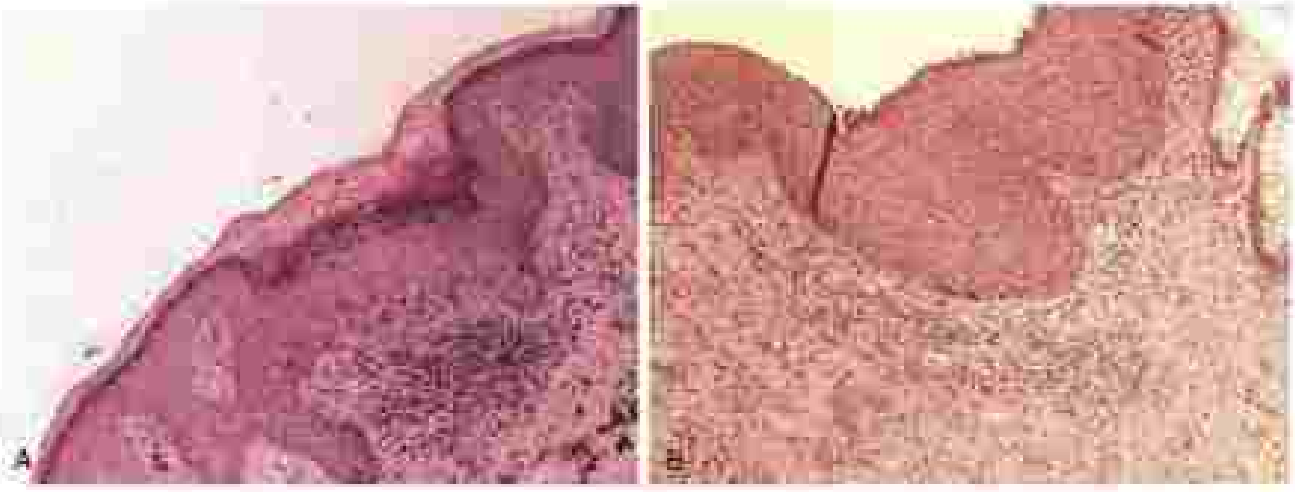

FIG. 4 (A) Low-grade squamous intraepithelial lesion demonstrating atypia limited to the lower third of the epithelium characterized by increased nuclear: cytoplasmic ratio and nuclear irregularity. (B) HSIL showing dysplastic cells throughout the epithelium. Note there is no keratinized basal layer with the top of the epithelium identical in appearance to the bottom. (Courtesy Dr Dennis O'Brien, Memphis, TN.)

epithelium by abnormal cells, while in HSIL the middle/upper thirds of the epithelium are also comprised of abnormal cells (Fig. 4). P16 is a cyclin dependent kinase inhibitor that is overexpressed in HPV-associated carcinogenesis, and its immunohistochemical expression has been utilized to better differentiate between benign/LSIL lesions and HSIL. HSIL demonstrates strong and diffuse nuclear staining of p16, while in LSIL benign lesions the expression is focal or patchy with minimal nuclear staining. Other markers of interest include Ki-67 and ProEx C, with some studies supporting improved sensitivity and specificity when used in combination with p16.

Diagnosis

The true burden of anal SIL is difficult to estimate in the general population due to a lack of population-based screening and validated testing; nonetheless, it is thought to be less than 1%. The risk factors typically associated with HPV infection include multiple sexual partners, anal receptive intercourse, immunosuppression (particularly HIV positivity), smoking, and genital dysplasia. Patients with SIL are typically asymptomatic, with lesions often presenting as an incidental finding after minor surgery. Symptomatic patients can present with rectal bleeding, irritation, pruritus, discharge, and/or soreness, with associated skin changes such as plaques, pigmentation or erythema.

There is limited literature on the natural history of SIL; however, both LSIL and HSIL have been noted to regress with observation alone. The estimated risks of progression have generally been derived from small cohort studies. In immunocompetent patients, the risk of progression from HSIL to SCC is not well documented, while

progression from LSIL to HSIL has been described to occur in less than 50% of HIV-positive MSM after 2 years and SIL to SCC in 10% to 15% of HIV-positive patients.

Anal cancer screening in high-risk populations such as HIV-positive and MSM patients remains controversial as there are false-negative rates of up to 42% and no definitive studies showing improved outcomes. Conversely, it has been suggested that targeted screening may be potentially cost effective by preventing anal SCC, and has been implemented suitably with annual anal Pap smear followed by high-resolution anoscopy (HRA) for any ASCUS or dysplasia.

HRA involves the application of high-magnification colposcopy to the anal canal. Enhancement of visualization is achieved by the use of 3% acetic acid solution with dysplastic areas demonstrating acetowhite staining. The mucosa is also inspected for characteristic HSIL-associated changes that consist of punctation and mosaicism of the vasculature as well as hyperpigmentation of the epithelium. Lugol's iodine solution can also then be applied to the anal canal, causing browning of the normal mucosa and yellowing of areas with HSIL due to the absence of glycogen (Fig. 5). This approach can facilitate targeted biopsies and subsequent therapeutic management.

Management

LSIL, and possibly even select cases of HSIL, can be managed with surveillance every 3 to 6 months, with or without HRA, as there is a reasonably low risk of disease progression and directed treatment is not without associated morbidity. Nevertheless, directed therapy has been reported to clear up to 80% of HSIL with less than 5% progression to SCC, and therefore local therapy is currently recommended for HSIL, while the role of local therapy for LSIL remains controversial. The Anal Cancer HSIL Outcomes Research study is a multicenter, randomized phase III trial that is currently accruing patients and aims to clarify whether topical therapy, ablative therapy, or observation should be used to manage HSIL in HIV-positive patients.

Topical therapies include 3% imiquimod cream, 5-FU, or TCA. Imiquimod is an immune modulator with cohort and case studies demonstrating 77% to 86% response rates; however, there are substantial recurrence rates, and side effects such as irritation, burning, and erosions may affect compliance. Similarly, topical 5-FU has demonstrated response rates up to 80% with recurrence in 50%, while TCA has been reported in retrospective studies to result in a 71% to 79% response rate. Although well tolerated, there are a significant proportion of nonresponders and high recurrences after topical therapy, and they should therefore be considered adjuncts to local therapies. Photodynamic therapy, which involves the application of photosensitizing creams to the affected area followed by laser treatment, has also been described; however, data are too limited to draw any conclusions regarding its efficacy.

Local ablative therapies include radiofrequency ablation (RFA), infrared coagulation, and electrocautery. Electrocautery has been reported to result in 66% response rates in HIV-positive MSM, with higher response rates after multiple sessions, although recurrence rates were 25% at 30 months. Studies examining RFA's initial efficacy are limited at this point; however, they typically show high initial response rates from 68% to 80% followed by more than 40% recurrence. These studies demonstrate that HIV-positive patients consistently experience significantly higher rates of recurrence, potentially due to ongoing exposure to predisposing risk factors.

Although surgical therapy continues to remain a viable option, particularly for lesions occupying less than 30% of the anal circumference, its utility is limited in SIL, despite 1 cm margins and the use of frozen section, clearance of all disease is difficult and recurrence rates are high. Historically, perianal mapping was routinely used in the setting of perianal SIL and currently continues to be applied; however, it is more recently considered potentially unnecessary. Frequently, WLE results in high rates of wound complications such as stenosis and incontinence as well as in significant deficits requiring the use of local flaps.

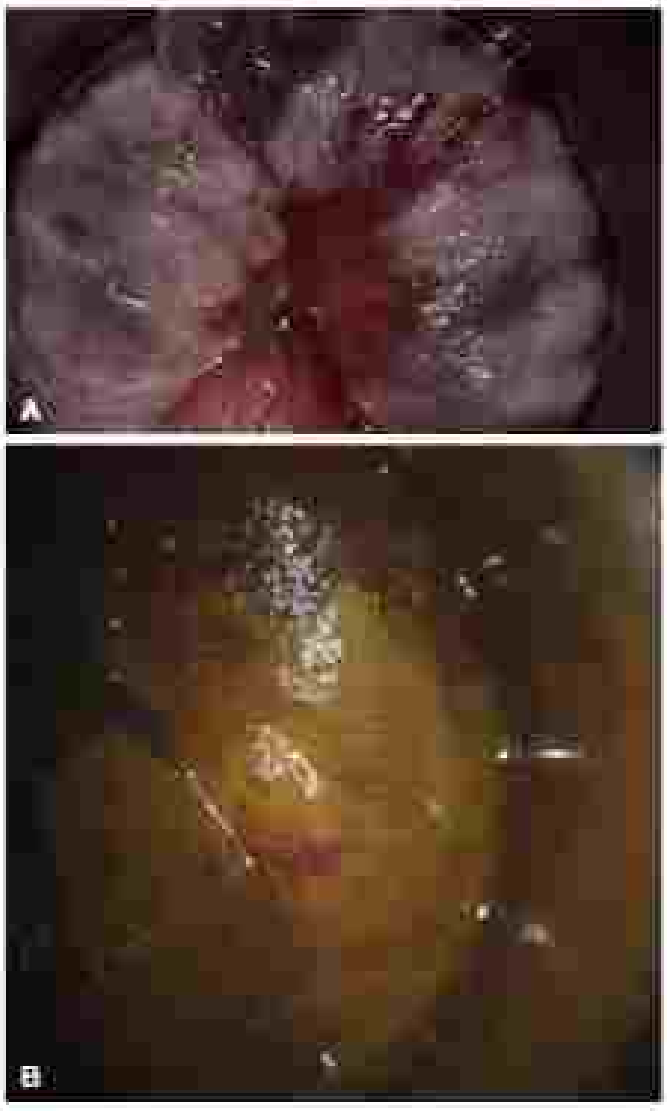

FIG. 5. High-resolution anoscopic view of high-grade squamous intraepithelial lesion (HSIL). (*A*) Acetowhite staining of dysplasia with vascular punctation. (*B*) Mustard yellow staining of HSIL with Lugol's solution (arrow). Note normal mucosa stains brown. (*Courtesy Dr Stephen Goldstone, New York, NY.*)

Recurrence rates for SIL are not insignificant, and therefore ongoing surveillance is paramount. The ideal surveillance interval and modality, however, remains up for debate. The American Society of Colon and Rectal Surgeons recommends 3- to 6-month intervals in the setting of dysplasia, with follow up consisting of digital rectal exam and office-based anoscopic examination with or without HRA, acetic acid, or Lugol's (Fig. 6).

Superficially Invasive Squamous Cell Carcinoma

Superficially invasive squamous cell carcinoma of the anus is a minimally invasive form of anal cancer defined by the College of American Pathologists as a completely excised anal cancer with 3 mm or less basement membrane invasion and a maximal horizontal spread of 7 mm or less. It is typically diagnosed incidentally on excisional biopsy and is unique in that excision alone is associated with good outcomes, with rates of 90% success reported after 4 years.

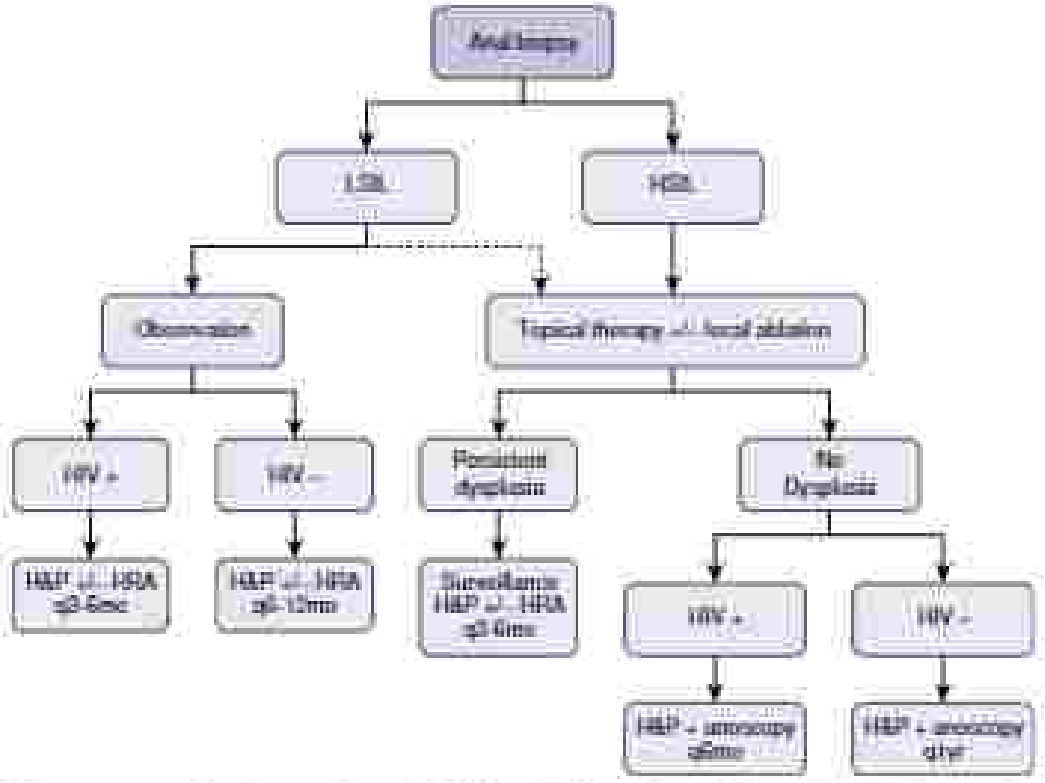

FIG. 6 Algorithm for the management of anal squamous intraepithelial lesions. HIV, Human immunodeficiency virus; H&P, history and physical examination; HRA, high-resolution anoscopy; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion.

Squamous Cell Carcinoma

Presentation

At the time of diagnosis, 68% of anal carcinomas are confined to the primary site, 32% involve regional lymph nodes and 3% are associated with metastatic disease. Anal cancers are frequently diagnosed late, as 20% of patients are asymptomatic and 45% present with anorectal bleeding, which is commonly attributed to hemorrhoids (Fig. 7). Thirty percent of patients experience anorectal pain and fullness, while others experience narrowing of stool caliber, a change in bowel habits, and tenesmus. Initial evaluation involves a detailed history to assess for risk factors such as MSM, receptive anal intercourse, and immunosuppression, as well as details of local regional symptoms such as groin pain/discomfort. The patient's baseline sphincter continence should be established, and any anorectal bleeding should be quantified. A history of poorly controlled HIV or previous radiation is important to elicit, as this may limit subsequent therapeutic approaches. Physical examination should involve thorough inspection of the perianal skin/anal margin and a digital rectal exam. Attention should be paid to sphincter tone, size and location of the tumor as well as fixation to nearby structures such as the vagina and prostate. The bilateral inguinal basins should be examined for lymphadenopathy. Women should undergo cervical and vulvar evaluation, while men should receive a penile/scrotal exam.

FIG. 7 Anal squamous cell carcinoma targeting mass at the anal verge.

Staging

According to the American Joint Committee on Cancer 8th edition, anal cancers are staged according to tumor size and involvement of adjacent structures, nodal involvement, and distant metastases. All staging occurs prior to initiation of any treatment and begins with digital rectal exam, anoscopy, and biopsy of the primary tumor. Histologically, SCC is defined by invasion of tumor cells into the basement membrane, which differentiates it from SIL. Any concerning groin lymphadenopathy on physical exam should be biopsied with fine needle aspiration to rule out lymphatic spread. Radiologic staging involves computed tomography (CT) of the chest, abdomen, and pelvis as recommended by the National Comprehensive Cancer Network (NCCN) guidelines. Magnetic resonance imaging of the pelvis can be used for more detailed local regional evaluation but is not mandatory. Similarly, positron emission tomography/CT (PET/CT) may provide additional information for staging verification, but it is not mandatory nor is it a replacement for standard CT imaging. The use of PET/CT for the enhancement of radiation oncology treatment planning has also been described.

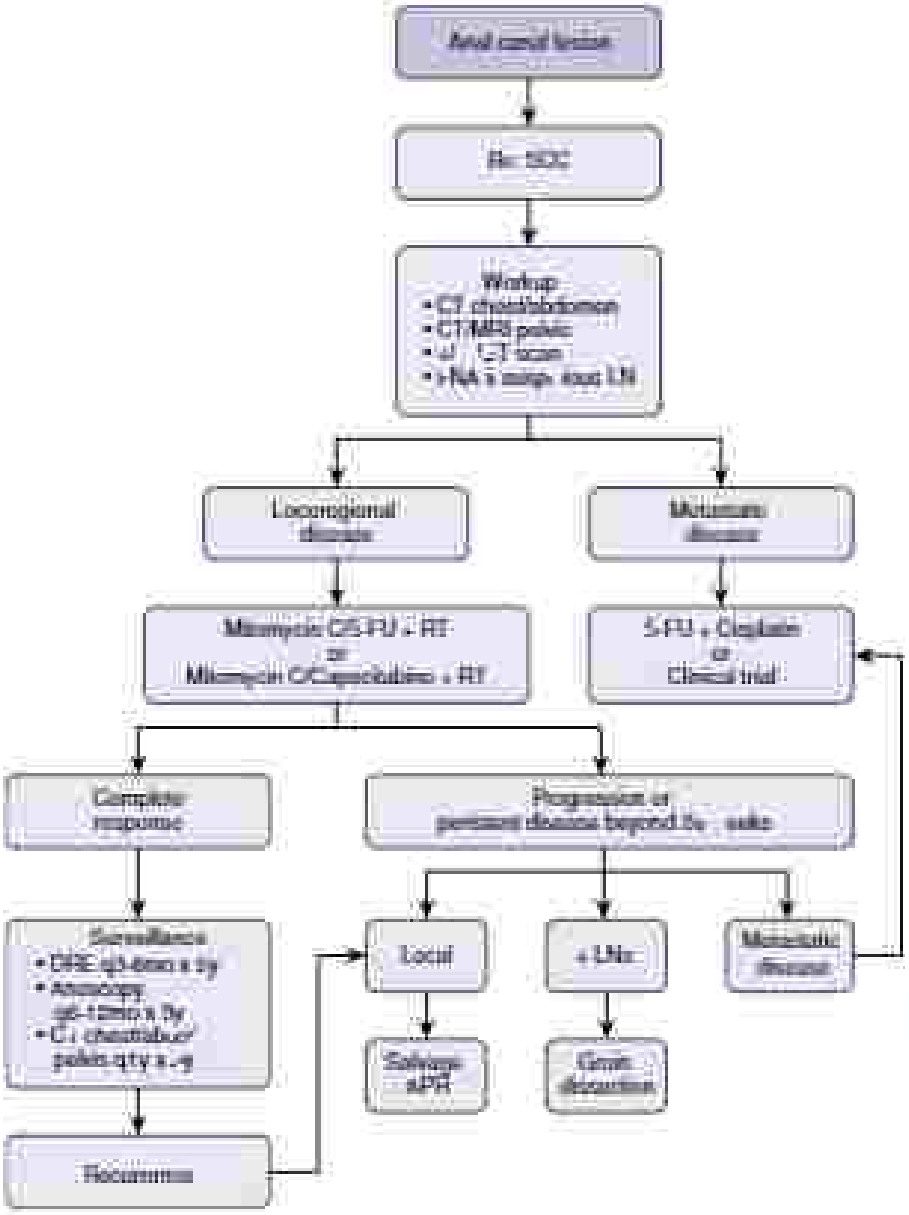

FIG. 8 Algorithm for the workup and management of anal canal squamous cell carcinoma (SCC). Abbr: AAdenocarcinoma; APR, abdominoperineal resection; Bx, biopsy; CT, computed tomography; DRE, digital rectal examination; FNA, fine needle aspiration; LN, lymph node; MRI, magnetic resonance imaging; PET, positron emission tomography; RT, radiotherapy; 5-FU, 5-fluorouracil.

Treatment

Prior to the 1980s, SCC of the anal canal was treated definitively with radical surgical resection. This involved an abdominoperineal resection (APR), which left patients with a permanent end colostomy, a perineal wound at significant risk for complications, and a 3% risk of perioperative mortality, all with a 5-year overall survival rate between 40% and 20%. In 1974, Dr. Norman Nigro and colleagues sought to decrease surgical failure rates by administering neoadjuvant chemoradiation with 5-FU, mitomycin C (MMC) and 30 Gray (Gy) of radiation to the full pelvis over 3 weeks in 3 patients. It was subsequently observed that following APR, specimens very frequently revealed no evidence of tumor on final pathology. This led to a substantial paradigm shift towards the nonsurgical management of anal cancer. Since then, numerous randomized controlled trials (RCTs) have confirmed the efficacy of concurrent 5-FU and MMC with radiation, even in the setting of HIV positivity, resulting in the preservation of surgery as a salvage option for persistent/recurrent disease after definitive chemoradiation (Fig. 8).

Continued modality therapy has undergone several revisions since the initial Nigro protocol. Current protocols typically involve 5-FU based concurrent chemotherapy (infusional or orally as capecitabine) with MMC on days 1 or 1 and 29 with a minimum of 45 Gy radiation administered over 5 weeks. The radiation fields include the pelvis, anus, perineum and inguinal nodes, with boosts based on areas of involvement, combined modality therapy is the treatment of choice for local regional disease. The radiation potentiating effects of chemotherapy are significant, as this regimen leads to complete tumor regression in 80% to 90% of cases compared with 45% to 65% with radiation alone, and 5-year operative survival rates as high as 65% with chemoradiation.

Cisplatin has been examined as a replacement for MMC in the Radiation Therapy Oncology Group (RTOG) and United Kingdom Coordinating Committee on Cancer Research Anal Cancer Trial (ACT) II trials in an attempt to decrease hematologic toxicity; however, it demonstrated inferior outcomes, and therefore MMC remains standard of care. Other studies have investigated the addition of epidermal growth factor receptor inhibitors cetuximab or panitumumab to standard chemoradiation; however, these were associated with high levels of toxicity and poor outcomes. Radiation has also continued to be refined over the years, and current guidelines recommend the

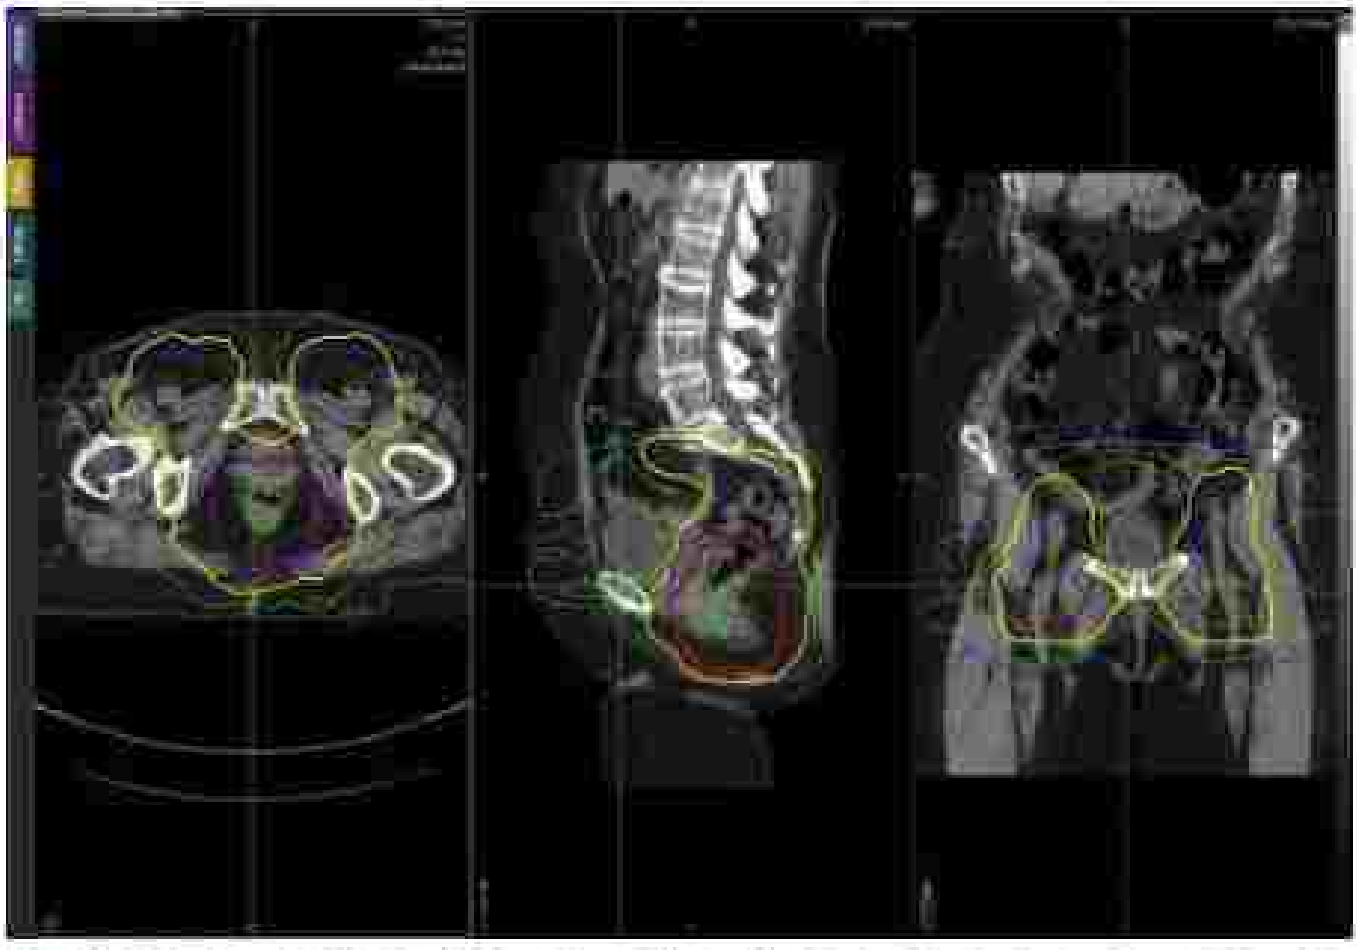

FIG. 4 Axial, sagittal, and coronal dose distributions of a planning computed tomography scan for anorectal intensity-modulated radiation therapy. Each colored line corresponds to a specific radiation dose. (Courtesy of Adam Kachnowski, Memphis, TN.)

use of intensity-modulated radiation therapy in order to spare adjacent organs and minimize toxicity. This technique breaks the radiation field into multiple beamlets of varying intensity administered in a three-dimensional fashion, allowing for increased precision, albeit at a higher up-front cost (Fig. 4). Application of this method also requires expertise and careful design to minimize reductions in local control, limiting its widespread use at all centers. Side effects of chemoradiation can be acute and/or chronic, and include gastrointestinal side effects (e.g., diarrhea, nausea, incontinence, and pain), urinary symptoms (e.g., frequency, incontinence, and dysuria), and sexual side effects (e.g., decreased libido, erectile dysfunction, and dyspareunia).

Role of Surgery

Anal SCC response to chemoradiation continues even beyond completion of treatment, and guidelines therefore recommend re-evaluation with visual exam and digital rectal exam (DRE) at 8 to 12 weeks after completion of chemoradiation. Patients are then classified into complete response, persistent disease, or progressive disease. In a subanalysis of the ACCUI trial comparing mitomycin versus cisplatin in 5-FU–based chemoradiation, 72% of patients without a complete response at 11 weeks achieved a complete response by 26 weeks. Persistent disease without evidence of progression can therefore be reassessed short term (4 weeks) for regression up to 6 months. Progressive or persistent disease beyond 6 months warrants repeat biopsy.

Surgery is typically reserved for local regional recurrence/persistence after chemoradiation, which has been reported to occur in 10% to 30% of patients. For patients recurring locally within the anal canal/perineum, salvage APR is the primary treatment, with a 5-year OS of 25% to 60% compared to a 5-year OS of 5% for patients who are not surgical candidates. Large recurrences, adjacent organ involvement, persistent disease, positive resection margins, and HIV positivity portend a worse prognosis. Many patients requiring salvage APR are predisposed to poor perineal healing due to prior chemoradiation and the need for wide margins and thus may benefit from reconstructive tissue flaps such as the vertical rectus abdominis myocutaneous (VRAM) flap or local myocutaneous flaps (e.g., gracilis, gluteal). Patients undergoing minimally invasive APR may preferentially undergo local myocutaneous flaps, as open approach VRAM flap harvest negates the benefits of a minimally invasive approach. There is growing interest in minimally invasive harvesting techniques for rectus abdominis flaps. It is generally recommended that patients presenting with isolated inguinal recurrence after chemoradiation undergo inguinal node dissection.

Posttreatment Surveillance

The NCCN guidelines recommend evaluation with physical exam, DRE, and anoscopy every 3 to 6 months for 5 years for patients with a complete response after chemoradiation. Additionally, patients with T3/T4 or N-positive disease on initial presentation or patients who received salvage APR should undergo CT chest, abdomen, and pelvis for the first 3 years.

Metastatic Disease

Ten to twenty percent of patients will present with metastatic disease, most commonly in the liver, lungs, lymph nodes, peritoneum, bones, and brain. Due to its rarity, there is a paucity of evidence supporting

the use of chemotherapy in this setting, however, the most common regimen is 5-FU and cisplatin. Most studies have demonstrated a response rate of approximately 60%, most of which are partial responses, and many patients experience disease progression within the first 12 months. Several small, retrospective studies have also examined carboplatin plus paclitaxel as a first line option with some durable responses. More recently, nivolumab and pembrolizumab, immunotherapy against the programmed cell death ligand receptor (PD-1), have been examined in phase I and II trials as second line therapy with response rates of 17% to 24%.

Perianal Cancer

Tumors at or within 5 cm distal to the anal margin (squamous mucocutaneous junction) are typically described as perianal cancers if they can be seen in their entirety with gentle traction placed on the buttocks. Traditionally, such lesions have been thought to behave similarly to skin cancers, however, they are staged in the same manner as anal canal cancers. National and international guidelines recommend WLE with 1 cm margins for T1N0, well differentiated perianal SCC, while more advanced perianal cancers are managed with definitive chemoradiation.

ADENOCARCINOMA

Most anal adenocarcinomas originate from the columnar epithelium in the upper anal canal or glandular cells of the ATZ and can be difficult to differentiate from low rectal adenocarcinomas. They can also originate from anal glands and chronic fistula tracts, which are typically defined as perianal adenocarcinomas. Patients can present with anal pain, discomfort, or abscess formation. Due to its rarity, treatment recommendations are based on small cohort studies and experiences with low rectal adenocarcinoma. Although WLE can be considered for T1 well differentiated tumors with no high risk features, T2 lesions and greater should generally be managed with neoadjuvant chemoradiation using a rectal adenocarcinoma protocol followed by APR and adjuvant chemotherapy.

PAGET'S DISEASE

Extramammary Paget's disease occurs where apocrine glands are found, including the perianal region. Diagnosis is typically delayed, as signs and symptoms are limited and can be mistaken for eczema or dermatitis. Skin biopsy is confirmatory, with histology revealing an intraepithelial adenocarcinoma characterized by large rounded vacuolated Paget cells. Paget's disease can be a primary lesion arising from the apocrine glands or as a synchronous or metachronous lesion from another site, with 33% to 86% of patients having previous or concurrent colorectal or genitourinary malignancy. It has therefore been suggested that patients undergo colonoscopy, evaluation as well. It is recommended that complete assessment of the anal margin with random mapping biopsies be performed to detect microscopic disease. This typically involves random biopsies taken at radial intervals beginning at the dentate line and around the anus in a clocklike fashion (Fig. 18).

The mainstay of treatment is WLE with a 1 cm margin. Frequently, the remaining defect is not amenable to primary closure and requires the use of myocutaneous or cutaneous flaps. Based on small series, recurrence rates after WLE have been reported to be 30% to 40%, with 5 year OS rates of 60% to 67%, suggesting that despite high local recurrence rates, Paget's disease does not tend to be systemically aggressive. If lesions are locally invasive or occur in conjunction with an anorectal adenocarcinoma, neoadjuvant chemoradiation followed by APR is the treatment of choice.

MELANOMA

Anal melanoma is rare and accounts for less than 2% of all melanomas. Patients typically present with bleeding, pain, or perianal mass, with pigmented lesions commonly mistaken for thrombosed hemorrhoids, while 30% are amelanotic. Prognosis is poor regardless of surgical approach with median survival reported to be less than 2 years. Retrospective studies have demonstrated the development of early distant metastases in most patients, therefore, where possible, preferred surgical treatment is typically WLE, with APR reserved for patients with extensive sphincter involvement, particularly bulky tumors or significant incontinence.

FIG. 18 Anal mapping. Four quadrant biopsies are obtained, starting at the dentate line, at the anal verge, and on the perianal skin. They are sent separately to the pathologist for permanent section.

NEUROENDOCRINE TUMORS AND MESENCHYMAL TUMORS

Neuroendocrine tumors arising from colorectal type mucosa or in the ATZ can occasionally arise in the anal canal, as well as mesenchymal tumors such as smooth muscle tumors or gastrointestinal stromal tumors. Typically, lesions are small and can be managed with local excision alone, with radical resection reserved for larger or locoregionally advanced tumors.

MALIGNANT LYMPHOMA

Although rare, Hodgkin's and non-Hodgkin's lymphomas have been reported in the anal canal, particularly in immunocompromised patients. These are typically high grade B cell lymphomas and are primarily treated with chemoradiation.

PET Scanning in the Management of Colorectal Cancer

James Taylor, MBBChir, MPH, and Bashar Safar, MBBS

Fluorine-18 fluorodeoxyglucose (¹⁸F-FDG) is a glucose analogue that carries a positron emitting isotope (¹⁸F). ¹⁸F-FDG is preferentially taken up by metabolically active cells; however, unlike glucose, FDG cannot be metabolized and therefore accumulates within cells. The subsequent emission of photons and the intensity of the positron emission tomography (PET) signal are proportional to the accumulation of FDG in cells; thus those that are more active, such as cancer cells, will have a greater signal intensity than surrounding tissue.

Cancer cells are not the only metabolically active cells with increased glucose uptake. Inflammatory tissue and even some benign lesions accumulate FDG, therefore resulting in low sensitivity and specificity when trying to differentiate between cancerous and non-cancerous tissue. In addition, slow growing tumors with low metabolic activity, such as mucinous carcinomas, will not have a high signal with FDG PET, thus limiting its clinical use.

The positron-emitting radioisotopes used in PET imaging have a short half-life and thus minimize the radiation absorbed by the patient. Tissue activity is measured at a fixed point and normalized to body surface area. This technique is called standardized uptake value (SUV).

The main limitation of PET is the lack of anatomic correlation; for this reason it is often integrated with a contrast-enhanced computed tomography (ceCT) scan to provide further anatomic information.

INCIDENTAL DETECTION OF COLORECTAL CANCER

Incidental ¹⁸F-FDG uptake within the gastrointestinal tract frequently represents malignant or premalignant lesions. The rate of detected colorectal incidental foci ranges from 1% to 9% of FDG-PET/CT scans done for other reasons, and subsequent colonoscopy detects cancer or polyps in more than 50% of these patients.

Kayser published a retrospective study of 9023 patients who underwent PET/CT over a 4-year period for a wide variety of reasons, including cancer and nononcologic workups. A total of 82 patients without a history of colonic disease had focal colonic FDG uptake and underwent colonoscopy. From these patients, 107 foci of colonic FDG uptake at PET/CT and 150 lesions at colonoscopy were detected. Among the 107 foci of FDG uptake, 63% corresponded to a lesion at colonoscopy (true positive), whereas 39% did not (false positive). Among the 158 lesions, 57% were not FDG avid (false negative). The authors subsequently concluded that subsequent colonoscopy should not be limited to the FDG-avid region of the colon, but that the entire colon should be investigated.

A further study by van Derzy and colleagues aimed to discover whether the SUV of incidental lesions could be used to differentiate between benign and malignant lesions, and thereby help to guide the urgency of colonoscopy. They found, in a study of 2318 patients, that maximum standardized uptake value (SUVmax) was significantly higher in malignant lesions; however, it was not possible to differentiate between benign lesions and adenomas. Thus any incidental finding on PET/CT within the colon should be investigated with a full colonoscopy, without delay.

TUMOR STAGING

Initial staging of the primary tumor is paramount in the workup of colorectal cancer (CRC) to determine the best treatment strategy. The decision to opt for early surgical intervention, versus neoadjuvant therapy, hinges on accurate staging. After a histologic diagnosis of CRC, CT scanning of the chest, abdomen, and pelvis should be done to rule out malignant disease. In rectal cancer, magnetic resonance imaging (MRI), transrectal ultrasonography (TRUS), or both are performed to provide local staging information. FDG PET/CT does not play a significant role in the initial clinical assessment of CRC, but it can be of value in patients with advanced disease (stage III and IV).

COLORECTAL CANCER

The role of FDG PET/CT in primary CRC is considered limited (Table 1). In 2013 Ogo and colleagues prospectively evaluated 64 patients with CRC, mostly nonmetastatic at initial diagnosis. In their series, PET/CT changed surgical management in only two (3.2%) patients (one had a liver metastasis, whereas one had a positive supraclavicular lymph node). The authors thus conclude that FDG PET/CT should not be routinely performed as part of the initial staging protocol.

Peterson and colleagues reviewed 67 patients in a retrospective analysis, all of whom had advanced CRC. They underwent FDG-PET/CT in addition to conventional CT staging, with changes in management occurring in 20 (30%) patients. The differences in findings between the two studies are likely attributed to the different patient populations.

A study by Engelman and colleagues aimed to compare the diagnostic accuracy of FDG PET/CT with conventional CT. The accuracy for tumor, nodal disease, and metastases by FDG-PET/CT were 82%, 66%, and 80%, respectively, compared with 77%, 69%, and 69% for conventional CT. The authors noted that FDG PET/CT was particularly helpful in discriminating and characterizing "indeterminate lung lesions" found on CT. They therefore concluded that FDG PET/CT found metastatic staging showed better specificity and higher accuracy than CT for unusual metastatic deposits. These results have been echoed in a recent publication by Lee and colleagues, who noted the increase in specificity and accuracy of FDG PET/CT compared with CT for detection of lymph node metastases.

A recent meta-analysis conducted by Ye and colleagues concluded that FDG PET/CT shows good performance in preoperative tumor detection rate, T staging and M staging in patients with CRC compared with CT alone. However, they highlight that the quality of prior studies is a limiting factor. FDG PET/CT should therefore be seen as a useful diagnostic tool for staging select patients with advanced disease, suspected distal metastases, or both; however, at this time it should not be part of the initial staging workup in the majority of patients with CRC.

RECTAL CANCER

Preoperative staging for rectal cancer dictates the sequence of treatment modalities, and therefore staging accuracy is imperative. Depth of tumor penetration, the presence of lymph node metastases, adjacent organ involvement, and distant metastases, all play a role in staging rectal cancer. Treatment options based on stage range from local resection to radical surgery with either neoadjuvant or adjuvant chemoradiation therapy for more advanced lesions.

Accurate staging is traditionally accomplished using MRI, TRUS, or both to define the T and N stage and ceCT to evaluate and define the M stage. The literature is sparse regarding the use of FDG PET/CT to stage primary rectal cancer (Fig. 1).

In 2014, Ono and colleagues prospectively evaluated 97 patients diagnosed with primary rectal adenocarcinoma, who first underwent traditional ceCT, followed by FDG PET/CT. Most of the patients

TABLE 1 Effect of FDG-PET/CT on Changing Management in Patients with Newly Diagnosed Colorectal Cancer

Study	n	Study Design	Modality	Changes Resulting From PET Imaging
Park et al (2006)	100	Prospective	FDG-PET/CT	Change in management in 14%

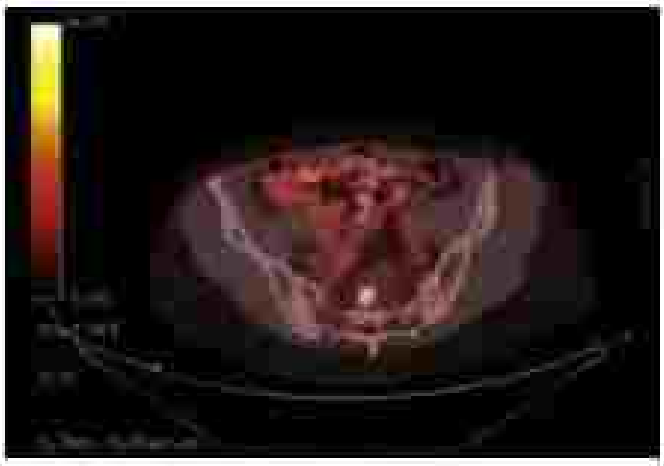

FIG. 2. Proximal jejunal mass identified on positron emission tomography-computed tomography.

were stage II or higher. CeCT and FDG-PET/CT were comparable in 62 (72%) patients; however, FDG-PET/CT provided additional data for 21 (24.4%, $P = .01$) of 97 patients. Specifically, FDG-PET/CT detected more distant metastases and lymph nodes (Fig. 2). In 14 patients (14.4%), the stage of the disease was changed, and there was a need to make adjustment to the patient's treatment strategy (n = 10) or operation type (n = 4).

The role of FDG-PET/CT in primary staging of rectal cancer remains to be fully elucidated. New techniques are being piloted, including the fusion of continuously moving table MRI and PET, which appear to improve lesion detection, especially in the case of recurrent lesions. At present, the recommendation is to reserve FDG-PET/CT for patients with advanced disease, to which the CT, MRI, or TRUS results are equivocal.

Liver Metastases

Liver metastases are present in 25% of patients at the time of initial diagnosis of CRC (Fig. 3). An additional 50% of patients will develop metastases during follow up. The liver is the most common site of hematogenous spread, and in 80% of cases this is the only organ involved. Resection of a liver metastasis is the only potential curative therapy at present, and 5 year overall survival (OS) is greater than 40% after this intervention. Predictors of early recurrence and a poor outcome include presence of extrahepatic disease, carcinoembryonic antigen (CEA) of more than 200 ng/mL, more than one tumor, size of a single tumor exceeding 5 cm, and a short disease free interval. These criteria are continuously changing, and the survival rates are improving.

Several anatomic factors should be considered before planning hepatic resection, especially the number of segments involved, proximity to major arteries, veins, and bile ducts, and the predicted volume of liver remnant that would be left after resection. The goal of liver surgery for metastatic disease is the removal of all metastatic lesions with negative margins, while preserving sufficient liver parenchyma. Often ceCT is used to evaluate the presence of metastases. Lesions are typically hypovascular during the portal venous phase. However, suboptimal accuracy has been reported for lesions less than 1cm in diameter, thus requiring a second imaging modality. MRI has a greater sensitivity compared with ceCT (95% vs 63%), especially

FIG. 3 Axial positron emission tomography-computed tomographic image showing a metastatic lesion in the left lobe of the liver.

for smaller lesions. MRI is considered the current gold standard for evaluating the liver when CRC metastases are detected by ceCT. The clinical benefit of FDG PET/CT in the assessment and surgical planning of liver metastases lies primarily in the detection of extrahepatic metastatic disease (Fig. 4), thus avoiding unnecessary laparotomies or palliative liver resections.

Several studies have investigated the value added of FDG PET/CT before liver resection on the surgical management of colorectal metastases. Moulton and colleagues randomized 404 patients with metastatic CRC (mCRC). Of the 404, 229 were randomly assigned to FDG PET/CT, whereas 134 patients were randomized to the control group of ceCT only. Of the 263 FDG PET/CT scans finally performed (seven patients dropped out of the trial), 111 provided new information; 62 were classified as negative (i.e., lesions seen on prior CT and considered malignant, but not identified on PET/CT), and 49 had abnormal or suspicious lesions as interpreted by the PET/CT reader. This resulted in a change in management in 23 patients (8%) in the FDG PET/CT group: 7 patients (2.7%) did not undergo laparotomy, 4 (1.5%) had more extensive surgery, 9 (3.4%) had additional organ surgery, and the abdominal cavity was opened, but the procedure was abandoned in 1 patient. Of note, OS was not impacted by the use of FDG PET/CT.

Huebner et al compared the rates of futile laparotomy among 188 patients who had preoperative PET/CT versus those not having PET/CT (20% and 45%, respectively). Again, despite the changes in the rate of laparotomy performance, OS and disease-free survival were not significantly affected between the FDG PET/CT group and conventional ceCT (61.3% and 35.5% vs 63.8% and 29.0%, respectively). Several other studies have found that FDG PET/CT offers potential benefit in selecting the appropriate candidates for resection; this information is summarized in Table 2.

Despite the potential benefits of FDG PET/CT in reducing futile surgical procedures, a recent study by Schulz and colleagues looked at the sensitivity and specificity of ceCT, FDG PET/CT and MRI for patients scheduled for resection of suspected CRC liver metastases. They found that for small sensitivity/specificity was 89%/81% for ceCT, 90%/87% for MRI, and 81%/99% for PET/CT. Thus they conclude that MRI should be used for detection of CRC liver metastases; however, they note that evolving techniques combining MRI and PET could potentially optimize the diagnostic performance.

Several recent studies have looked at the economic impact of adding FDG PET/CT to the workup for CRC with liver metastases. Wirring and colleagues noted in a randomized trial that the addition of FDG PET/CT to a conventional workup for potentially resectable CRC liver metastasis results in a reduction in futile laparotomies by 38%. When considering a follow-up period of 3 years and including all health care costs accumulated in this time, the addition of FDG PET/CT resulted in higher costs. However, the authors concluded in a cost-effectiveness analysis that the avoidance of unnecessary laparotomies justifies the expense. The economic benefits would be logistical, that is, improving hospital performance and quality of care because of more effective planning of operating room capacity and hospital resources. In conclusion, FDG PET/CT can improve the staging accuracy of patients with CRC liver metastases, particularly when extrahepatic disease is suspected.

FIG. 4 Sagittal positron emission tomography-computed tomographic image highlighting extensive fluorodeoxyglucose activity in the peritoneum, bowel, and diaphragm.

LUNG NODULES

The lungs are the most common extraabdominal site of metastases in CRC. The 5-year OS after resection of a lung metastasis can range between 24% and 67.8%, however, still only 4.1% of patients with synchronous pulmonary lesions are treated with surgical curative intent. Indeterminate lung lesions (ILL) are found in 4% to 42% of patients when staged with ceCT.

FDG-PET and FDG-PET/CT are well established staging modalities to assess ILL greater than 1 cm in diameter, with a sensitivity of 97% and specificity of 78%. A study by Yim et al retrospectively reviewed 106 pathologically proven ILL and showed that PET/CT had an accuracy of 81.2% in diagnosing malignancy, with a sensitivity of 86.7%, and specificity of 50%. They also noted that the likelihood of malignancy increased with SUVmax. The authors also elucidate that false-negative results can occur with small lesions, because of PET's limited spatial resolution, leading to considerable underestimation of the true anatomic or activity within the lesion.

Sim and colleagues prospectively analyzed 230 patients who underwent operation for CRC and were followed up for a median of 24 months. In 20% of them, an ILL was detected by preoperative ceCT. Patients with ILL had a FDG PET/CT performed at 3 months and a low dose ceCT performed at 6, 12, 18, and 24 months after surgery. Four patients (8.5%) had lung metastases identified at a median of 9 months after surgery, whereas two (4.3%) had other lung malignancies. In the patient population that had normal preoperative ceCT, 10 of the 180 (5.6%) developed lung metastases, detected at

TABLE 2. Management Changes by FDG-PET/CT of Patients with Colorectal Liver Metastases

Study	n	Design	Management Change (%)	Investigator Conclusions
Ruers (2006)	150	Prospective	39%	FDG PET/CT significantly reduces the number of futile laparotomies due to unsuspected extrahepatic disease.
Schmidt (2004)	36	Prospective	22%	Important additional information provided by FDG PET/CT in patient with presumed resectable CRC liver metastases.
Briggs (2011)	94	Retrospective	30%	FDG PET/CT improves staging accuracy, characterizes indeterminate lesions and helps assign patients to appropriate treatment.
McLarty (2012)	54	Retrospective	67%	FDG PET/CT profoundly affects management of patients with resectable CRC liver metastases.
Georgakopoulos (2013)	19	Prospective	37%	FDG PET/CT provides relevant information for patients with CRC liver metastases.
Chua (2007)	76	Retrospective	25%	FDG PET/CT performed better in detecting both colorectal and noncolorectal liver metastases and frequently altered patient management.
Moulton (2014)	404	Prospective	8%	FDG PET/CT compared with CT alone did not result in frequent change in surgical management.

CT, Computed tomography; FDG, fluorodeoxyglucose; PET, positron emission tomography.

a median 16 months after surgery. This was significantly later than the patients with H.L. ($P = .001$). The authors concluded that, despite the relatively low number of H.L. that turn out to be malignant, it is advisable to use FDG PET/CT scan in the follow up to detect lung metastases as soon as possible to better the prognosis.

A recent study by Shimo and colleagues found significant correlation between OS and SUVmax values of patients with pulmonary metastases who underwent resection. The 5-year OS rates of patients with SUV max of 4.5 or greater and less than 4.5 were 51.6% and 74.0%, respectively. Thus they conclude that FDG PET/CT can play a role in estimating a patient's prognosis. FDG PET/CT can be used to detect and characterize H.L during primary staging of CRC and follow up of these lesions for detection, surgical management, and perhaps even provide counseling on prognosis.

ASSESSMENT OF TREATMENT RESPONSE

Patients with mCRC usually are treated on the location and extent of disease with systemic chemotherapy and monitored by CECT. On the basis of changes in cancer cell glucose metabolism, FDG-PET/CT is able to detect response to therapy during the early phases of treatment, before morphologic changes become evident.

Colorectal Cancer

Treatment effect during chemotherapy is measured by the Response Evaluation Criteria in Solid Tumors (RECIST), which looks at changes in the morphology or size of the lesion. The main limitation of RECIST is that a decrease in size does not necessarily translate into an improvement in prognosis, and it may take several weeks before changes in size become apparent. Patients often receive a full course of chemotherapy, with its associated toxicity and side effects, before a size change is detectable. This led to the development of the Positron Emission Tomography Response Criteria in Solid Tumors, whereby FDG PET/CT is used to measure a metabolic response to a tumor. Metabolic changes can occur before an anatomic change occurs, thus defining early response to treatment and potentially predicting histopathologic response and patient outcomes.

Reports on the correlation of patient outcomes with FDG PET/CT–based metabolic response after 1 to 2 months of chemotherapy are inconsistent, partially due to methodologic issues in multimodality assessment. Hyslop and colleagues assessed 54 patients with mCRC with FDG PET before treatment and after two cycles of irinotecan-based combination chemotherapy. They measured visual changes in tumor FDG uptake and also compared it to radiologic response on CECT after 4 and 8 cycles. Using the surrogate for tumor response of a change in SUV by more than 25% during treatment, as defined by the European Organization for Research and Treatment of Cancer guidelines, they found a strong correlation between metabolic response and objective response ($r = 0.52$, $P = .00001$), with a sensitivity of 77% and a specificity of 76%. However, in contrast to radiologic response, metabolic response did not reflect survival, indicating that factors additional to the immediate inhibition of tumor cell metabolism can influence long-term outcome. This contrasts the work of de Geus-Oei, which revealed that changes in tumor glucose metabolism were highly predictive for patient outcomes. Increased rates of death and progression were associated with worse response on FDG-PET.

Mertens and colleagues used FDG PET/CT to look at 38 mCRC patients with liver metastases before and after five cycles of second-line chemotherapy. SUVmax and standardized added metabolic activity (SAM) was correlated with morphologic response, as well as progression free (PFS) and OS. Seven of the original 38 patients underwent resection of their liver lesions, and strong correlation was seen between metabolic and morphologic response. Although there was no correlation with the baseline FDG PET/CT with PFS or OS, the follow up SUVmax and SAM were found to be prognostic factors. The median PFS and OS in the patient group with a high follow-up SUVmax were 10.4 months and 32 months, compared with 14.7 months PFS and a yet unreached median OS in the low follow up SUVmax group.

In conclusion, baseline parameters measured by FDG PET/CT do not correlate with prognosis in patients with mCRC, however, changes in metabolic activity before and after chemotherapy can help to predict treatment response and can be used as prognostic indicators. Several multicenter clinical trials are currently underway to further assess the prognostic potential of FDG PET/CT.

Rectal Cancer Response to Neoadjuvant Chemoradiation

Patients with locally advanced rectal cancer (LARC) are offered neoadjuvant chemoradiation (nCRT) as a standard of care, followed by radical surgery and adjuvant chemotherapy. Assessing the treatment response can be challenging, with MRI, rectal US, or EUS often unable to differentiate between fibrosis, necrosis, inflammatory tissue, or residual tumor foci. Studies have suggested that FDG PET/CT is a more accurate method of assessing treatment response.

Li and colleagues investigated the association between FDG PET/CT parameters, CEA and tumor response in LARC patients receiving nCRT. Of the 64 patients that were prospectively studied, 38 patients were identified as responders and 19 exhibited pathologic complete response (pCR). The response index of SUVmax (RI_SUVmax) was the most accurate measure of predicting responders, whereas the CEA post and change in CEA exhibited the greatest accuracy in predicting pCR. The authors concluded that FDG PET/CT is an accurate tool for predicting tumor response to nCRT in LARC. These results were further echoed by Koo and coauthors, who looked at 107 patients with LARC who underwent nCRT with FDG PET/CT and to predict pCR. They found that a pCR occurred in 22 patients (21.4%) and showed that post nCRT SUVmax and change in the SUVmax (ΔSUVmax) were significant predictors of pCR. They also highlighted that low SUVmax (<2.5) after nCRT and a high ΔSUVmax (>62.5%) were associated with increased OS.

Recent studies have focused on detecting early response after 1 to 2 weeks of therapy, to either modify therapy or to spear unnecessary morbidity of radiation therapy. Cascini and colleagues performed a baseline FDG PET, with further scans at 12 days after initiation and at completion. They were able to correctly identify responders by decrease in SUVmean (mean value of SUV, decrease >22%, accuracy 100%) and SUVmax (decrease >42%, accuracy 94%). Ianson and colleagues also confirmed these findings, showing a significant reduction in SUVmax was detectable after the first week of therapy.

A meta-analysis performed by Mullenix and colleagues looked at 10 studies, with a total of 200 patients, to evaluate the value of FDG PET/CT to detect early response of patients with LARC receiving nCRT. FDG PET/CT was found to have a sensitivity and specificity of 79% and 78%, respectively.

Patients who achieve a pCR after nCRT have a better disease-free survival (DFS) and OS compared with partial responders and nonresponders. As such, a watch and wait approach can be adopted, with robust surveillance and early detection of regrowths allowing for a high rate of successful salvage surgery. FDG PET/CT has been suggested to form part of the surveillance algorithm. Perez and colleagues prospectively monitored 98 patients who underwent FDG PET/CT at baseline and after 6 weeks and 12 weeks after completion of neoadjuvant treatment before clinical assessment. Sixteen patients (16%) had a pCR and were managed without surgery. FDG PET/CT was used during a strict follow-up program; however, the authors found that at 6 weeks the scan was able to detect less than 50% of true complete responders.

The use of FDG PET/CT in the management of LARC continues to evolve; however, as of yet there is no definitive consensus. It has the potential to detect early responders, predict survival, and aid in the determination of pCR to guide nonoperative intervention.

DETECTION OF RECURRENCE

Local and systemic recurrence after CRC surgery occurs in up to 30% of patients in the first 2 years. Early detection allows for higher resectability and better survival, with 5-year survival rates of 30% to 40% in selected patients with single organ metastatic disease. The most common sites for recurrence are liver locally—especially for rectal cancer—and lung.

Postoperative surveillance protocols based on the site and stage of the original cancer include clinic visits with history and physical examination, CEA levels, endoscopy (sigmoidoscopy or colonoscopy), and CT scanning for 5 years after surgical resection. Intensive follow-up to ensure the detection of recurrences does not always diminish mortality rates, thus the optimal monitoring strategy remains in doubt.

Several studies have shown that FDG PET is sensitive and specific in detecting recurrence in CRC patients, thus affecting management. This remains the most common use of FDG PET in data, particularly in patients who have had potentially curative resection of liver or lung metastases. However, the clinical value and overall efficacy of FDG PET/CT in surveillance are not yet established. A recent open-label multicenter trial conducted by Subhani and colleagues enrolled patients in remission of CRC (stage II perforated, stage III, or stage IV) after curative surgery. One hundred twenty patients were in the intervention arm of 6-monthly FDG PET/CT for 3 years, whereas 119 patients in the control arm underwent usual monitoring alone (3-monthly physical and tumor marker assay, 6-monthly liver ultrasonography and chest radiography, and 6-monthly whole-body ceCT). The trial found that the failure rate (unresectable recurrence or death) was not significantly different between the intervention and control arms (29.2% and 33.7%). Multivariate analysis also showed no difference. The median time to diagnosis of unresectable recurrence (months) was significantly shorter in the intervention group (7 [range, 3–30] vs 14.5 [range, 7.5–27], $P = .016$); however, the mean cost per patient was significantly higher in the intervention group. The authors concluded that, when FDG PET/CT is added every 6 months, increased costs are seen without decreasing treatment failure rates in patients in remission of CRC. Also, neither OS nor DFS was better in the intervention arm.

Several other studies have found improved survival with intensified follow-up; however, the components of monitoring vary considerably, so that no definitive conclusions can be drawn. A Cochrane review of 15 studies including 5403 participants with stage II or III CRC—despite variability in settings and follow-up intensity—showed more salvage surgery with curative intent in patients in the group undergoing intensified follow-up. However, a meta-analysis from Verga and colleagues of 16 randomized controlled trials, including 11 with survival data, revealed that intensified monitoring was not associated with better survival. So, although FDG PET/CT appears to detect recurrence at an earlier time point, doing so does not appear to impact survival but does incur a financial burden.

Detection of Recurrence in Patients with Elevated Carcinoembryonic Antigen

CEA is produced by the columnar and goblet cells of the colon, as well as colonic cancer cells, and has a half-life of 5 to 11 days. Serial determination of plasma CEA concentrations is widely used in the postoperative surveillance of CRC; however, clinicians face a major challenge when the CEA is elevated but no evident relapse can be localized. CEA can also be elevated in smokers, patients with inflammatory bowel disease, or other epithelial tumors, resulting in 60% to 70% sensitivity and 80% specificity in the diagnosis of recurrent CRC. Studies have demonstrated a median lead time of 9 months between serum CEA elevation and detection of recurrent disease. Furthermore, normal CEA levels do not exclude tumor recurrence, and an increased CEA does not provide information of the location of the recurrence. Thus imaging is required to confirm and localize recurrence, and in current clinical practice ceCT is the modality of choice. However, it is often difficult to differentiate between pelvic recurrence and postoperative fibrosis.

To discover the value of FDG PET or FDG PET/CT in the detection of recurrent CRC in patients with elevated CEA, Liu and colleagues conducted a systematic review and meta-analysis of the literature to 2013. A total of 510 patients from 11 studies (10 retrospective) were included. The authors showed that both FDG PET and FDG PET/CT performed well with a high sensitivity (90.3% and 94.8%, respectively for FDG PET and FDG PET/CT) and specificity

(80% and 77.2%, respectively), with equally impressive accuracy (89% and 92.3%, respectively). In addition, FDG PET or FDG PET/CT detected 20% of patients with CEA elevation resulting from other causes.

Vallam and colleagues demonstrated a correlation between the degree of CEA elevation and the likelihood of recurrence of CRC. They retrospectively analyzed all PET/CT scans performed for elevated CEA during surveillance after complete resection of primary tumor followed by adjuvant therapy. In their sample of 104 patients with elevated CEA, 62 patients (59.6%) were found to have recurrent disease. At CEA levels less than 5, 5.1 to 10, 10.1 to 15, 15.1 to 50, and greater than 50 ng/mL, disease recurred in 10%, 43%, 70%, 94%, and 100% of patients, respectively. Sensitivity and specificity of PET/CT to were 92.7% and 95.2%, respectively, thus indicating that PET/CT is a valuable tool to detect recurrence.

When comparing standard ceCT imaging with FDG PET/CT, the latter appears to be superior in detecting recurrence in patients with elevated CEA. This was confirmed by Ozkan and colleagues in a retrospective study that included 69 patients, showing a sensitivity and specificity of 97% and 61% for FDG PET/CT, compared with 73% and 61% for ceCT.

Detection of Recurrence in Patients With Normal Carcinoembryonic Antigen

Several studies have looked at the utility of FDG PET/CT to detect recurrence in patients with normal CEA levels. Sanli and colleagues retrospectively reviewed 236 patients with recurrence, of which 118 had a normal CEA. The sensitivity and specificity of detecting recurrence were 100% and 84%, respectively, whereas in those with elevated CEA the sensitivity was 97.1%, and specificity was 84.6%. The investigators therefore concluded that, regardless of the CEA levels, FDG PET/CT can successfully detect recurrence.

These results have been supported by several other studies, including the work of Zhang and colleagues, who compared ceCT to FDG PET/CT in patients with different CEA concentrations. FDG PET/CT had a sensitivity, specificity, and accuracy of 95.2%, 82.6%, and 92.3%, respectively, whereas ceCT showed values of 80.7%, 73.9%, and 93%. The sensitivity and accuracy were significantly higher for FDG PET/CT compared with ceCT, and no statistical difference was found between patients with normal and increased CEA levels. Thus, even when CEA levels are not elevated, clinical, endoscopic, or conventional suspicion of recurrence should be evaluated with FGD PET/CT.

CONCLUSIONS

The use of FDG PET and FDG PET/CT in the evaluation of CRC continues to evolve. Although the use of PET for initial staging appears to be limited and not cost effective, it is evident from the data presented in this chapter that PET can play an important role at several key stages in a patient's journey through CRC treatment. In patients with suspected recurrent disease and in patients with liver metastases who might not be amenable to surgery, PET has been shown to have a distinct advantage compared with conventional imaging. In addition, PET can help to determine response to neoadjuvant therapy, especially in the case of rectal cancer, and can help to guide prognosis.

Despite these findings, the database for PET remains largely retrospective, with few prospective studies or clinical trials contributing to the field. More randomized controlled trials would add greater weight to the evidence presented in this chapter.

Neoadjuvant and Adjuvant Therapy for Colorectal Cancer

Ron G. Landmann, MD, and Alexandra W. Elias, MD

Colon and rectal cancer, or colorectal cancer (CRC), is a common disease in the United States with an estimated 97,220 new cases of colon cancer and 43,030 new cases of rectal cancer in 2018. The lifetime risk of developing CRC is approximately 1 in 22 (4.49%) for men and 1 in 24 (4.15%) for women. Although the mortality and incidence rates have been declining over the last few decades, CRC remains the third leading cause of cancer-related deaths among both men and women in the United States, with an estimated 50,630 cancer-related deaths in 2018. The decline in both incidence and mortality is likely due to several factors, such as cancer prevention, improved screening, and potentially curative therapies. There are currently more than 1 million CRC survivors in the United States.

For early stage CRC (stages I through III), surgical resection remains the basis of curative treatment. Recurrence, particularly distant recurrence, despite appropriate surgical resection is common and thought to be due to micrometastatic disease that is not readily detectable by current methods. For this reason, neoadjuvant and adjuvant therapies are often utilized to target micrometastases with the goal of complete eradication and prolonged survival. The challenge lies in determining which patients will benefit from additional therapy beyond surgical resection. The decision to add neoadjuvant or adjuvant therapy is based in large part on risk calculators, which take into consideration not only clinical tumor stage, but also patient-specific data, clinicopathologic features, such as lymphovascular invasion, and molecular profiling, such as microsatellite instability (MSI) status, KRAS, NRAS, and BRAF mutations. Surgical, adjuvant, and neoadjuvant therapeutic approaches to CRC are different for colon versus rectal cancer and are discussed separately in this chapter (Fig. 1).

STAGING

Formal CRC staging is essential to risk stratification for guiding clinicians' treatment decisions for individual patients. Guidelines from the National Comprehensive Cancer Network (NCCN) for preoperative workup of newly diagnosed CRC should include the following: colonoscopy (plus consideration of rigid proctoscopy for rectal cancer) with biopsy and pathology review; complete blood counts; chemistry profile, and carcinoembryonic antigen (CEA) serum level; computed tomographic (CT) scan of chest, abdomen, and pelvis for colon

(80% and 77.2%, respectively), with equally impressive accuracy (90% and 92.3%, respectively). In addition, FDG PET or FDG PET/CT detected 20% of patients with CEA elevation resulting from other cancers.

Vallam and colleagues demonstrated a correlation between the degree of CEA elevation and the likelihood of recurrence of CRC. They retrospectively analyzed all PET/CT scans performed for elevated CEA during surveillance after complete resection of primary tumor followed by adjuvant therapy. In their sample of 104 patients with elevated CEA, 62 patients (59.6%) were found to have recurrent disease. At CEA levels less than 5, 5.1 to 10, 10.1 to 15, 15.1 to 20, and greater than 20 ng/mL, disease recurred in 10%, 43%, 70%, 94%, and 100% of patients, respectively. Sensitivity and specificity of PET/CT to were 92.7% and 95.2%, respectively, thus indicating that PET/CT is a valuable tool to detect recurrence.

When comparing standard ceCT imaging with FDG PET/CT, the latter appears to be superior in detecting recurrence in patients with elevated CEA. This was confirmed by Ozkan and colleagues in a retrospective study that included 69 patients, showing a sensitivity and specificity of 97% and 61% for FDG PET/CT, compared with 57% and 61% for ceCT.

Detection of Recurrence in Patients With Normal Carcinoembryonic Antigen

Several studies have looked at the utility of FDG PET/CT to detect recurrence in patients with normal CEA levels. Sanli and colleagues retrospectively reviewed 236 patients with recurrence, of which 118 had a normal CEA. The sensitivity and specificity of detecting recurrence were 100% and 84%, respectively, whereas in those with elevated CEA the sensitivity was 97.1%, and specificity was 84.6%. The investigators therefore concluded that, regardless of the CEA levels, FDG PET/CT can successfully detect recurrence.

These results have been supported by several other studies, including the work of Zhang and colleagues, who compared ceCT to FDG PET/CT in patients with different CEA concentrations. FDG PET/CT had a sensitivity, specificity, and accuracy of 95.2%, 82.6%, and 92.3%, respectively, whereas ceCT showed values of 80.7%, 73.9%, and 93%. The sensitivity and accuracy were significantly higher for FDG PET/CT compared with ceCT, and no statistical difference was found between patients with normal and increased CEA levels. Thus, even when CEA levels are not elevated, clinical, endoscopic, or conventional suspicion of recurrence should be evaluated with FGD PET/CT.

CONCLUSIONS

The use of FDG PET and FDG PET/CT in the evaluation of CRC continues to evolve. Although the use of PET for initial staging appears to be limited and not cost effective, it is evident from the data presented in this chapter that PET can play an important role at several key stages in a patient's journey through CRC treatment. In patients with suspected recurrent disease and in patients with liver metastases who might not be amenable to surgery, PET has been shown to have a distinct advantage compared with conventional imaging. In addition, PET can help to determine response to neoadjuvant therapy, especially in the case of rectal cancer, and can help to guide prognosis.

Despite these findings, the databank for PET remains largely retrospective, with few prospective studies or clinical trials contributing to the field. More randomized controlled trials would add greater weight to the evidence presented in this chapter.

Neoadjuvant and Adjuvant Therapy for Colorectal Cancer

Ron G. Landmann, MD, and Alexandra W. Elias, MD

Colon and rectal cancer, or colorectal cancer (CRC), is a common disease in the United States with an estimated 97,220 new cases of colon cancer and 43,030 new cases of rectal cancer in 2018. The lifetime risk of developing CRC is approximately 1 in 22 (4.49%) for men and 1 in 24 (4.15%) for women. Although the mortality and incidence rates have been declining over the last few decades, CRC remains the third leading cause of cancer-related deaths among both men and women in the United States, with an estimated 50,630 cancer-related deaths in 2018. The decline in both incidence and mortality is likely due to several factors, such as cancer prevention, improved screening, and potentially curative therapies. There are currently more than 1 million CRC survivors in the United States.

For early stage CRC (stages I through III), surgical resection remains the basis of curative treatment. Recurrence, particularly distant recurrence, despite appropriate surgical resection is common and thought to be due to micrometastatic disease that is not readily detectable by current methods. For this reason, neoadjuvant and adjuvant therapies are often utilized to target micrometastases with the goal of complete eradication and prolonged survival. The challenge lies in determining which patients will benefit from additional therapy beyond surgical resection. The decision to add neoadjuvant or adjuvant therapy is based in large part on risk calculators, which take into consideration not only clinical tumor stage, but also patient-specific data, clinicopathologic features, such as lymphovascular invasion, and molecular profiling, such as microsatellite instability (MSI) status, KRAS, NRAS, and BRAF mutations. Surgical, adjuvant, and neoadjuvant therapeutic approaches to CRC are different for colon versus rectal cancer and are discussed separately in this chapter (Fig. 1).

STAGING

Formal CRC staging is essential to risk stratification for guiding clinicians' treatment decisions for individual patients. Guidelines from the National Comprehensive Cancer Network (NCCN) for preoperative workup of newly diagnosed CRC should include the following: colonoscopy (plus consideration of rigid proctoscopy for rectal cancer) with biopsy and pathology review; complete blood counts; chemistry profile, and carcinoembryonic antigen (CEA) serum level; computed tomographic (CT) scan of chest, abdomen, and pelvis for colon

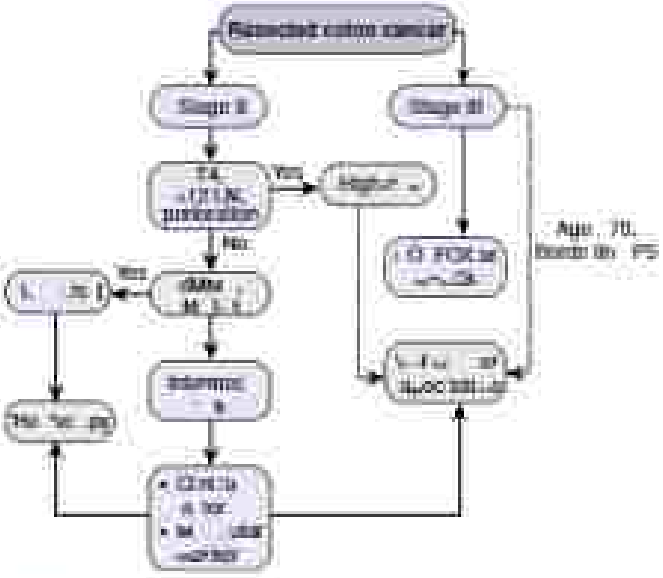

FIG. 1 Algorithm for use of adjuvant treatment for colorectal cancer. 5-FU/LV, 5-fluorouracil and leucovorin; *5-FU*, 5-fluorouracil; *cetuximab*, CM, lymph nodes; *dMMR*, deficient mismatch repair; *MSI-H*, microsatellite instability high; *PS*, performance status; *XELOX*, capecitabine and oxaliplatin.

cancer versus CT chest with magnetic resonance imaging (MRI) of the abdomen and pelvis with contrast for rectal cancer. Endorectal ultrasound for rectal cancer is no longer indicated unless a patient has contraindications to MRI, such as an incompatible pacemaker. One of the reasons preoperative staging is particularly important in rectal cancer is because it determines whether patients receive neoadjuvant radiation therapy (RT), with the goal of down staging. Positron emission tomography is not recommended (NCCN Guidelines, 2018).

CRC is staged based on the TNM staging system (T, primary tumor; N, regional lymph nodes; M, distant metastasis) adopted by the American Joint Committee on Cancer (AJCC; Table 1). In the most recent version of the *AJCC Cancer Staging Manual* (8th edition, 2016), several modifications were made to assist clinicians with prognostication, including the additional subdivision of M1c, which details peritoneal carcinomatosis as a poor prognostic factor; clarification in how tumor deposits in lymph nodes are defined; reintroduction of the "C" and "V" elements to further identify lymphatic and vessel invasion; and the identification of MSI status, KRAS, NRAS, and BRAF mutation as additional prognostic and predictive factors. This is discussed further in later sections. The importance of accurate staging is reflected in Fig. 2, which outlines the predicted 5-year survival rates.

RESECTED COLON CANCER

Adjuvant Therapy for Colon Cancer

Stage II Colon Cancer

For stage III colon cancer, the addition of adjuvant fluorouracil-containing chemotherapy regimens has demonstrated a significant survival benefit and has been established as the standard of care since a systematic review in 1988; however, the use of adjuvant chemotherapy in stage II colon cancer is controversial. Trials for adjuvant chemotherapy in stage II disease have not shown a clear benefit, although some studies have shown small increases in disease free survival (DFS), particularly in patients with high risk disease. Because most patients with III resections of stage II disease have a good predicted 5-year survival rate (see Fig. 2), an excellent benefit from adjuvant therapy would be needed to demonstrate improved overall outcomes. Additionally, stage IIC patients have a poorer overall survival (OS) at 5 years compared with stage IIIA patients; thus there may be a subset of patients who would derive improved long-term outcomes with adjuvant chemotherapy. Although randomized trials have failed to demonstrate a statistically significant improvement in OS with adjuvant chemotherapy for patients with stage II cancer, the number of patients with high risk stage II disease in these studies is likely inadequate to demonstrate benefit. For this reason, the American College of Clinical Oncology states the risks and benefits of adjuvant chemotherapy should be discussed with patients, and individualized treatment plans should be constructed.

There are three AJCC approved web-based prognostic tools which can be used to help counsel patients. To predict recurrence and survival, these tools take into consideration such factors as age, sex, race, body mass index, performance status, T category, tumor differentiation/grade, number of regional lymph nodes evaluated, number of positive regional lymph nodes, and tumor location. In addition, gene assays such as Oncotype DX Colon and Colaprint, as well as circulating DNA profiles, can help predict recurrence and response to therapy; however, they should be used with caution, as prospective trials have not demonstrated that these tests can determine which patients benefit from adjuvant chemotherapy.

High risk features for which a clinician may be more inclined to offer adjuvant therapy to a patient with stage II colon cancer include having inadequate lymph node sampling (<12 nodes in the surgical specimen), T4 stage, perforation/obstruction, poorly differentiated histology (except with microsatellite instability high [MSI-H] or mismatch repair deficiency [dMMR] as discussed later in this chapter), lymphovascular or perineural invasion, indeterminate/positive margins, high preoperative CEA levels, or mutations in KRAS/NRAS/BRAF, or loss of heterozygosity at chromosome 18q, 17p, or 8p. Additional research is ongoing to identify further genetic features that can be used to guide therapy.

Although many large studies have failed to show significant improvements with adjuvant chemotherapy in stage II disease in unselected patients, most of these studies have not separately analyzed patients with the aforementioned high risk features. For patients who are low risk or average risk, NCCN recommends discussion of observation versus clinical trial versus 6 months of adjuvant 5-fluorouracil (5-FU) and leucovorin (LV) or capecitabine, whereas for patients who are high risk, NCCN recommends discussion of clinical trial versus standard adjuvant regimens for stage III disease, including infusional 5-FU/LV and oxaliplatin (FOLFOX), capecitabine-oxaliplatin (CapeOx), infusional 5-FU/LV and oxaliplatin (FLOX), or 5-FU/LV versus capecitabine without oxaliplatin.

Tumors with a dMMR or MSI-H phenotype (approximately 20% of tumors) have an excellent prognosis in early stage disease but should not receive adjuvant 5-FU due to high rates of resistance. Pembrolizumab (PD-1 immunotherapy drug) was granted accelerated approval by the Food and Drug Administration for MSI-H dMMR tumors in 2017, after a study of 149 patients with metastatic or unresectable solid tumors (90 of whom had CRC) had a response rate of 34.2% with sustained response at 6 months in 78% of responders.

Several studies (Table 2) have helped guide current recommendations. A 2011 analysis of SEER (Surveillance, Epidemiology, and End Results) data, which included 24,047 patients with stage II cancer, of whom 25% had one or more poor prognostic features and 38% received chemotherapy, did not demonstrate a survival advantage with adjuvant therapy regardless of presence of risk factors. The study did, however, demonstrate benefit for stage III disease.

The United Kingdom QUASAR (Quick And Simple And Reliable) trial demonstrated that patients with stage II colon cancer who are not selected based on risk have a 3% benefit in 3-year DFS and OS with bolus 5-FU/LV (± levamisole) as adjuvant chemotherapy.

The Intergroup Analysis was a meta-analysis with multiheart, six analysis adjusted for T stage, histologic grade, and nodal status, designed to evaluate the benefit of adjuvant 5-FU based chemotherapy, which demonstrated a statistically significant improvement in 5-year DFS favoring chemotherapy (72% vs 72%), without a statistically significant difference in OS (81% vs 76%).

The International Multicenter Pooled Analysis of Colon Cancer Trials (IMPACT) was a meta analyses that assessed the benefit of adjuvant fluoropyrimidine based chemotherapy to patients with resected stage II colon cancer, which did not support the use of 5-FU/LV to all patients with stage II colon cancer.

The Multicenter International Study of Oxaliplatin/5-FU/LV in Adjuvant Treatment of Colon Cancer (MOSAIC) showed the addition of oxaliplatin affected a small survival benefit for stage II patients with high risk features, but there was no overall improvement in outcome with FOLFOX.

The Ontario group analysis compared 5-FU/LV versus observation for stage II colon cancer by analyzing 37 trials and 11 meta-analyses, and determined chemotherapy was associated with a small but significant absolute improvement in DFS (5% to 10%) without a statistically significant difference in OS (risk ratio, 0.87; 95% confidence interval [CI], 0.75 to 1.02; P = .07).

Additional key trials are summarized in Table 2. A meta analysis of chemotherapy by portal vein infusion has also shown a benefit to DFS and OS for stage II patients, however results have been difficult to reproduce.

TABLE 1 TNM Criteria and Staging of Colorectal Cancer

Definition of Primary Tumor (T)

T Category	T Criteria
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ, intraepithelial carcinoma (involvement of lamina propria with no extension through muscularis mucosae)
T1	Tumor invades the submucosa (through the muscularis mucosa but not into the muscularis propria)
T2	Tumor invades the muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissue
T4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organ or structure
T4a	Tumor invades through the visceral peritoneum (including gross perforation of the bowel through tumor and continuous invasion of tumor through areas of inflammation to the surface of the visceral peritoneum)
T4b	Tumor directly invades or adheres to adjacent organs or structures

Definition of Regional Lymph Nodes (N)

N Category	N Criteria
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One to three regional lymph nodes are positive (tumor in lymph nodes measuring ≥0.2mm), or any number of tumor deposits are present and all identifiable lymph nodes are negative
N1a	One regional lymph node is positive
N1b	Two or three regional lymph nodes are positive
N1c	No regional lymph nodes are positive, but there are tumor deposits in the: • subserosa • mesentery • or nonperitonealized pericolic, or perirectal mesenteral tissues
N2	Four or more regional nodes are positive
N2a	Four to six regional lymph nodes are positive
N2b	Seven or more regional lymph nodes are positive

Definition of Distant Metastasis (M)

M Category	M Criteria
M0	No distant metastasis by imaging, etc., no evidence of tumor in distant sites or organs (this category is not assigned by pathologists)
M1	Metastasis to one or more distant sites or organs or peritoneal metastasis is identified
M1a	Metastasis to one site or organ is identified without peritoneal metastasis
M1b	Metastasis to two or more sites or organs is identified without peritoneal metastasis
M1c	Metastasis to the peritoneal surface is identified alone or with other site or organ metastases

Stage III Colon Cancer

In stage III colon cancer, adjuvant chemotherapy has been the standard of care since 1990, with several large randomized clinical trials showing benefits in both OS and DFS (Table 3). The addition of adjuvant chemotherapy to surgical resection in patients with stage III colon cancer leads to an approximately 30% reduction in recurrence and 22% to 32% reduction in mortality.

The National Surgical Adjuvant Breast and Bowel Project (NSABP) C-01 was conducted between November 1977 and February 1983. It randomly assigned 1156 patients to semisynchronous 5-FU (MOF) versus observation, and was the first trial to demonstrate 5-year OS benefit for adjuvant therapy in colon cancer.

Unfortunately, both the MOF regimen and adjuvant 5-FU plus levamisole regimen, a regimen with benefit demonstrated by the North Central Cancer Treatment Group (NCCTG) trial, had unacceptable side effects.

The NSABP C-03 trial, along with other smaller studies, demonstrated inferiority of MOF to 5-FU/LV regimens. Other studies examined method of delivery, and although continuous infusional 5-FU did not demonstrate superiority over bolus 5-FU in first trials, it was shown to have a more favorable side effect profile. Subsequently, oral fluoropyrimidine (capecitabine), which is metabolized to fluorouracil was demonstrated to be noninferior to 5-FU/LV.

The benefit of the addition of FOLFOX was demonstrated by the MOSAIC trial (n = 2246), in which the 5-year DFS was significantly higher (73% vs 67%, hazard ratio [HR], 0.8), although febrile neutropenia, peripheral neuropathy, and grade 3 to 4 diarrhea were also more common. The benefit for patients with stage III disease was significantly higher than for those with stage II disease, as discussed in the previous section.

Additional trials examined different 5-FU/LV + oxaliplatin regimens. The NSABP U-07 trial utilized FLOX (weekly bolus 5-FU/LV + oxaliplatin), which was more effective than nonoxaliplatin regimens, but more toxic than FOLFOX. XELOX has also been shown to be inferior to FOLFOX in the setting of metastatic disease.

When capecitabine was combined with oxaliplatin (XELOX or CapeOx) and compared to bolus 5-FU/LV, XELOX demonstrated significantly improved DFS (HR for DFS, 0.80; 95% CI, 0.69 to 0.93) after a median follow-up of 7.6 months.

Irinotecan is another drug that was studied as an additive to 5-FU/LV; however it failed to demonstrate a benefit in resected stage III

disease. CALGB 89803 was a randomized prospective trial that compared bolus 5-FU/LV with or without irinotecan. The group treated with the addition of irinotecan experienced significantly more side effects without demonstrating a survival benefit.

Although targeted agents such as bevacizumab and cetuximab have demonstrated a benefit in OS for metastatic disease, benefits in DFS or OS have not been demonstrated when used as adjuvant therapy for stage III disease. Panitumumab may be considered for MSI-H 4MMF disease, as discussed in the prior section.

The International Duration Evaluation of Adjuvant Chemotherapy (IDEA) collaboration analyzed a randomized trials of 6 versus 3 months of oxaliplatin-based adjuvant therapy. Results suggested that 6 months of therapy remains the standard of care for high risk cancers; however, in light of the small difference in DFS (absolute difference 0.9% at 3 years) but significantly lower rates of oxaliplatin neuropathy, shorter duration of therapy may be considered for low risk disease (T1–T3, N1).

The current recommendation for adjuvant therapy for stage III colon cancer is 4 to 6 months of an oxaliplatin containing regimen such as FOLFOX or XELOX. For patients with significant comorbidities, peripheral neuropathy, or age greater than 70 years, 6 months of infusional 5-FU/LV or capecitabine without oxaliplatin can be considered. Unlike rectal cancer adjuvant regimens, radiotherapy is generally not indicated for colon cancer.

As new biomarkers and predictors of recurrence/prognosis are discovered, and as more antineoplastic agents are developed, treatment guidelines will continue to be updated, likely leading to more highly individualized cancer therapy algorithms.

NEOADJUVANT AND ADJUVANT THERAPY FOR RECTAL CANCER

Although rectal cancer has similar pathogenesis and molecular phenotypes to colon cancer, local recurrence rates in rectal cancer are significantly higher than in colon cancer. This discrepancy may be secondary to both differences in tumor factors, such as differences in vasculature and lymphatic drainage patterns associated with the anatomic location, and surgical factors, such as completeness of excision of mesorectum and extent of lymphadenectomy.

As many as 10% of patients with T1–T2 rectal cancer, 15% to 20% of patients with T3N0 rectal cancer, and 45% to 65% of patients with node positive T3–T4 rectal cancer will experience local recurrence with standard resection without neoadjuvant or adjuvant therapy. These rates can be decreased with total mesorectal excision (TME) to 10% in stage II and 17% with stage III. Local recurrence rates can be further decreased with chemoradiotherapy.

This emphasizes the importance of appropriate resection (i.e., TME) in conjunction with neoadjuvant and/or adjuvant therapy for reducing the risk of local recurrence and its associated morbidity (pain, bleeding, obstruction, abscess, fistulas) in addition to controlling distant metastasis.

Adjuvant Therapy

Although neoadjuvant therapy is now the standard of care (as discussed in the next section), initial rectal cancer studies attempting to reduce local recurrence focused on adjuvant pelvic RT with or without chemosensitization. Currently, indications for consideration of surgical resection without neoadjuvant therapy include proximal cT1N0 tumors for which RT may not be recommended after TME, or a tumor with borderline cT2 versus cT3 status on preoperative imaging.

One of the main trials which established combined chemoradiation as a key to therapy was the Gastrointestinal Tumor Study Group trial, in which 227 patients were randomly assigned to observation, postoperative RT alone, chemotherapy alone, or postoperative RT with concurrent chemotherapy. In this trial, recurrence rates were significantly reduced with combined chemoradiotherapy (33%) versus observation (59%), chemotherapy alone (66%), or radiotherapy alone (48%). OS was longer for combined chemoradiotherapy as well, although it did not reach statistical significance.

Two widely utilized adjuvant chemoradiotherapy regimens were 2 months of chemotherapy, 6 weeks of concomitant chemoradiation (5-FU/LV or capecitabine for radiosensitization and radiation with 5 daily fractions of 1.8 Gy per week up to a total of 45 Gy), followed by 2 additional months of chemotherapy versus 4 months of chemotherapy followed by 6 weeks of concomitant chemoradiation.

Neoadjuvant Therapy

Neoadjuvant therapy with 5-FU as a radiosensitizer was established as standard of care for stage II and III rectal cancer after a large randomized trial (The German Rectal Cancer Trial) was published, which compared continuous infusion 5-FU plus radiation after TME versus before TME for T3–T4 or node positive rectal cancer. This study demonstrated a reduction in local recurrence (13% vs 6% at 5 years) and toxicity (both acute and chronic) with a higher rate of sphincter preservation ($P = .006$) for neoadjuvant therapy.

The only definitive indication for neoadjuvant therapy is a T3–T4 tumor, but relative indications include clinically evident node-positive disease, distal rectal tumors, and evidence of mesorectal fascial invasion on preoperative imaging.

Currently, the majority of United States cancer centers utilize a combined modality approach to neoadjuvant therapy with radiosensitizing chemotherapy (5-FU/LV or capecitabine) and concurrent radiotherapy (50.4 Gy total radiation dose over the course of 5 to 6 weeks), known as 50.4/5FU/CMT, followed by surgical resection 5 to 8 weeks after completion of chemoradiotherapy. Although still controversial, the majority of patients also receive adjuvant chemotherapy similar to adjuvant therapy for resected colon cancer (e.g., 6 months of FOLFOX, 5-FU/capecitabine, or FLOX).

Although both adjuvant and neoadjuvant combined modality chemoradiation can cause acute (e.g., grade 3–4 diarrhea, proctitis, cystitis, bone marrow suppression) and long-term complications (e.g., sexual dysfunction, sacral fractures), neoadjuvant therapy seems to be better tolerated without creating additional perioperative morbidity/mortality risks. Additional benefits of neoadjuvant as opposed to adjuvant chemoradiation include increased rates of sphincter preservation, decreased local recurrence, and lower rates of anastomotic strictures and chronic enteritis.

Owing to the apparent benefits of neoadjuvant therapy, studies began analyzing the advantages of total neoadjuvant therapy (TNT; preoperative systemic chemotherapy in combination with chemoradiation) compared with the traditional approach of preoperative chemoradiation and postoperative adjuvant chemotherapy in patients with locally advanced (T3/4 or node positive) rectal cancer. In one retrospective cohort analysis, in which 308 patients treated with TNT were compared with 328 patients treated with neoadjuvant chemoradiation with planned adjuvant chemotherapy, patients in the TNT cohort received greater percentages of the planned systemic chemotherapy, had higher rates of complete pathologic response (in patients who underwent surgery) and sustained clinical response (in patients who did not undergo surgery) (36% for TNT vs 21%), and were more likely to have temporary ileostomy reversed within 15 weeks of proctectomy. This study supported NCCN guidelines that categorize TNT as a viable treatment strategy for rectal cancer, but long-term follow-up is still needed to determine whether TNT leads to improved OS. Additionally, researchers proposed that given its high CR rate, TNT may facilitate nonoperative treatment strategies aimed at organ preservation.

Given patients whose tumors respond to chemotherapy and radiation are more likely to be cured than those whose tumors do not, controversy exists as to whether surgery is necessary in patients with pathologic complete response to neoadjuvant therapy, or whether watchful waiting is a reasonable option. One small study demonstrated 40 of 53 patients who had a complete clinical response after 6 weeks of chemoradiation (determined by CT/MRI 6 weeks after treatment with no metastases and complete tumor regression with negative tumor site biopsies), who underwent observation had only a 13.5% rate of local recurrence at 4 years (95% CI, 3.9% to 24.3%). Authors of the study concluded watchful waiting after high dose chemoradiotherapy without TME may not compromise outcomes in selected patients. Additional large studies, including a phase II randomized trial that opened for accrual in January 2006, evaluating 3-year DFS in patients with locally advanced rectal cancer treated with chemoradiation plus induction or consolidation chemotherapy and TME or nonoperative management, are ongoing to further assess the viability of a watchful waiting approach.

Because of the undesirable side effects from radiation, several small studies have also assessed the use of neoadjuvant chemotherapy with the selective use of radiotherapy and demonstrated promising results. In one such study, 30 of 32 patients had good clinical response after 6 cycles of FOLFOX + bevacizumab and went on to TME without chemoradiation; at 4 years, local recurrence rate was 0 and DFS was 84% (95% CI, 67% to 94%). Currently, a large phase III randomized prospective trial (PROSPECT N0398) is ongoing to assess chemotherapy alone versus chemotherapy plus RT in treating patients with locally advanced rectal cancer (T2N1, T3N0, T3N1) undergoing surgery. Primary outcome measures include R0 resection rate, DFS, and time to local recurrence. Secondary outcome measures include rate of pathologic complete response, OS, adverse event profiles, and rates of receiving preoperative or postoperative 5FU/CMT. Event monitoring of patients will continue up to 8 years post-randomization.

Endorectal brachytherapy/high dose rate brachytherapy (HDR) are alternative methods of delivering radiation that are being investigated. Endorectal brachytherapy is ideal for patients with mid-distal rectal cancers not involving the anal sphincters and lymphadenopathy confined to the mesorectum, as it is able to deliver higher doses of radiation to the tumor and mesorectum with less chronic toxicity. Typically, this treatment is delivered once a week for a total of 5 weeks, with concurrent capecitabine (oral 5-FU) chemotherapy. Currently, some centers advocate for use of HDR for patients with locally persistent or recurrent disease after chemoradiation who decline to undergo or are unfit for abdominal resection. In addition, a phase I dose escalation study is underway to evaluate the safety of endorectal brachytherapy with concurrent capecitabine or 5-FU in the management of locally recurrent/residual rectal cancer in patients who have received pelvic external beam radiation with or without chemotherapy.

Just as in colon cancer, there is clear heterogeneity in tumor responses to treatment despite being of the same stage. Therefore studies seeking to identify molecular profiles and biomarkers that are better able to predict which patients will benefit from specific therapies are ongoing.

SURVEILLANCE

Despite the ever-evolving therapies for CRC, distant and local recurrence rates can be as high as 40%, with the majority of recurrences occurring in the first 2 years after completion of initial definitive therapy. Early identification of recurrence or new primary tumors may allow for potentially curative therapy (surgical resection or systemic therapy) and improved outcomes. For this reason, appropriate aggressive surveillance is imperative. Although there are subtle differences among professional organizations, most guidelines are generally in line with the NCCN guidelines, 2018.

For patients with stage I colon or rectal cancer, recommended surveillance is colonoscopy 1 year after resection, with subsequent colonoscopies dependent on findings (as detailed later in this section). For patients with rectal cancer who underwent transanal local excision only, the addition of proctoscopy with endoscopic ultrasound scan or MRI with contrast is recommended every 3 to 6 months for the first 2 years, then every 6 months until year 5.

For patients with stages II through IV colon or rectal cancer, surveillance recommendation is history and physical examination with serum CEA (only if patient is a candidate for further intervention) every 3 to 6 months for 2 years, then every 6 months until year 5; colonoscopy within 1 year of resection (within 3 to 6 months if not completed preoperatively) and subsequent colonoscopies dependent on findings (as detailed later in this section); and CT chest, abdomen, and pelvis, with frequency dependent on stage at diagnosis: for stage II or III, perform every 6 to 12 months for 5 years versus for stage IV, perform every 3 to 6 months for 2 years, then every 6 to 12 months until year 5. Positron emission tomography/CT is not indicated for routine surveillance.

For screening colonoscopies following resection, if there is no advanced adenoma, repeat colonoscopy in 3 years, then every 5 years; if an advanced adenoma is present, repeat colonoscopy in 1 year.

Management of Colon Polyps

Erica Ferthe, MD, and Richard L. Whelan, MD

The adenoma to carcinoma progression is well established. Colonic screening programs to remove adenomas have been shown to decrease the incidence of adenocarcinoma. The great majority of colon polyps are smaller than 0.5 cm and are readily removed endoscopically using either a cold biopsy forceps or a snare. Sessile polyps smaller than 2 cm and larger pedunculated polyps can usually be removed with a hot snare; for sessile polyps, a saline lift before snare application is advised. Larger sessile polyps pose difficulties and challenges in regard to endoscopic treatment. This chapter concerns the management of these larger sessile polyps.

There are few areas of medicine where the treatment of a condition in first world countries varies as widely as for large sessile benign polyps of the colon. Large polyp management is also an area in which there is a great deal of innovation occurring that has the potential to notably facilitate the removal of these lesions. In Japan and much of the Far East, these lesions are routinely removed via the technically challenging endoscopic submucosal dissection (ESD) technique. This technique permits en bloc removal of the mucosal lesion with a margin of normal mucosa as well as much of the submucosa beneath the polyp. Of note, there is also a growing body of data that suggests that en bloc removal of a superficial invasive cancer (<1000 µm invasion) via ESD constitutes definitive treatment. En bloc removal allows for a more thorough pathologic evaluation and margin assessment. Our position is that ESD is superior to en bloc resection, to the gold standard endoscopic polypectomy method for large flat polyps.

Endoscopic mucosal resection (EMR), which is most commonly used in the United States, removes most large polyps in a piecemeal manner with a snare. By repetitively applying the snare, large polyps can be removed. Critically important to both ESD and EMR methods is the establishment of a "lift" by injecting saline or other solution into the submucosal layer beneath the lesion to increase the thickness of the bowel wall, which decreases the risk of perforation.

In the West, particularly the United States, where the penetration of ESD methods has been limited, the vast majority of these lesions (about 28,000 cases per year) are dealt with via segmental colorectal resection with its attendant morbidity and mortality (approximately 1.5%, 420 patients/y). In contrast, the mortality associated with ESD is about 1 in 10,000 cases. Also, the cost of ESD is a fraction of that of a segmental colectomy. In the United States, there is a considerable effort underway in both the gastroenterology and colorectal surgery fields to teach and popularize ESD and advanced polyp removal methods. These efforts coincide with the introduction of a number of innovative devices designed to facilitate en bloc removal (e.g., snare cautery devices, improved needle knives) as well as the release of better lift solutions. The goal is to avoid colectomy (notably higher costs, morbidity, and mortality) for benign colon polyps and for SM1 superficially invasive colon cancers. It is a very interesting time in this field.

CHALLENGE OF LARGE FLAT POLYPS

The problem posed by large flat benign lesions is that the bowel wall is thin and there is a considerable risk of perforation when an attempt is made to remove these polyps with a standard snare, which simply burns through the encircled and snare-entrapped tissue. For these reasons, EMR methods were developed and introduced. As mentioned, central to advanced colon polyp removal methods is the creation of a mucosal lift, which increases the thickness of the submucosal layer of the bowel wall by injection of saline or another solution. A perforation is far less likely when a snare or needle knife is used at the mucosal surface of a lifted area because the deep muscle and serosa are a good distance away. EMR permits piecemeal removal of large polyps with repeated application of a snare to a "lifted" area. Although large polyps can be removed via EMR only, a limited pathologic evaluation can be carried out because the pathologist receives disarticulated pieces of the polyp that do not permit lateral margin assessment. Largely in response to this issue, ESD methods were developed and introduced in Japan and have become the gold standard for the treatment of large sessile benign polyps.

Unlike snare polypectomy and EMR, with ESD the polyp is "surgically excised" with a needle knife by progressively scoring, in segments, the mucosal surface around the lesion and then dividing the submucosal attachments below the lesion. Ideally, an en bloc excision is achieved. When performing ESD, to cut the tissue the endoscopist must move the scope tip with a hot needle knife extended in a coordinated and controlled manner. This is in contrast to snare polypectomy or cold biopsy, which is done with the scope tip held stationary while the forceps or snare is pushed out of or pulled into the scope. Learning to finely control the moving scope tip is a challenging task. A training strategy and much practice are needed to acquire these skills.

MUCOSAL LIFT

The mucosal lift increases the thickness of the submucosal layer of the bowel wall. The lift is established via sclerotherapy needle or needle-less high-pressure injection device. The sclerotherapy needle (either 23 or 25 gauge) method is most commonly used. There are two drawbacks to this method. First, it is difficult to puncture the mucosa because it has a relatively "loose" surface layer that slides away from the needle; a hard push is most always needed to breech the mucosa and, invariably, the needle tip ends up deep in the wall (muscularis propria or submucosa layer) or transmural. Because of the deep starting position of the sclerotherapy needle, it is possible to expand the submucosal or muscularis propria space, which will not facilitate submucosal dissection. Care must be taken to ensure a superficial submucosal lift is made and not a deep wall lift. To decrease the chances of generating a deep wall lift, position the scope tip such that the scope is as close to and as tangential to the polyp bearing side of the bowel wall as possible to ensure that the sclerotherapy needle enters the wall at a minimal angle. This increases the chances of keeping the needle in the submucosal layer. A more acute angle of entry is likely to put the needle tip deeper in the wall. The second downside to the sclerotherapy needle method is that each needle puncture leaves a mucosal defect through which lift fluid can leak out. The alternative to the sclerotherapy needle approach is needleless high-pressure injection.

To generate a lift without puncturing the mucosa, the blunt tip of the needleless high-pressure injection tubing is advanced and positioned so that it touches the mucosal surface at a 90 degree angle. Next, a lift is established by pumping the saline or other lift solution through the tubing either by hand (gun-like device similar to through the channel endoscopic balloon dilating devices) or electric foot controlled pump. Because there is no actual puncture of the mucosal surface, this method is not likely to result in a deep

wall lift (expansion of the muscularis propria or submucosal layer). Also, because the hole made in the mucosal surface is very small, there is little or no leakage of lift solution. Of note, the electric pump can be paired with an ESD capable electrosurgical generator such that a hollow needle knife can be used. This knife pumps saline into the submucosa via the central hollow channel either above or at the same time the needle knife is activated, thus, "debulking" the lift as the knife is used.

A variety of different solutions have been used to lift the mucosa, including normal saline (+ epinephrine), sodium hyaluronate, albumin, 10% glucose, glycerol, hypromellose (ophthalmic solution, Akorn Company), and Viscoat (Alcon Pharmaceuticals). Usually, methylene blue or other dye is added to the solution to facilitate identification of the submucosal layer. The duration of the lift is a key attribute; the longer the duration, the better. A number of studies have compared the various solutions; however, the parameters and solutions considered varied widely and thus there is no clear consensus regarding the best lift solution. Hyaluronate solutions have been widely used in Japan but are not commercially available in the United States. Several new lifting solutions are currently in development.

Unfortunately, incising the mucosa and dividing the submucosal fibers promotes leakage of lift solution from the wall and decreases lift duration. Periodically, the lift needs to be reestablished with additional bowel wall injections. It gets more difficult to regenerate the lift as the resection progresses because the submucosal plane is widely exposed. Maintaining a substantial lift is critical to ESD and EMR.

BASIC EMR

The use of a lift agent after establishment of a mucosal lift to remove a polyp constitutes an EMR. In expert hands, the en bloc resection rate with EMR methods is between 33% and 57%. Most often, full removal requires multiple applications of the snare, which means that the lesion is removed piecemeal. The lift decreases the chances of perforation. A variety of snares available: large or small, flexible or stiff, and round or hexagonal in shape. Some EMR proponents do not routinely establish a mucosal lift before snare application. This approach is hard to defend; the addition of the lift facilitates the safe performance of the polypectomy. The snared tissue is retrieved via suctioning through the scope into a trap, pulling larger fragments out of the anus after applying suction, a basket net, or a wire basket. Endoscopic clips can be used to bring together the mucosal edges of small and moderate-sized mucosal defects after EMR. The EMR perforation rate in two decent-sized studies was 0% to 1.2%. The polyp recurrence rate is between 14% and 21%. The rate of bleeding complications ranges from 3.1% to 11.3%.

ESD

ESD is performed with a needle knife that consists of an insulated sheath containing a wire or other metal tip that can be advanced several millimeters from the sheath's edge. The knife is connected to a specialized electrosurgical generator that can generate a variety of different currents to either mark or incise the mucosa or cut the submucosal fibers. A plastic hollow dissection cap is attached to the endoscope tip so that cap dissection can be performed, if desired. The endoscopist must be able to finely control the moving scope tip with the knife protruding to cut tissue. The patient should be positioned so that the polyp is in the "up" position; this allows gravity to retract the partly detached polyp downward. At times, considerable torque needs to be applied to the scope shaft to obtain the desired orientation between the scope and the polyp. The steps involved with ESD are the following: (1) initial marking of the outlines of the planned excision with a series of superficial mucosal spot burns, (2) incising 15% to 20% of the mucosal circumference, (3) cutting the submucosal fibers beneath the polyp adjacent to the incised mucosa, (4) inserting the scope tip with plastic cap affixed to allow cap dissection (optional), (5) scoring of additional mucosal margins and then dividing adjacent submucosal fibers, and (6) repeating these steps until the polyp has been excised and fully detached (Fig. 1). Depending on the size of the polyp and the technique of the endoscopist, cap dissection may be used during the case. Cap dissection refers to inserting the scope tip (with cap in place) into the submucosal layer and pushing forward, which stretches the submucosal fibers and "presents" them to the needle knife (Fig. 2).

When ESD is used, the en bloc resection rate is 84% to 92%, rate of bleeding complications is 1.5% to 3.7%, perforation rate is 2% to 10%, and recurrence rate is 0% to 2% in expert hands.

HANDLING OF THE POLYPECTOMY WOUND

Some polypectomy wounds lend themselves to closure with through-the-channel endoscopic clips that draw the mucosal edges together. Larger "bear claw" type clips can also be applied. There is an endoscopic suturing device that is affixed to the scope tip that can be used to close partial or full thickness colon wall defects; this innovative tool, however, has a notable learning curve. Provided the muscularis propria is intact and the bowel wall is healthy, it is reasonable to leave the mucosal defect open. If ESD/EMR is done in the operating room setting and the patient has consented, a perforation can be closed or the bowel wall mitigated laparoscopically after the endoscopic polypectomy has been finished (see the following section).

OPERATING ROOM SETTING FOR ESD AND LAPAROSCOPIC EVALUATION POSTPOLYPECTOMY

Incorporating ESD into one's practice is a challenge. The necessary skill set needs to be acquired (see the "Training" section) and a general resection strategy chosen (e.g., proximal to distal, distal to proximal). One approach, which we use, is to perform these cases in the operating room with the understanding that if a colonic ESD is completed, a laparoscopic evaluation will be done immediately after (under the same anesthesia) to assess the integrity of the bowel wall and, if necessary, suture repair or imbricate the bowel wall. In the case that endoscopic removal of the polyp was judged not feasible or failed, an immediate laparoscopic segmental colectomy would be performed. Of course, the patient needs to have signed a very broad consent and fully understand that the endoscopic polypectomy, even if successful, will be followed by a laparoscopy. Only carbon dioxide gas should be used for colonic insufflation via the colonoscope since it is fully absorbed within 15 minutes, thus permitting laparoscopy under the same anesthesia.

The surgical endoscopist needs to be willing to use a combination of ESD and EMR methods early on to destroy the lesion. Although en bloc resection is the goal, a colectomy can be avoided via EMR. In some instances, the polyp turns out to best dealt with via EMR (large, partly pedunculated purely sessile lesions or smaller lesions that do not warrant ESD). Regardless of whether an ESD or EMR is carried out, a follow-up colonoscopy 3 to 6 months later is advised to check the site for a persistent or recurrent polyp.

NEW TECHNOLOGY

This is an exciting time because a number of new devices and instruments designed to facilitate endoscopic polypectomy are being introduced and assessed. Two new devices allow the

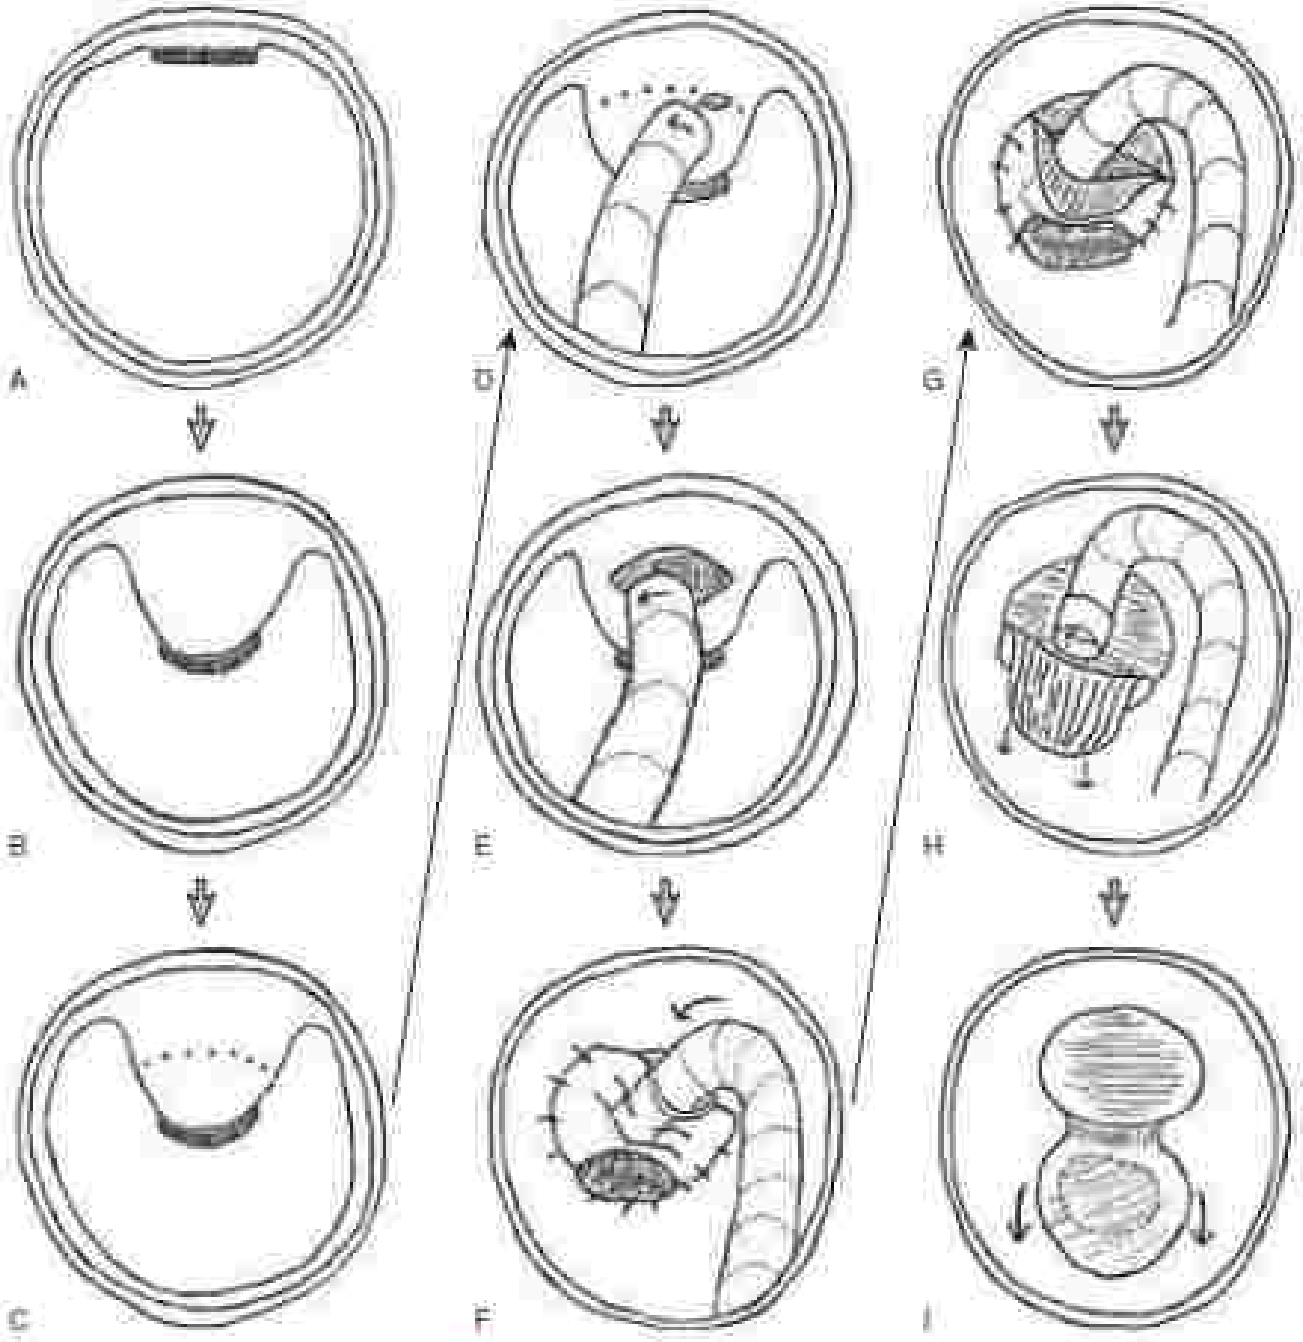

FIG. 1 (A–I) Endoscopic submucosal dissection.

endoscopist to establish a therapeutic work zone in the polyp-bearing segment. Presently, both are mainly being used and assessed for left-sided polyps. The colonoscope is passed through both flexures before insertion into the patient. The Cuscuff device (Cuscuff Corporation) has two separate collapsed balloons that are part of the cuffrube located close to the scope tip. When the scope is at the level of the polyp and the scope oriented tangential to the polyp, the balloon closest to the scope tip is advanced into the colon until it is well proximal to the polyp, at which point it is inflated. Next, the second, more distal, balloon, situated along the scope shaft close to the tip, is also inflated. This locks the colonoscope in position and creates a zone maintained by the balloons as well as by the insufflated carbon dioxide or air. This device frees the surgeon from having to maintain the torque on the scope shaft, which facilitates the ESD or EMR.

The Boston Scientific device (for sigmoid or rectal lesions only) is a series of plastic tube struts and plastic flat, which, when extended beyond the scope tip create a "therapeutic zone" that supports about two-thirds of the colon circumference to the area surrounding the lesion (the polyp sits in the open part of the colon wall). When deployed, a stable working space is created. Two instrument channels run along the outside of the device through which hollow tubes can be placed that have a 30- or 45-degree angled distal end. Tissue graspers can be inserted through these tubes. The angled end of the cuffrube directs

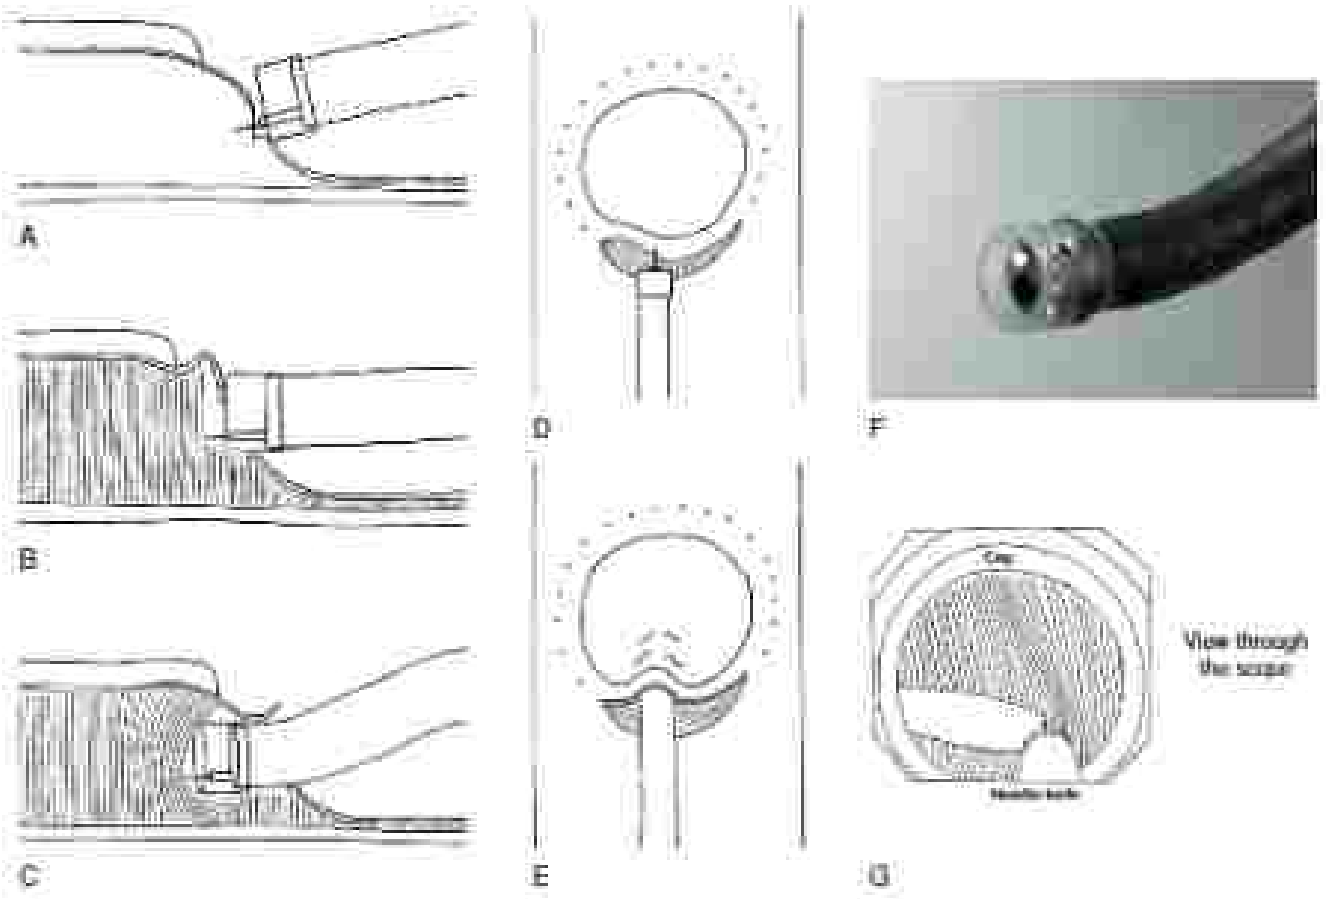

FIG. 2 (A–G) Cap dissection.

the grasper toward the polyp sitting at the bottom of the field. The best polypectomy strategy using this device has yet to be determined, however, after the snaress has been twisted around the polyp, the cut mucosal edge is grasped and then lifted by tensioning the grasper eversely. This provides traction that greatly facilitates detachment of the polyp using a needle knife placed through the colonoscope's instrument channel.

A second-generation Lasso-it device with external cutting channels is soon to be released. Conceptually, a grasper and tissue cutting device can be passed through the channels and finely controlled such that the polypectomy can be performed using the colonoscope as a camera only. Tissue cutting does via one of the external channels while the polyp edge is retracted by the grasper1. There are other new treatment platforms being introduced including several robotic approaches.

Several new lifting solutions are also soon to be released that have the potential to facilitate ESD and EMR. A variety of unique and novel needle knives are also in development by a number of companies that facilitate safe tissue cutting and ESD type polypectomy.

COSTS AND NEED FOR CPT PROCEDURE CODES

ESD and EMR are quite expensive from the viewpoint of disposable needle knives, special lift solutions, sclerotherapy catheter or high-pressure insufflation device, or flush net or wire basket. These new polypectomy facilitating tools and devices will add considerably to the cost of the procedure; in the case of the therapeutic tissue cutting devices, this could be several thousands of dollars. Presently, in the United States, there is no CPT code for ESD; therefore, physicians performing ESD must use the existing codes or bill the procedure under the "unlisted code" category, which is time consuming and does not ensure fair payment to either the institution or the physician. Presently, the performance of ESD or complex EMR are money losing endeavors for both the institution and the physician. The great majority of existing polypectomy codes refer to simple snare removal (15- to 20-minute procedure) and not a several-hour long ESD or EMR. There is a new EMR code, but in the opinion of advanced endoscopists and administrators, it does not fairly reimburse for complex polypectomies. It is critical, therefore, that new codes be developed to cover the costs of the instruments as well the time investment on the part of the endoscopist. For this to happen, patients, gastroenterologists, surgeons, and industry must work together to lobby Congress and the appropriate federal agencies for new fair codes. In the absence of new codes, it will be difficult to popularize these important advanced endoscopic techniques that allow patients to avoid a considerably more costly and morbid segmental colectomy.

TRAINING

The endoscopic skill set necessary for ESD is not easily come by. The ability to finely control and direct the moving scope tip with an active, extended cutting device requires hours of practice and training. "Surgically" detaching a polyp in the submucosal plane with only

gravity as retractor is a challenging and frustrating job. New training approaches are needed.

To teach scope tip control, an inanimate model that uses a bell-low plastic tube with a window cutout can be used. A piece of paper with line figures can be placed in the window and a modified echinotherapy catheter "gun" that is passed through the scope instrument channel used to trace the line figures. Saline with methylene blue or other dye serves as the "ink." Actual ESD procedures can be carried out on pieces of pig stomach with an overlying Rowy pad cut that are placed over the tube's window cutout. Excised but intact bovine colon and rectum (3–4 feet long) can also be used to perform ESD. The bovine model is more realistic since it requires insufflation of the bowel (proximal end sealed with large clip and rip tie placed around the anus); this model is more versatile since the position of the "polyp" target and the shape of the colon is be varied. We believe that by performing 30 to 40 full ESD cases using the porcine and bovine models, surgeon trainees will be able to start a clinical program, perhaps doing the lower outlined above (operating room setting with goal being ESD/EMR with fluoroscopy backup).

One could argue that, with the advent of new tools and platforms that it is not necessary to learn ESD methods. For the foreseeable future, however, even with the new tools, successful en bloc polypectomy requires a submucosal lift and the ability to navigate and work with a needle knife in the submucosal space. Thus, fine motor control of the moving scope tip is still required. These training approaches will teach these skills and, hopefully, prepare the next generation of endoscopists to perform these endoscopic sparing procedures.

SUMMARY

It is now possible to remove the great majority of large sessile adenomas endoscopically. These lesions can be removed via EMR; however, ESD methods are the gold standard because they permit en bloc resection which allows for pathologic determination of both the horizontal and vertical margins. En bloc resection and detailed pathologic evaluation, in turn, have led to the realization that for superficial invasive cancers (SM1, <1000 μm depth of invasion) segmental colectomy is not necessary. ESD utilization rates around the world are steadily increasing and new tools are being introduced that will considerably simplify the removal of these lesions. New procedural codes that take into account the complexity of these procedures as well as the increased cost of the required disposable tools are needed. Where advanced endoscopic polypectomy methods have been widely embraced and implemented the rate of colectomy for benign lesions should dramatically decrease from the current level of 28,000 cases/y in the United States. The next 10 years will see much movement in this area.

MANAGEMENT OF PERITONEAL SURFACE MALIGNANCIES

Joel M. Baumgartner, MD, MAS, Kaitlyn J. Kelly, MD, Julia Rosenspan, MD, and Andrew M. Lowy, MD

Peritoneal surface malignancies (PSMs) describe a heterogeneous collection of histopathology affecting the peritoneal lining of the abdominopelvic cavity. They encompass primary malignancies, such as diffuse malignant peritoneal mesothelioma or primary peritoneal carcinoma, as well as peritoneal metastases from gastrointestinal, gynecologic, and uncommon etiologies. Traditionally, the diagnosis of a PSM portended a poor prognosis with limited role for surgical intervention, and its diagnosis still may elicit substantial nihilism from clinicians. However, certain histopathologic subtypes in select patients have now been shown to be amenable to surgical debulking with significant impact on overall survival (Table 1). Cytoreductive surgery (CRS), which entails macroscopic tumor removal and commonly multivisceral resection, is often combined with hyperthermic intraperitoneal chemotherapy (HIPEC) to maximize therapeutic benefit. This chapter focuses on the approach to the management of PSM arising secondary to peritoneal mesothelioma, appendiceal adenocarcinoma, and colorectal malignancies.

APPENDICEAL NEOPLASMS

Epidemiology and Classification

The true incidence of epithelial appendiceal cancers is unknown but is thought to be about 8 to 10 million per year, with primary malignant tumors of the appendix being incidentally discovered in about 1% of appendectomy specimens. Primary cancers may have mucinous or nonmucinous (colorectal type) histology, and either can contain a signet ring cell component. Appendiceal neoplasms with mucinous histology may give rise to the clinical entity known as *pseudomyxoma peritonei* (PMP), which is a condition characterized by mucinous ascites and peritoneal implants. Because of the rarity of appendiceal neoplasms and their unique biologic behavior, terminology and classification can be a source of confusion and debate. In 1995, Ronnett et al. described and classified peritoneal metastases resulting from PMP into three distinct groups: disseminated peritoneal adenomucinosis (DPAM), peritoneal mucinous adenocarcinosis (PMCA), and an intermediate group (PMCA I). A subsequent retrospective multiinstitutional review of 2298 patients with PMP of appendiceal origin has since validated the prognostic value of this histopathologic classification in predicting overall survival. Multiple terms have been applied to primary appendiceal neoplasms of mucinous histology as well. The 2010 World Health Organization recognized three categories of primary appendiceal neoplasms: mucinous adenoma, low grade appendiceal mucinous neoplasm, and mucinous adenocarcinoma. The 2016 Peritoneal Surface Oncology Group International Consensus developed a classification to correctly describe both the primary lesion and peritoneal disease. It also further classified noncarcinoid epithelial neoplasms of the appendix itself and added a new term, high grade appendiceal mucinous neoplasm for lesions with the low grade architectural features of low grade appendiceal mucinous neoplasm but with high grade cytologic features (Box 1). Finally, to further delineate the nomenclature to describe PMP and retained Ronnett et al.'s terminology of DPAM and PMCA (Table 2).

Clinical Manifestations

Clinical symptoms on presentation can be vague and nonspecific. The most common symptom in both men and women is increasing abdominal girth. Patients often complain of weight loss despite increasing abdominal girth, fatigue, bloating, pain, and constipation. The diagnosis is sometimes made incidentally after initial presentation for acute appendicitis with perforation. Men may also present with inguinal or umbilical hernias, whereas women may often present with a pelvic mass. It is not an uncommon scenario for a woman to be treated initially by a gynecologic oncologist for a pelvic mass presumed to be ovarian cancer, only to be determined at the time of surgical exploration that there is an appendiceal primary. In some patients, ascites may have been detected on axial imaging triggering an initial workup for cirrhosis before a diagnosis is made. Since it is not uncommon for patients often arrive to the surgeon's office by a circuitous route

Diagnostic Tests and Preoperative Workup

Patients who present with appendiceal neoplasms should be staged with axial imaging. Computed tomography of the chest, abdomen, and pelvis is commonly obtained for staging purposes, but delayed gadolinium enhanced magnetic resonance imaging has been used in some institutions with reportedly increased accuracy for staging and selection for surgical intervention. The role for positron emission tomography is limited as the mucinous content of tumors often dilutes the metabolic signal. In addition to routine laboratory tests of complete metabolic panel, complete blood count, and coagulation panel, tumor markers consisting of CEA, CA 19-9, and CA 125 should be obtained. Although none of these tumor markers are specific for appendiceal malignancies, in about 50% to 70% cases, at least one marker may be elevated, allowing for postoperative surveillance. A colonoscopy should be performed if one has not been performed, however, results are frequently negative for any detectable intraluminal malignancy. It is also our routine practice to have the slides reviewed by a pathologist with expertise in gastrointestinal malignancies if this was not done previously; we have observed a diagnostic discordance of approximately 30%. In patients who do not have an established diagnosis in the setting of radiographic findings of peritoneal disease and/or ascites, a diagnostic paracentesis or image guided biopsy (fine needle aspiration or core biopsy) may be performed, although it is not uncommon for these tests to be nondiagnostic. In the absence of a diagnosis, we have found diagnostic laparoscopy to be extremely valuable as a means to obtain tissue and to stage the extent of disease. At laparoscopy, ascites should be aspirated and biopsies of the peritoneum or omentum should be performed. Laparoscopic trocars may be placed midline to facilitate easy excision of port sites if needed at the time of cytoreduction. Laparoscopy provides additional information on tumor burden and the potential for complete gross cytoreduction. Extensive involvement of the serosal surfaces of the bowel may preclude a complete cytoreduction, and the patient may then be rapidly referred to medical oncology for consideration of systemic chemotherapy.

Patient Selection for Surgery

Patients who have peritoneal metastases without evidence of extraperitoneal metastases from appendiceal cancer with a disease burden amenable to complete cytoreduction (resection of all gross disease) are potential candidates for CRS with HIPEC. Disease location that often precludes a complete cytoreduction include the serosal surfaces of the small bowel or encasement of the porta hepatis. Those with high grade histology (PMCA/high grade mucinous carcinoma peritonei) and disease unresectable by imaging are initially treated with systemic chemotherapy to better assess disease biology and determine surgical candidacy because patients who progress on systemic chemotherapy are much less likely to benefit from CRS/HIPEC

TABLE 1 Histopathologic Subtypes Amenable to Cytoreductive Surgery

Origin	Histopathologic Subtype
Primary disease of peritoneum	Diffuse malignant peritoneal mesothelioma Gynecologic: Primary peritoneal carcinoma
Metastatic disease of peritoneum	Gastrointestinal: Appendiceal mucinous neoplasms and adenocarcinoma Colorectal cancer Gynecologic: Epithelial ovarian cancer Fallopian tube cancer Borderline mucinous ovarian tumor Sarcoma: Desmoplastic small round cell tumor Other: Urachal adenocarcinoma Mucinous adenocarcinoma of unknown origin

The outstanding survival observed in the PSOGI 2016 study following complete cytoreductive surgery clearly suggests that surgical excision of isolated peritoneal metastases from colorectal cancer should be adopted as a standard of care, whereas the addition of hyperthermic intraperitoneal chemotherapy deserves further study, particularly in patients with intermediate disease burden.

BOX 1 PSOGI 2016 Classification of Noncarcinoid Appendiceal Epithelial Neoplasms

Tubular, tubulovillous or villous adenoma, low- or high-grade dysplasia
Serrated polyp with or without dysplasia (low or high grade)
Low-grade appendiceal mucinous neoplasm
High-grade appendiceal mucinous neoplasm
Mucinous adenocarcinoma, well, moderately or poorly differentiated
Poorly differentiated (mucinous) adenocarcinoma with signet ring cells
(Mucinous) signet ring cell carcinoma
Adenocarcinoma, well, moderately, or poorly differentiated

PSOGI, Peritoneal Surface Oncology Group International.

Those with low-grade histology (LAMN/low-grade mucinous carcinoma peritonei) who are not candidates for complete cytoreduction because of disease burden but who have surgically manageable symptomatic disease (i.e., obstructive symptoms) may be treated with palliative debulking without HIPEC (Fig. 1).

COLORECTAL CANCER

The care of patients with stage IV colorectal cancer (CRC) has evolved significantly over the past several decades. Advances in multiagent systemic therapy have increased median survivals from 12 months in the 5-FU alone era to approximately 30 months in the current age. Unfortunately, the majority of studies contain very few patients with peritoneal metastases. Data from multiple phase III studies revealed poorer outcomes for patients with peritoneal metastases treated with systemic therapy than for those patients with visceral metastatic disease. During this time, the practice of surgical resection of patients with isolated hepatic metastatic disease was broadened to include patients with (1) larger burdens of liver involvement, (2) isolated lung metastases, (3) liver and lung metastases, and (4) other isolated sites of metastatic disease. There is now an abundance of retrospective and an increasing amount of prospective data demonstrating that, in selected patients, surgical resection of all visible peritoneal metastases often combined with regional hyperthermic chemotherapy can result in long-term survival and cure for patients with CRC, not generally achievable with systemic therapy alone.

TABLE 2 Classifications of Pseudomyxoma Peritonei

Ronnett et al. 1995 Classification	WHO 2010 Classification	PSOGI 2016 Classification
DPAM PMCA I	Low-grade appendiceal mucinous neoplasm	Acellular mucin Low-grade mucinous carcinoma peritonei or DPAM
PMCA	Invasive mucinous adenocarcinoma	High-grade mucinous carcinoma peritonei or PMCA High-grade mucinous carcinoma peritonei with signet ring cells or PMCA I

DPAM, disseminated peritoneal adenomucinosis; PMCA, peritoneal mucinous adenocarcinoma; PMCA I, peritoneal mucinous adenocarcinoma intermediate.

Epidemiology

Among patients with CRC, the peritoneum is a common site of metastatic disease both at diagnosis (10%–15%) and at the time of relapse (35%–50%). Retrospective series vary but suggest that in 2.5% to 55% of CRC patients, the peritoneum will be the only site of metastatic disease. Risk factors for peritoneal metastases include mucinous histology, T4 cancer, and perforation, either spontaneous or iatrogenic.

Clinical Manifestations

As in the case of other histologies, peritoneal metastases secondary to CRC may present with ascites manifest as increasing intra-abdominal girth, pain, or small bowel obstruction. However, just as often, synchronous peritoneal disease may be asymptomatic and detected at the time of primary surgery. For patients with metachronous disease, it is most common to identify peritoneal metastases during surveillance given the intensity of imaging use in current practice.

Preoperative Workup

Patient selection for CRS HIPEC is always critical, but even more so for high-grade malignancies such as CRC. The principal goals of the workup are to (1) ensure that the peritoneal surfaces are the only site of metastatic disease, (2) determine the potential for complete cytoreduction, and (3) determine the patient's medical fitness for the procedure.

Preoperative evaluation should consist of a complete history and physical examination, with attention to any signs of inherited cancer susceptibility. Axial imaging (computed tomography or magnetic resonance imaging) of the chest/abdomen and pelvis are essential. In reality, we have observed most patients referred to our practice have had positron emission tomography imaging as well, though it is unclear as to its value as a routine study. We do believe positron emission tomography has clear value in the setting of equivocal findings on axial imaging. Routine preoperative bloodwork should include CEA at initial diagnosis or if it has been elevated previously. We suggest a full colonoscopy if it has not been performed within the past 2 years.

For the majority of patients, we have used diagnostic laparoscopy as a staging tool for several reasons. Axial imaging has poor sensitivity for the detection of peritoneal metastases; therefore, determining the potential for complete cytoreduction is challenging based on axial imaging alone. In our hands, diagnostic laparoscopy has an 83% positive predictive value to determine the potential for a complete cytoreduction. We find it extremely valuable in the informed consent process as well because it allows a much more accurate discussion regarding the planned procedure, its potential morbidities, and the anticipated length of stay. Obtaining photographs of the extent of disease also allows patients and families to better understand the disease process and the rationale for recommending or not recommending CRS/HIPEC.

Patient Selection for Surgery

Patient selection for CRS and HIPEC in metastatic CRC is even more stringent than for appendiceal neoplasms. Unlike mucinous appendiceal cancer, which frequently exhibits peritoneal only metastasis, CRC has a greater propensity for nodal and extraperitoneal metastasis. Also, unlike appendiceal primary neoplasms, patients with peritoneal metastatic CRC are less likely to benefit from incomplete debulking, including CC-1 cytoreduction.

We believe that patients with CRC with even limited resectable peritoneal disease at the time of synchronous presentation/diagnosis are best treated with neoadjuvant systemic therapy to select out those who have rapid disease progression and to assess response, before embarking on CRS. Patients with extraabdominal disease in the

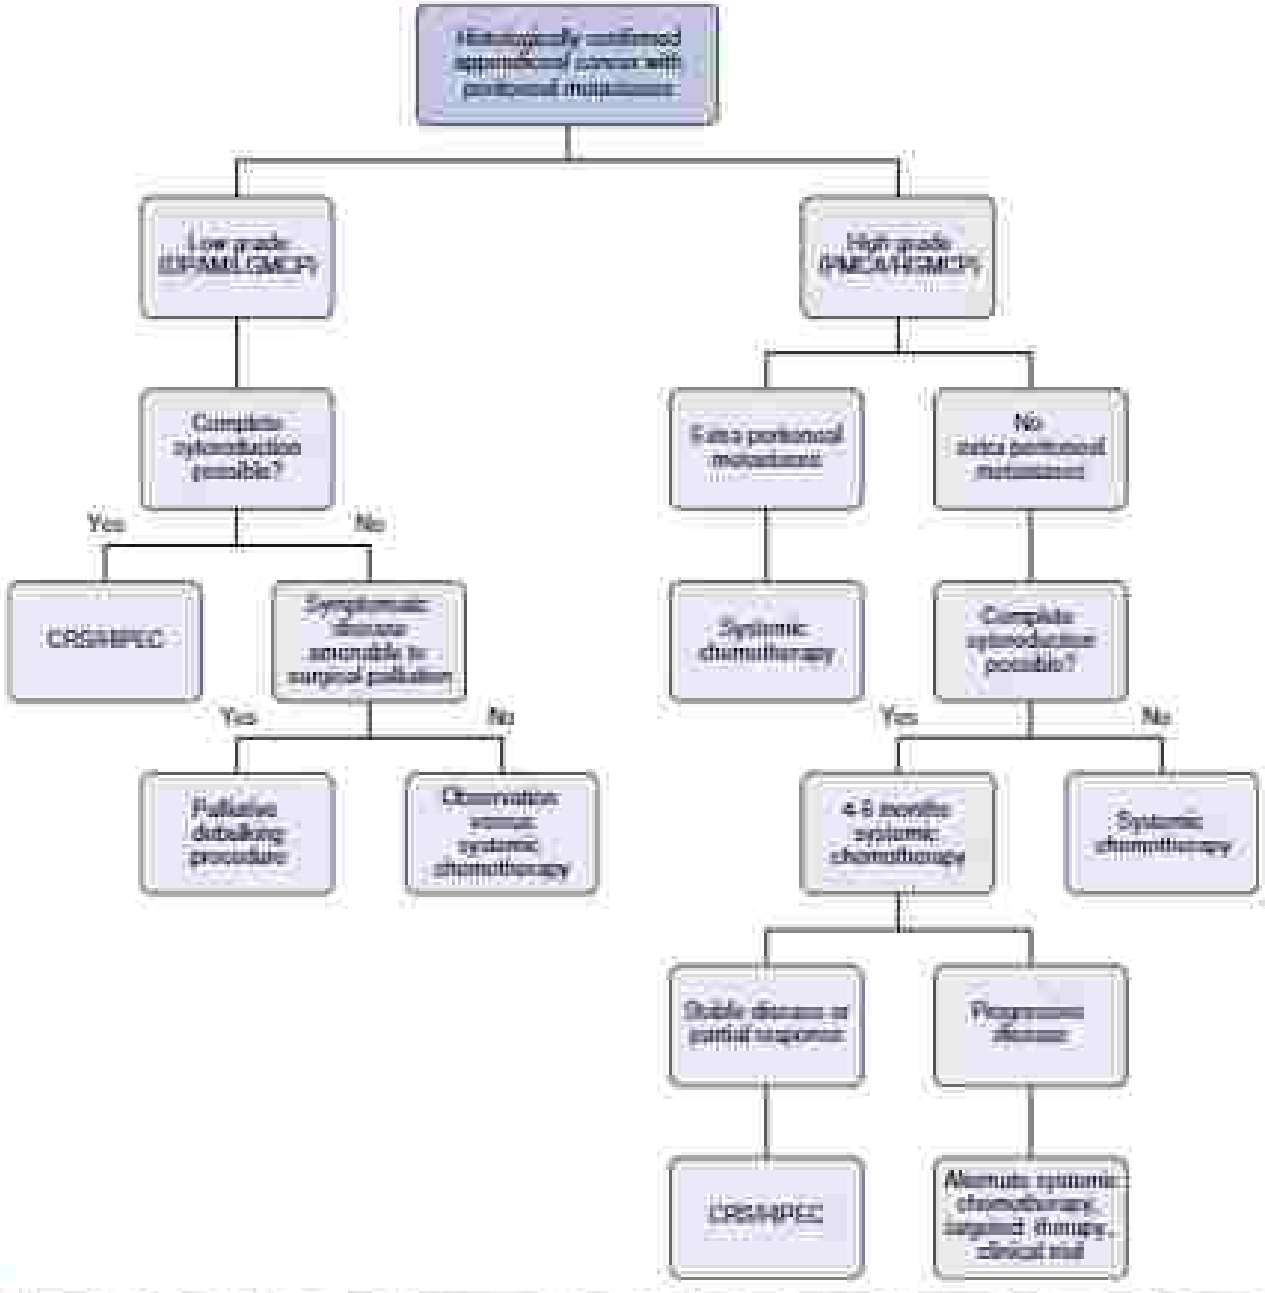

FIG. 1. University of California San Diego algorithm for management of patients with peritoneal metastasis from appendiceal neoplasms. CRS, cytoreductive surgery; CRSM, disseminated peritoneal adenomucinosis; HGMCP, high-grade appendiceal mucinous neoplasm; HIPEC, hyperthermic intraperitoneal chemotherapy; LGMCP, low-grade appendiceal mucinous neoplasm; PMCA, peritoneal mucinous adenocarcinoma.

peritoneum detected on surveillance imaging after previous curative-intent treatment for a primary CRC need careful staging, ideally with laparoscopy. Patients with metachronous peritoneal disease felt to be potential candidates for CRS should be discussed in a multidisciplinary tumor board setting to decide on an optimal sequence of therapy because they are likely to require further systemic treatment as well. Those who are fit for surgery have a limited peritoneal disease burden, and those who have had a long disease-free interval (>6 years) since their primary treatment may be considered to go straight to CRS, which may include HIPEC. More often though, patients develop peritoneal recurrence in the first few years after their primary treatment, and so upfront systemic therapy followed by CRS in those with responsive or stable disease is usually the best approach.

Patients presenting with synchronous or metachronous peritoneal metastases with symptoms, such as small bowel obstruction, have a worse prognosis and are less likely to benefit from CRS with HIPEC. As mentioned previously, the majority of patients with peritoneal metastases from CRC have at least one site of extraperitoneal disease as well, most commonly parenchymal liver and/or lung metastases. Although extraperitoneal disease has been shown to be a poor prognostic factor in some series, it is not an absolute contraindication to CRS with HIPEC in younger, fit patients who have had stable disease on systemic therapy and whose disease is amenable to complete resection. Table 3 summarizes relative and absolute contraindications to CRS with HIPEC that we use in practice our institution. In addition to the Peritoneal Cancer Index (PCI), scored on a scale from 0 to 39 (Fig. 2), the peritoneal surface disease severity score and, more recently, the colorectal peritoneal metastasis prognostic surgical score are prognostic nomograms that aim to guide patient selection for CRS and HIPEC. Both take PCI into account but also consider other clinical variables, and both have been validated in peritoneal metastatic CRC with reasonably good model performance.

TABLE 3 Relative and Absolute Contraindications to CRS With HIPEC in Patients With Peritoneal Metastatic CRC

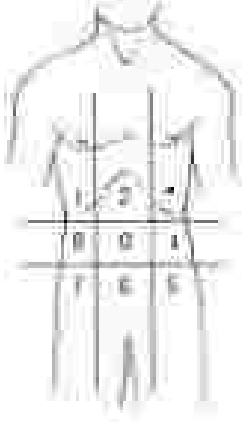
Absolute Contraindications	Relative Contraindications
Poor performance status/frailty	Short disease-free interval (if metachronous)
Disease not amenable to complete (CC-0) cytoreduction	PCI >20
Disease progression on systemic therapy	Serosa positive
Malignant small bowel obstruction	

CRS, cytoreductive surgery; HIPEC, hyperthermic intraperitoneal chemotherapy; PCI, Peritoneal Cancer Index.

PERITONEAL MESOTHELIOMA

Epidemiology, Classification, Clinical Manifestations, and Surgical Selection

Malignant peritoneal mesothelioma (MPM) is a rare, aggressive primary malignancy of the peritoneum. It comprises 10% to 15% of all mesotheliomas, and the annual incidence in the United States of MPM is approximately 400 cases. Asbestos exposure is the most well-characterized risk factor for mesothelioma, although the attributable risk of asbestos for MPM is only 25% to 50%. Other potential risk factors for MPM include prior radiation therapy, maternal fiber exposure, chronic peritonitis, and germline BRCA 1–associated protein (BAP 1) gene mutation. Histologic subtypes of MPM include epithelioid, which is the most common and least aggressive subtype; sarcomatoid, which is the most aggressive subtype; and biphasic, which has histologic and behavioral features of epithelioid and sarcomatoid. Patients with MPM often present similarly to other patients with PSM, with vague symptoms of abdominal distension, pain, and early satiety. Imaging findings are often subtle and include ascites and omental and/or mesenteric fatty infiltration. Diagnosis is obtained histologically, by percutaneous biopsy of a large omental/abdominal mass (if present), by laparoscopic biopsy, or by biopsy obtained during surgery for another indication when MPM is discovered incidentally. The natural history of MPM is aggressive; without treatment, median survival is approximately 6 months. Median survival of MPM with systemic chemotherapy alone is approximately 16 months. Patients with MPM are considered for surgical therapy with CRS/HIPEC if their disease burden is amenable to resection of all or nearly all (CC-0 or CC-1) visible disease, and they are suitable to for such extensive



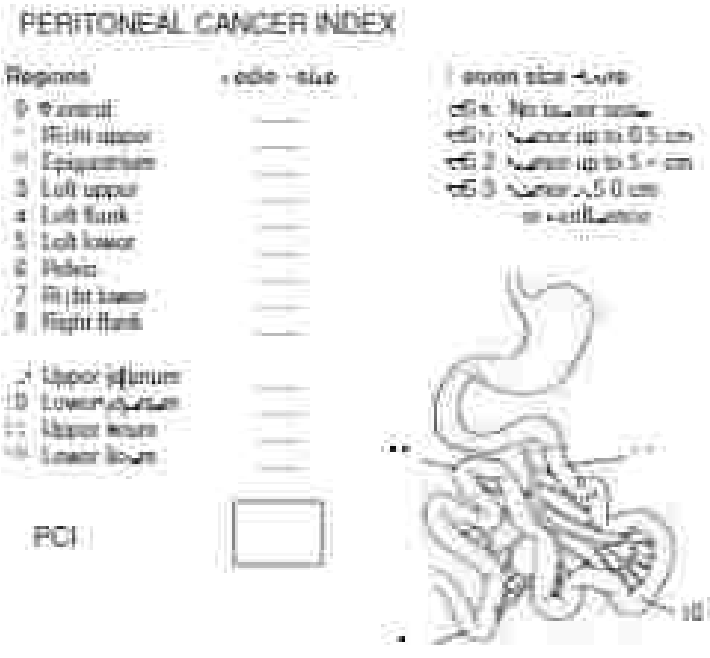


FIG. 2 The Peritoneal Cancer Index allows a quantitative assessment of the extent of peritoneal metastatic disease. The abdomen is divided into 13 quadrants and the small bowel into 4 distinct regions. Each is assigned a score of 0 to 3 based on the size of the metastatic lesions, if present, before cytoreductive surgery. (From Jacquet P, Sugarbaker PH. Clinical research methodologies in diagnosis and staging of patients with peritoneal carcinomatosis. In: Sugarbaker PH, ed. Peritoneal Carcinomatosis: Principles of Management. Boston: Kluwer Academic Publishers; 1996:359–374.)

surgery. We often use laparoscopy to determine if a complete cytoreduction can be performed because imaging generally underestimates the extent of disease in MPM. Preoperative chemotherapy with platinum-based regimens and pemetrexed are given to patients with disease burdens of borderline potential for complete cytoreduction.

INTRAOPERATIVE MANAGEMENT AND TECHNIQUE

The primary goal of CRS is to resect all visible peritoneal metastases. HIPEC involves perfusion of the peritoneal cavity with heated cytotoxic chemotherapy with the goal of eradicating residual microscopic disease, with a putative tissue penetration of 2 to 5 mm. Administration of the cytotoxic agent directly into the abdominal cavity takes advantage of the peritoneal plasma barrier and therefore allows for the delivery of a higher local concentration and less systemic toxicity than is possible via the intravenous route. Moreover, hyperthermia is toxic to malignant cells and can provide additive or synergistic benefit when combined with cytotoxic chemotherapy.

Patients typically undergo a mechanical bowel preparation with oral antibiotics prior to surgery. Because CRS with HIPEC procedures are often long, we prefer supine positioning whenever possible. If proctectomy is required, it usually involves the upper rectum at or above the peritoneal reflection (except in cases of rectal primary tumors) so very low rectal anastomoses are not usually required. We prefer a reverse end-to-end anastomosis technique in which the anvil of the circular stapler is placed in the rectal stump with a purse-string suture and the stapler is passed through a colotomy or enterotomy on the bowel on the proximal side of the anastomosis. This allows for the procedure to be performed without prolonged low lithotomy positioning and eliminates crossing staple lines during completion of the anastomosis. We routinely administer prophylactic subcutaneous heparin preoperatively as well as prophylactic antibiotics. Communication with the anesthesia team is important during CRS with HIPEC so that adequate urine output is maintained throughout and core body temperature is carefully monitored. Cooling blankets or ice packs applied to the patient's head and neck areas are sometimes required during the HIPEC portion of the procedure. An epidural catheter is preferred for postoperative pain control.

The procedure is begun with a complete evaluation of the extent of peritoneal metastases, generally via a full midline incision, to determine if a complete cytoreduction can be achieved. This exploration may require extensive adhesiolysis of benign or malignant adhesions from prior surgery or peritoneal metastases. A precytoreduction PCI is assessed, followed by complete cytoreductive surgery with resection of all visible peritoneal tumor if possible. Note that although a PCI score provides information about the amount of tumor burden, it does not necessarily convey if the patient is amenable to a complete cytoreduction. For example, a patient with low grade histology and a PCI score of 39 may be amenable to complete cytoreduction, whereas a patient with high grade histology and PCI score of 18 may not. A complete, systematic inspection of the peritoneal cavity is critical, including the bilateral diaphragm surfaces, the lesser sac, the porta hepatis, and the small bowel and its mesentery, and the pelvis. Particular areas that warrant careful inspection include the falciform ligament where it inserts into the liver parenchyma, the fold of peritoneum that makes up the ligament of Treitz, the pelvic cul-de-sac, and the base of the bladder. These are sites where small deposits of disease can be easily missed. We recommend complete running of the small bowel from the ligament of Treitz to the ileocecal valve or prior colonic anastomosis with assessment of all areas that might need resection prior to performing any resection. This allows for planning ahead to minimize the length of bowel to be resected. Generally, lesions without serosal invasion can be removed sharply with sweeping of resultant serosal defects. Full thickness/invasive lesions require either excision with primary repair or formal segmental resection. Both sides of the mesentery also need to be fully inspected. Very small (<2–3 mm) mesenteric implants or confluent areas of miliary deposits may be amenable to thermal ablation with an argon beam coagulator or other similar device. Extensive small bowel disease not amenable to resection with sufficient remnant or nodal disease involving the root of the mesentery are contraindications to complete cytoreduction.

Complete cytoreduction generally requires a greater amount of time, selective peritonectomy of diseased parietal peritoneum, and visceral resections as indicated for organs invaded by or with densely adherent, soft peritoneal tumor nodules. The parietal peritoneum on the surface of the diaphragm, particularly on the right side, is a common site of involvement. For complete diaphragm stripping, the liver must be mobilized away from the diaphragm by taking down the triangular ligament. The peritoneum is then carefully stripped. If a hole is made in the diaphragm during the dissection, a chest tube is recommended as reactive pleural effusions and residual pneumothorax is common.

If HIPEC is used, we begin once all visible disease has been removed and the patient is hemodynamically stable with adequate (1 mL/kg per hour) urine output. Although either an open or a closed perfusion technique may be used, we use a closed technique because it reduces chemotherapy exposure to the operating team. It is undertaken by inserting inflow and outflow cannulas along with thermistor probes for temperature monitoring and with temporary skin closure around the cannulas (Fig. 3). Using a hyperthermia perfusion pump, between 3 and 4 L of warmed perfusate (typically, lactated Ringer's) is instilled. Once adequate abdominal distention is achieved based on intraoperative assessment of the peritoneal cavity volume, the perfusate is then circulated at a flow rate of 1 L/min and heated using the perfusion pump, with a goal intraperitoneal temperature of 42°C to 43°C. When the target temperature is reached, the chemotherapy is infused into the perfusion circuit and the abdomen is manually agitated for the entirety of the chemoperfusion. For appendix and CRC's, mitomycin C or cisplatin are the two most common agents used, and cisplatin with or without gemcitabine is used for mesothelioma. The chemoperfusion is undertaken for 30 to 120 minutes (90 minutes at our institution). At the end of the chemoperfusion, additional perfusate is then added to the perfusion circuit and the residual chemotherapy is flushed out of the abdomen.

The abdomen is then reopened for reexploration, gastrointestinal reconstruction, and drain placement. We have a low threshold for placement of a decompressive Stamm gastrostomy tube (G tube). This is because postoperative ileus is common following CRS with HIPEC, and because patients are at risk for recurrent disease in the peritoneum and reaccumulation of ascites and/or ascites in the

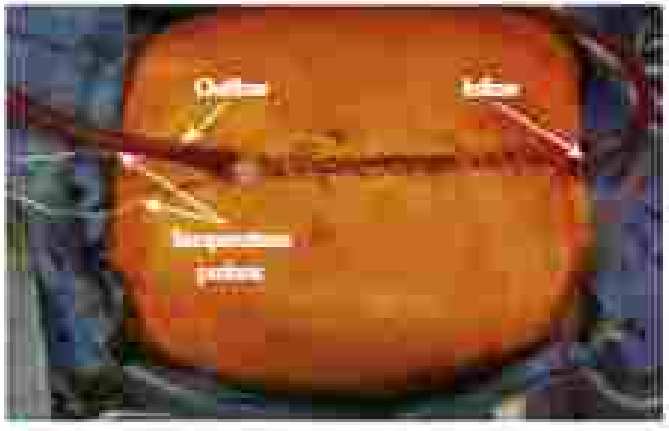

FIG. 3. Intraoperative image demonstrating the closed perfusion technique for hyperthermic intraperitoneal chemoperfusion. Inflow and outflow cannulas enter and exit the patient's abdomen after the skin is temporarily closed. Temperature probes monitor the intraperitoneal temperature consistently with a target of 42°C to 43°C.

future. Even once the initial tube has been removed, the stomach remains sutured to the anterior abdominal wall to facilitate easy tube replacement should the patient develop recurrence and require gastric decompression in the future. We also typically leave at least one surgical drain near any high-risk anastomoses. The fascia is then definitively closed. A completeness of cytoreduction score is assigned at the end of the case (Table 4).

MANAGEMENT OF INCIDENTALLY NOTED PERITONEAL METASTASES

One of the most taxing situations for many surgeons is determining management of patients with peritoneal metastases secondary to colorectal or appendiceal neoplasms noted at elective colectomy or at the time of appendicectomy (now most often laparoscopic appendectomy). When colorectal metastases are noted during elective colectomy for cancer, the proper management depends on several factors: (1) the extent of the disease and concomitantly, the ability of the surgeon to thoroughly assess this, and (2) whether the planned resection is purely elective or whether the patient has a component of obstruction, bleeding, or evidence of perforation. In all cases, biopsy of the peritoneal disease is critical because it is the accurate documentation of the extent of disease, as best can be determined. Most important, it is critical for the operating surgeon to assess and document the presence of visceral metastases, and the extent of disease involving the serosal surfaces of bowel and mesentery. If the operation is purely elective, then biopsy and documentation alone, without resection of the primary cancer is probably optimal because it will allow the patient to rapidly recover and go on to systemic chemotherapy and possible CRS at a later date as indicated. If the cancer is complicated by obstruction, perforation, or bleeding, then in addition to biopsy and documentation, colon resection should be performed in a conservative manner. In the rare circumstance in which peritoneal metastases are extremely limited (i.e., a single focus of disease to the omentum), it is reasonable for the surgeon to perform a colectomy and excision of all gross disease, ensuring that a complete exploration of the abdomen is possible.

In the setting of peritoneal metastases noted at laparoscopic appendicectomy, the appendicectomy may be completed if it is straightforward, but again, the most important aspects of the procedure are biopsy of the peritoneal metastatic disease and documentation of the status of the remainder of the abdomen.

POSTOPERATIVE MANAGEMENT

Patients are generally admitted to the intensive care unit postoperatively for the first 24 to 48 hours. Patients are initially allowed sips of water and ice chips with the decompressive G-tube open to gravity drainage. Ambulation and incentive spirometry are encouraged on the first postoperative day. We generally advance patients to a liquid diet as long as they are not reporting nausea and are not distended. The G-tube is kept open to gravity until there is flatus or a bowel movement. We then begin interval clamping of the G-tube with 1 hour clamped and 3 hours open for a day, then progressively clamp for longer periods until continuous clamping is tolerated. Once the patient is tolerating continuous clamping, we advance them to a soft or low residue diet. The G-tube may be removed before discharge depending on the length of stay, or more often in the clinic within 2 weeks of discharge. Patients are given prophylactic low molecular weight heparin during the entire postoperative hospital stay and for 2 weeks following discharge.

TABLE 4 Completeness of Cytoreduction Score

Score	Residual Disease
CC-0	No gross visible disease
CC-1	Tumor nodules <2.5 mm
CC-2	Tumor nodules between 2.5 and 2.5 cm
CC-3	Tumor nodules >2.5 cm

SURGICAL OUTCOMES

Recent large series from high volume CRS/HIPEC centers report postoperative mortality rates of 1% to 3%. Major postoperative morbidity occurs in 15% to 35% of patients from major CRS/HIPEC centers. The most common causes of surgical morbidity of Clavien Grade 3 or higher include (Table 5) include enteric leak or fistula (in 5%–10%), intraabdominal abscess (in 10%–15%), venous thromboembolism (in 5%–15%), as well as other less common major complications, including pleural effusion, pneumonia, renal failure, and wound dehiscence. Other less severe, but more common complications include prolonged ileus (in 10%); superficial wound infection (in 10%–20%), and neutropenia (in up to 10%, depending on the HIPEC agent used). Long term risks include ventral hernia formation and adhesive bowel obstruction, which have a more uncertain incidence.

Appendiceal Neoplasms

Oncologic outcomes after CRS/HIPEC for appendiceal cancers vary greatly depending on histology. Median progression free survival after CRS/HIPEC for low grade appendiceal mucinous neoplasms with peritoneal dissemination (DPAM/low grade mucinous carcinoma peritonei) is 3 to 5 years from the largest published series and the median overall survival ranges from 10 to 15 years. Patients with high grade appendiceal mucinous tumors with peritoneal metastases (PMCA with or without signet ring cells) have a 12- to 18-month median progression free survival and a 24-month median overall survival. Risk factors for recurrence and disease related mortality among patients after CRS/HIPEC for appendiceal cancer include histologic grade, completeness of cytoreduction (with higher rates of progression and mortality with more residual disease after cytoreduction), and lymph node status.

CRC

Oncologic outcomes following CRS with HIPEC for colon cancers have been evaluated in both randomized, prospective clinical trials and in large retrospective series. Median overall survival for patients who undergo complete cytoreduction in modern series is approximately 20 to 40 months. Median recurrence free survival ranges from 11 to 14 months. Five-year overall survival rates are on the order of 15% to 25%.

TABLE 5 Potential Complications of CRS/HIPEC

Complication	Rate (%)
Death	1–3
Enteric leak or fistula	5–10
Deep/organ space surgical site infection	10–15
Venous thromboembolism	5–15
Prolonged ileus	10
Superficial surgical site infection	10–20
Neutropenia	10

CRS, cytoreductive surgery; HIPEC, hyperthermic intraperitoneal chemotherapy.

As of this writing, the results of the PROPHECY-3 study were reported in abstract form. This study randomized 265 patients with isolated peritoneal metastasis from CRC who had undergone a complete or near complete cytoreduction (residual tumor nodules <2 mm) to receive HIPEC with oxaliplatin and intraoperative systemic 5-FU/folinic acid versus CRS alone. At a median follow up of 63.8 months, the median survival was 41.2 months in the new HIPEC arm and 41.7 months in the HIPEC arm. The median relapse free survival was 14.1 months in the new HIPEC arm and 13.1 months in the HIPEC arm (hazard ratio, 0.90), whereas the 1 year relapse-free survival rates were 56.1% in the new HIPEC arm and 59% in the HIPEC arm. Interestingly, a subgroup analysis did find a significant improvement in survival (hazard ratio, 0.40) favoring the HIPEC arm for patients with a PCI of 11 to 15, whereas no difference was observed for patients with either low or high burdens of disease. The particular HIPEC regimen of a 30 minute perfusion with oxaliplatin, popular in Europe has not been used extensively in the United States, where mitomycin C for 90 minutes has been the preferred regimen.

MPM

The median survival after CRS+HIPEC for MPM is 4 to 5 years based on retrospective series. The best predictors of outcome after CRS+HIPEC are (1) histologic subtype, with patients with epithelioid subtype having much more favorable survival than those with biphasic or sarcomatoid subtypes; and (2) completeness of cytoreduction, with patients undergoing CC-0 cytoreduction demonstrating the most favorable outcomes (96 month median survival vs 47 months for CC-1, 48 months for CC-2, and 12 months for CC-3).

CONCLUSIONS

Although the low incidence of the disease has precluded conduct of randomized trials, the role of CRS with HIPEC in the treatment of appendiceal neoplasms and peritoneal neoinclusions has been well established via a large number of single and multiinstitutional studies. Future efforts are underway to better understand molecular aberrations in these neoplasms and to identify or develop novel agents for intraperitoneal administration.

Appendicitis

Mark L. Kovler, MD, and David J. Mackam, MD, PhD

Appendicitis represents one of the most common causes of an acute surgical abdomen worldwide, and in the United States alone, more than 300,000 appendectomies are performed each year. The lifetime risk of developing appendicitis is greater than 12%, and the global burden of disease appears to be rising. Despite centuries of experience with the diagnosis and treatment of appendicitis, a clear understanding of its pathogenesis remains lacking. In general terms, the development of appendicitis is thought to arise from an obstruction of the appendiceal lumen, resulting in impaired blood flow and bacterial infection. The conceptual approach to the management of appendicitis should be one of the most straightforward tasks in all of surgery and requires removal of the inflamed appendix, administration of antibiotics directed toward the subsequent bacterial infection, and careful dietary advancement. That said, various factors have altered the traditional management of appendicitis, including the widespread implementation of minimally invasive approaches, a greater understanding of the role of percutaneous drainage for perforated appendicitis, a recognition that chronic appendicitis is a condition amenable to appendectomy, and most recently, various reports indicating the success of patients with appendicitis after treatment nonoperatively.

Anatomy of the Appendix

The appendix is a hollow viscus with a blind ending tip and a base located at the confluence of the three taenia coli of the cecum. Knowledge of its location at the confluence of these muscular, easily identifiable bands is critical because these bands provide confirmation of the base of the appendix during appendectomy and help ensure that the entire appendix is removed. The tip of the appendix can vary in location, which may contribute in part to the challenges associated with establishing a diagnosis of acute appendicitis (Fig. 1). The appendix may be positioned adjacent to the ileocecal valve, retrocecal or pelvic, and these different locations often result in diverse presenting signs and symptoms. Pain may be difficult to localize when the appendix is retrocecal or when the tip is oriented toward the center of the abdomen. The blood supply is from the appendicular artery, a terminal branch of the ileocolic artery that traverses the mesoappendix.

Pathophysiology of Acute Appendicitis

Acute appendicitis is thought to result from a fairly well described sequence of pathologic events, although there is actually little definitive proof that these events mediate the onset of appendicitis in all patients, and even less proof that appendicitis is the same disease in all patients. It is well accepted that obstruction of the appendiceal lumen leads to appendiceal distention, resulting in bacterial overgrowth and venous congestion. The ongoing obstruction can then progress

As of this writing, the results of the PROPHECY-3 study were reported in abstract form. This study randomized 265 patients with isolated peritoneal metastasis from CRC who had undergone a complete or near complete cytoreduction (residual tumor nodules <2 mm) to receive HIPEC with oxaliplatin and intraoperative systemic 5-FU/folinic acid versus CRS alone. At a median follow up of 63.8 months, the median survival was 41.2 months in the new HIPEC arm and 41.7 months in the HIPEC arm. The median relapse free survival was 14.1 months in the new HIPEC arm and 13.1 months in the HIPEC arm (hazard ratio, 0.90), whereas the 1 year relapse-free survival rates were 56.1% in the new HIPEC arm and 59% in the HIPEC arm. Interestingly, a subgroup analysis did find a significant improvement in survival (hazard ratio, 0.40) favoring the HIPEC arm for patients with a PCI of 11 to 15, whereas no difference was observed for patients with either low or high burdens of disease. The particular HIPEC regimen of a 30 minute perfusion with oxaliplatin, popular in Europe has not been used extensively in the United States, where mitomycin C for 90 minutes has been the preferred regimen.

MPM

The median survival after CRS+HIPEC for MPM is 4 to 5 years based on retrospective series. The best predictors of outcome after CRS+HIPEC are (1) histologic subtype, with patients with epithelioid subtype having much more favorable survival than those with biphasic or sarcomatoid subtypes; and (2) completeness of cytoreduction, with patients undergoing CC-0 cytoreduction demonstrating the most favorable outcomes (96 month median survival vs 47 months for CC-1, 48 months for CC-2, and 12 months for CC-3).

CONCLUSIONS

Although the low incidence of the disease has precluded conduct of randomized trials, the role of CRS with HIPEC in the treatment of appendiceal neoplasms and peritoneal neoinclusions has been well established via a large number of single and multiinstitutional studies. Future efforts are underway to better understand molecular aberrations in these neoplasms and to identify or develop novel agents for intraperitoneal administration.

Appendicitis

Mark L. Kovler, MD, and David J. Mackam, MD, PhD

Appendicitis represents one of the most common causes of an acute surgical abdomen worldwide, and in the United States alone, more than 300,000 appendectomies are performed each year. The lifetime risk of developing appendicitis is greater than 12%, and the global burden of disease appears to be rising. Despite centuries of experience with the diagnosis and treatment of appendicitis, a clear understanding of its pathogenesis remains lacking. In general terms, the development of appendicitis is thought to arise from an obstruction of the appendiceal lumen, resulting in impaired blood flow and bacterial infection. The conceptual approach to the management of appendicitis should be one of the most straightforward tasks in all of surgery and requires removal of the inflamed appendix, administration of antibiotics directed toward the subsequent bacterial infection, and careful dietary advancement. That said, various factors have altered the traditional management of appendicitis, including the widespread implementation of minimally invasive approaches, a greater understanding of the role of percutaneous drainage for perforated appendicitis, a recognition that chronic appendicitis is a condition amenable to appendectomy, and most recently, various reports indicating the success of patients with appendicitis after treatment nonoperatively.

Anatomy of the Appendix

The appendix is a hollow viscus with a blind ending tip and a base located at the confluence of the three taenia coli of the cecum. Knowledge of its location at the confluence of these muscular, easily identifiable bands is critical because these bands provide confirmation of the base of the appendix during appendectomy and help ensure that the entire appendix is removed. The tip of the appendix can vary in location, which may contribute in part to the challenges associated with establishing a diagnosis of acute appendicitis (Fig. 1). The appendix may be positioned adjacent to the ileocecal valve, retrocecal or pelvic, and these different locations often result in diverse presenting signs and symptoms. Pain may be difficult to localize when the appendix is retrocecal or when the tip is oriented toward the center of the abdomen. The blood supply is from the appendicular artery, a terminal branch of the ileocolic artery that traverses the mesoappendix.

Pathophysiology of Acute Appendicitis

Acute appendicitis is thought to result from a fairly well described sequence of pathologic events, although there is actually little definitive proof that these events mediate the onset of appendicitis in all patients, and even less proof that appendicitis is the same disease in all patients. It is well accepted that obstruction of the appendiceal lumen leads to appendiceal distention, resulting in bacterial overgrowth and venous congestion. The ongoing obstruction can then progress

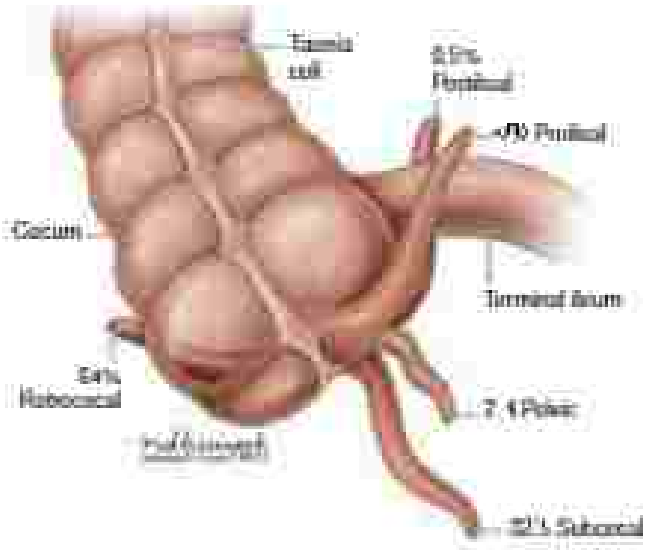

FIG. 1 Variations in the position of the vermiform appendix.

TABLE 1 Clinical Signs and Symptoms of Acute Appendicitis

History	Onset of vague abdominal discomfort, cramping, nausea, progressing to right lower quadrant pain, with associated anorexia, vomiting, and general malaise
Physical examination	Right lower quadrant tenderness, voluntary and involuntary guarding, fever, tachycardia, occasionally palpable mass
Laboratory examination	Typically leukocytosis, normal urinalysis, negative pregnancy testing
Diagnostic imaging	Distended fluid filled appendix with surrounding inflammation, perforation, abscess, fecalith

is ischemia and necrosis. The inciting luminal obstruction may be secondary to a fecalith in the appendiceal orifice (appendicolith), although a fecalith is actually seen in only 15% to 30% of cases, which raises questions about the validity of this pathophysiologic framework. A more precise understanding of appendicitis may be limited by the lack of adequate animal models to gain specific insights into its pathogenesis and by the fact that the disease is readily cured with simple removal of the appendix in so many cases. A greater understanding of the role of nonoperative management of appendicitis may shed light on the pathogenesis of this disease while also providing greater insight into how best to care for patients.

CLINICAL PRESENTATION AND DIAGNOSIS

History, Physical Examination, and Blood Work

The classic presentation of acute appendicitis is an otherwise healthy individual who complains of the vague onset of diffuse, periumbilical abdominal discomfort, which progresses to cramping, and nausea, and becomes localized to the right lower quadrant pain (Table 1). Although these symptoms strongly point to the diagnosis of appendicitis, they occur with such precision in only approximately half of patients. The physical examination reveals fever, tachycardia, and an ill-appearing patient. Abdominal findings typically include right lower quadrant tenderness, which is most intense at McBurney's point, which is the point one third of the distance from the right anterior superior iliac spine to the umbilicus. Although rebound tenderness may be present, eliciting this sign adds little to the diagnosis and causes pain, and is both nonspecific and inaccurate. Additional physical examination maneuvers that elicit localized peritoneal inflammation in acute appendicitis include Rovsing's sign, when palpation in the left lower quadrant increases pain in the right lower quadrant; obturator sign, when pain on internal rotation of the right hip indicates a pelvic appendix; and psoas sign, when pain is produced with extension at the right hip in order to reveal the presence of a retrocecal appendix. Table 2 summarizes the operating characteristics of these maneuvers in the literature and indicates that some of these maneuvers has very high sensitivity.

TABLE 2 Clinical Examination Operating Characteristics for Diagnosis of Acute Appendicitis

	Sensitivity (%)	Specificity (%)
Rovsing's sign	22–68	58–96
Obturator sign	21–34	79–96
Psoas sign	16–39	90–95

Despite a classic history and physical examination, the differential diagnosis for patients remains broad and includes ovarian pathology, urinary tract, trauma, musculoskeletal pain, Meckel's diverticulum, and inflammatory bowel disease, among others. Ancillary laboratory studies and imaging can assist in the diagnosis of acute appendicitis and decrease negative appendectomy rates.

Various blood tests may add to the diagnostic accuracy of acute appendicitis, including the white blood cell count and measurement of C-reactive protein. The white blood cell count is commonly elevated in acute appendicitis. In 2003, Andersson published a large meta-analysis of more than 3000 patients that showed that a white blood cell (WBC) count higher than 10,000 cells/mm³ had a sensitivity of 83% and specificity of 67% for acute appendicitis. Wang et al. validated the utility of WBC counts in children, demonstrating the high negative predictive value of a low or normal WBC count in the pediatric population (negative predictive value 89%–96% depending on age). Therefore, a WBC level elevated beyond 10,000 raises the suspicion for acute appendicitis, whereas a broader differential should be considered in patients with a normal WBC level. A normal urinalysis and negative pregnancy test are also consistent with acute appendicitis. Elevated C-reactive protein has been shown to be a strong predictor of acute appendicitis in young children, especially when its value is 10 or greater.

Diagnostic Imaging

The role of diagnostic imaging is to both ascertain a diagnosis of acute appendicitis preoperatively and to plan a safe resection while excluding the possibility of other intraabdominal or retroperitoneal diagnoses. The choice of a particular radiographic study is based on patient age, body habitus, and risks of radiation exposure. In the adult population, computed tomography (CT) is the most widely used study, although Applegate et al. note in a large meta-analysis that magnetic resonance imaging (MRI) may be gaining in popularity. A CT can be obtained rapidly, is relatively inexpensive, and can provide the diagnosis with sensitivity and specificity of near 100%. Two large meta-analyses by Terasawa et al. and van Randen et al. demonstrated the accuracy of CT scan for diagnosis of acute appendicitis and the ability of CT scan to detect an alternative diagnosis when appendicitis was not present. Colitis, diverticulitis, small bowel obstruction, inflammatory bowel disease, gynecologic pathology, and omental infarction

were identified on CT scans, which had been obtained for suspected acute appendicitis. Additional retrospective data suggest the use of CT scan in evaluation of appendicitis is associated with a reduction in both negative appendectomy rate and cost of care. Therefore, the American College of Radiology continues to recommend CT scan as appropriate for the initial evaluation of suspected acute appendicitis in nonpregnant adults. In children, both the National Cancer Institute and the American Pediatric Surgical Association recommend the use of nonionizing radiation where possible. Similar recommendations are in place for pregnant women. Chandy et al. report the largest series of almost 3000 ultrasound examinations to evaluate acute appendicitis in children, with a diagnostic accuracy of 92.5% and sensitivity and specificity of 97.1% and 94.8%, respectively. When ultrasound is equivocal, the literature supports cross-sectional imaging in the form of MRI. When CT scanning is performed in children, low dose radiation techniques should be used. Both a systematic review by Aly et al. and a prospective randomized controlled trial by the Low Dose CT for the Diagnosis of Appendicitis in Adolescents and Young Adults Trial demonstrate that low dose CT is not inferior to standard dose CT in the diagnosis of acute appendicitis.

MANAGEMENT OF ACUTE APPENDICITIS

The management of children with appendicitis follows surgical principals of resuscitation, antibiotics, and prompt operative intervention. Resuscitation occurs with intravenous crystalloid, and antibiotics with broad gram negative coverage should be initiated. The results of a 2005 Cochrane systematic review by Andersen et al. emphasized the consensus that all patients with acute appendicitis should receive preoperative antibiotics because they decrease the rate of wound infection and abscess. Kumar Mittinus et al. showed a cephalosporin and metronidazole combination led to the greatest reduction in infections compared with piperacillin-tazobactam and metronidazole-ciprofloxacin in a randomized controlled trial. Preoperative antibiotic choice at our institution is ceftriaxone and metronidazole. In cases of nonperforated acute appendicitis, the current approach is to perform an appendectomy. If the diagnosis is certain and the patient has been prepared for surgery, there is no advantage to delaying surgical treatment, and appendectomy should be performed promptly. However, there is now high level evidence that suggests a short in-hospital delay is not associated with an increased rate of perforated appendicitis or postoperative complications. In the most comprehensive prospective study to date, Bhangu et al. showed that the odds ratio of complicated appendicitis was not significantly increased when appendectomy was delayed between 12 and 24 hours after presentation. More extensive delays should be avoided. In cases in which the symptoms are longer than 4 to 5 days in duration, or preoperative imaging reveals the presence of an abscess, patients should be managed with percutaneous abscess drainage, antibiotics, pain management, and considered for interval appendectomy at 6 to 8 weeks to allow for the inflammatory process to subside as is described in the following section.

Laparoscopic Appendectomy

Laparoscopic appendectomy has emerged as the gold standard approach to appendectomy because it results in faster recovery, lower rates of wound infection, decreased pain, and improved cosmesis compared with open appendectomy. Sixty seven studies comparing laparoscopic and open appendectomy are summarized in Sauerland et al.'s 2010 Cochrane review, which favors the minimally invasive approach. Although the primary open approach through a McBurney's muscle splitting incision is still described, most open appendectomies are performed as a conversion from a laparoscopic approach through a low midline laparotomy. The most common reasons for conversion from laparoscopic to open appendectomy include dense adhesions and difficulty with removing the appendix secondary to perforation.

Details of the Operation

The patient is positioned on the operating table supine with the left arm tucked for ease of laparoscopy from the left side (Fig. 2). Patients are encouraged to void immediately before surgery, and in most cases a Foley catheter can be avoided. Laparoscopic access is gained through an umbilical port placed using either an open Hasson or Veress needle technique. After insufflation and under direct visualization, two 5-mm working ports are placed in the left lower quadrant and suprapubic positions. Many surgeons avoid the suprapubic port to decrease bladder injury risk and place an umbilical port as well as two ports on the patient's left side, spaced as far apart as possible. In cases of severe inflammation of the appendix, or in the presence of significant ileus resulting in distention of the intestinal contents, a fourth port may be placed for retraction purposes; this can be most helpful if placed in the central or left upper abdomen. Placing the patient in Trendelenburg

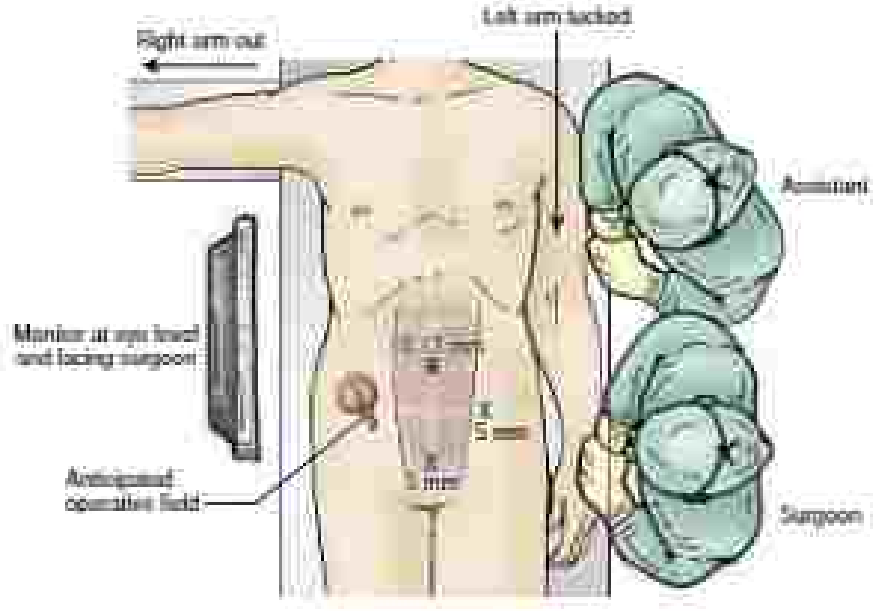

FIG. 2 Operating room, patient positioning, and port placement for laparoscopic appendectomy in pediatric patients. The right arm may also be easily tucked and smaller ports may be utilized.

position with the left side down increases exposure. When a normal-appearing appendix is found at laparoscopy for suspected appendicitis, it should be removed to decrease future diagnostic uncertainty. The base of the appendix is exposed at the convergence of the taenia coli of the cecum. Careful blunt and sharp dissection is carried out to identify the tip of the appendix, which is grasped and elevated toward the anterior abdominal wall. This can be quite challenging in the case of severe inflammation. It may be helpful to mobilize the cecum and the ascending colon, especially in the case of an inflamed retrocecal appendix. A tunnel is then created bluntly at the base of the appendix, and the mesoappendix is divided with an endoscopic vascular stapler, leaving the uninflamed base of the appendix exposed. In children, we have used hook electrocautery to divide the mesoappendix instead of a stapler. An endoscopic gastrointestinal stapler is then placed across the base of the appendix and fired, and the specimen is placed in an endoscopic bag and removed through the initial umbilical port site (Fig. 3). It is critical to ensure that the entire appendix is removed, which is accomplished by careful attention to the presence of the base at the confluence of the taenia coli.

When obviously murky fluid is encountered, it should be aspirated completely. In the presence of an abscess, the cavity should be aspirated. Data from prospective randomized trials by Irish Peter et al. and Akkersdijk and Tuma show no benefit of moderate peritoneal irrigation with normal saline. Other reports have shown irrigation may actually increase postoperative intra-abdominal abscess formation.

Postoperatively, most patients advance to a regular diet within 1 day and are discharged the day following surgery. In properly selected patients who meet discharge criteria in the postanesthesia recovery unit, outpatient appendectomy can be considered. Fraser et al. performed outpatient appendectomy in more than 80% of cases, with low morbidity (7%), low readmission (1%), and high patient satisfaction (89% preference for outpatient management). No postoperative antibiotics are indicated for nonperforated acute appendicitis. In a randomized controlled trial of 268 patients, the rate of postoperative infectious complications was not significantly different between groups who received 1 dose of perioperative antibiotics, 3 doses of antibiotics, or 5 days of perioperative antibiotics (6.7%, 6.8%, and 3.6% respectively).

Risks of laparoscopic appendectomy include surgical site infection, bleeding, bowel injury, prolonged postoperative ileus, incisional hernia, and bowel obstruction. Although morbidity is quite rare and the risk of complications in simple appendicitis is low, postoperative morbidity can be expected more frequently after surgery for perforated appendicitis. After laparoscopic appendectomy for perforated appendicitis, median length of stay is 3.7 days vs 1.86 for simple appendicitis. Almost 10% of patients with perforated appendicitis will develop an intra-abdominal abscess after surgery, which can usually be treated with percutaneous drainage.

Management of Perforated (Complicated) Appendicitis

Perforation is confirmed in up to 20% of appendicitis at presentation. Some of these patients will have diffuse peritonitis, and others will have a well-formed periappendiceal abscess. The presence of a perforated appendix on preoperative imaging does not preclude up front surgery, and perforation is detected at laparoscopy in nearly half of all cases when perforation is not suspected, although a more difficult operation should be anticipated. The management of patients with perforated appendicitis is therefore dictated by the clinical presentation and illness severity. In patients with generalized peritonitis or septic shock, patients should be resuscitated and undergo immediate appendectomy, and the initial approach should still be laparoscopic. By contrast, patients with complicated appendicitis with phlegmon or abscess formation can be considered for treatment by antibiotics and radiographically guided percutaneous drainage. As shown in a meta-analysis of more than 1500 patients by Swallis et al., immediate appendectomy in this group is associated with higher incidence of bowel obstruction, prolonged ileus, intra-abdominal abscess, surgical site infection, and need for reoperation. Another meta-analysis of 61 studies by Andersson and Petrosil found similar results and showed that nonsurgical treatment was successful in 93% of cases. In contrast, some surgeons advocate for up-front appendectomy and Mentula et al. found operative abscess drainage to be feasible, safe, and associated with fewer readmissions and additional interventions. Because more than 10% of patients in that study required conversion to open surgery, bowel resection, and incomplete appendectomy, antibiotics and percutaneous drainage remains the recommended treatment. Empiric intravenous antibiotics follow preoperative recommendations for broad gram-negative coverage, and conversion to oral antibiotics occurs when a regular diet is tolerated. Antibiotic choice may be narrowed based on operative cultures. If source control is successfully achieved by radiographically guided percutaneous drain placement, antibiotics should be continued for four days only.

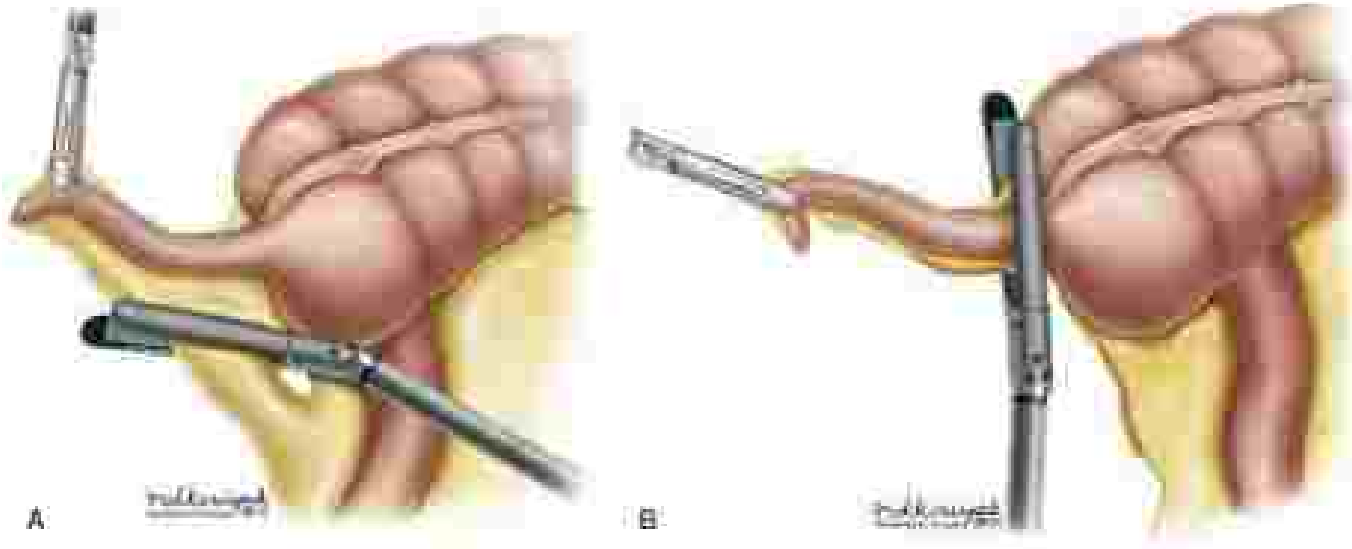

FIG. 3 (A) A window is created through the mesoappendix adjacent to the base of the appendix, and the mesoappendix is divided with a vascular stapler. (B) The base of the appendix is stapled and divided using an endoscopic gastrointestinal stapler.

as dictated by the SIS Multicenter Study of Duration of Antibiotics for Intraabdominal Infection trial. However, if there is no drainable collection and if source control cannot be achieved completely, a longer course of antibiotics (7 days) is warranted. If patients fail to improve clinically with antibiotics and drainage, operative intervention may be indicated.

CURRENT CONTROVERSIES AND SPECIAL PATIENT SITUATIONS

Nonoperative Management of Acute Appendicitis

Although appendectomy remains the treatment of choice for acute appendicitis, several randomized trials have compared appendectomy with a nonoperative approach that involves treatment with antibiotics alone. Results show that up to 37% of patients do end up requiring appendectomy within the first year after antibiotic treatment. Additionally, in a 5-year follow-up of the Antibiotic Therapy vs Appendectomy for Treatment of Uncomplicated Acute Appendicitis randomized controlled trial published in 2018, 64% of patients who were randomized to antibiotics alone underwent appendectomy between 1 and 5 years after diagnosis. Sakran et al compiled the highest quality meta-analysis of five randomized controlled trials of nonoperative management of acute appendicitis. They found treatment efficacy at 1 year was only 63.8% in nonoperative treatment versus 93% in patients who underwent appendectomy. Additionally, they found no advantage to nonoperative management with regard to length of hospital stay, duration of pain, and time off work. An important limitation is that all studies excluded immunocompromised and pregnant patients.

Interval Appendectomy

Interval appendectomy is considered in patients who have undergone initial nonoperative management of perforated appendicitis. Removal of the appendix is considered safe after 6 weeks or so, by which time the acute inflammatory process will have settled down. Those who advocate for performing an interval appendectomy state its role in eliminating recurrence while also excluding underlying appendiceal malignancy, whereas others caution that most patients will never develop appendicitis after an initial perforation, perhaps because the appendiceal lumen has become obliterated. For these reasons, interval appendectomy is not universally recommended, although patients 40 years and older should undergo interval CT scan and colonoscopy to rule out malignancy. In children, the 2017 multicenter randomized Children's Interval Appendectomy trial found that up to 23% of children randomized to "active observation" had an appendectomy within 1 year of initial occurrence, and the morbidity of interval appendectomy was low at 6% (half that of the reported morbidity in adults). Interval appendectomy is thus generally offered to children.

Appendicitis in Pregnancy

Acute appendicitis is the most common nonobstetric indication for surgery during pregnancy and affects 1 in 500 to 2000 pregnancies. The concern here is the development of both fetal and maternal morbidity, which is influenced by the severity of the underlying inflammatory process, the risk of surgery, the danger of performing a negative exploration, and the risks of anesthesia. Fetal loss is 1.5% in nonperforated appendicitis but rises to 36% in complicated appendicitis. A multidisciplinary approach with early anesthesia and obstetric consultation should be standard. In pregnant patients, appendectomy is highly recommended over a nonoperative approach, and laparoscopic appendectomy should be offered as the initial approach in all trimesters of pregnancy. A recent large meta-analysis shows potential advantages to laparoscopic appendectomy in pregnancy, despite prior low-level evidence that indicated it was associated with increased fetal loss and early delivery. General laparoscopic principles in pregnancy apply for appendectomy. Hasson's technique is preferred for access, pneumoperitoneal pressures should be minimized, and dependent positioning may alleviate hemodynamic derangements. Special consideration to the cephalad position of the appendix throughout pregnancy should be noted and necessitates adjusted port placement.

Appendicitis in Infants and Small Children

Acute appendicitis in infants and small children may raise additional diagnostic challenges, especially in the infant and toddler age ranges, in which high rates of perforation are seen and contributes to increased morbidity. Several studies reveal that children younger than 5 years represent approximately 17% of cases of pediatric appendicitis. Within this cohort, as age decreases, perforation rates increase: more than 80% of patients younger than 3 years present with perforated appendicitis. Presentation is often delayed, with average time from onset of symptoms to emergency department arrival of 1.6 days. Presenting complaints are more commonly fever (85%), vomiting (47%–56%), and diarrhea (13%–43%). The differential diagnosis for these symptoms includes more common ailments such as primary respiratory disease, intussusception, and gastroenteritis. Early pediatric surgical involvement is crucial to reduce rates of complicated appendicitis in infants and small children.

Incidental Appendectomy

Incidental appendectomy is the resection of the appendix accompanying a separate operation without overt or definitive evidence of appendicitis. The rationale for incidental appendectomy is to eliminate the risk of appendicitis in the future or in the setting of diagnostic uncertainty. The risks of incidental appendectomy include an increased risk of infection and potential loss of the appendix for subsequent gastrointestinal or urogenital reconstruction. Incidental appendectomy should therefore be strictly avoided in patients at risk for bowel and bladder incontinence, specifically those with choanal malformations, exstrophy, anorectal malformations, neurologic conditions including ventriculoperitoneal shunts for hydrocephalus, chronic constipation, and Hirschsprung's disease because the appendix may be used as part of the reconstruction. In general, incidental appendectomy should be reserved for cases in which future appendicitis will pose a particular diagnostic dilemma or future appendectomy is predicted to be unusually challenging.

Chronic Appendicitis

Various authors have described a subgroup of patients who present with chronic lower abdominal pain that is relieved by performing appendectomy. These patients have often been worked up for other known gastrointestinal conditions, most notably inflammatory bowel disease, and often have evidence on CT or MRI showing a dilated appendix or an appendicolith. In these patients, blood work is universally normal, and there are no particular aggravating or relieving factors linked with the lower abdominal pain. Although performing an appendectomy can be curative in selected patients, those patients who do not have chronic appendicitis will not benefit, and so patient selection is very important. Van Rossem et al report their series of successfully treating 10 patients with chronic right lower quadrant pain with elective appendectomy. In their strict selection process, patients underwent preoperative imaging and colonoscopy to rule out inflammatory bowel disease and malignancy. Only patients with typical localized pain were offered surgery, and the pain was often described as persistent and progressive. None of the patients in their cohort suffered infectious complications, and 8 of 10 specimens showed evidence of inflammation. Similarly, in a randomized controlled trial of 42 patients evaluating laparoscopic appendectomy for chronic right lower quadrant pain, Reumers et al found that removing the appendix was more likely to result in pain relief than not. Inclusion criteria in Reumers et al's study included at least 3 months of persistent right lower quadrant pain. Patients with chronic back

pain, previous abdominal surgery, inflammatory bowel disorder, and gynecologic disease were excluded. In summary, chronic right lower quadrant pain without evidence of acute inflammation may warrant elective appendectomy in selected patients.

SUMMARY AND FUTURE DIRECTIONS

Management of appendicitis remains one of the hallmarks of a well-qualified abdominal surgeon. That said, the diagnosis can be extremely challenging, in part because of the variable anatomic location of the appendix and significant uncertainty regarding the underlying pathogenesis of the disease. Although patients who undergo prompt appendectomy can be cured successfully, those who present after a prolonged duration of symptoms can have significant morbidity resulting from untreated abdominal sepsis. For these reasons, appendicitis remains a major cause of death in underresourced environments. In otherwise stable patients, controversy exists regarding the very need for appendectomy, given that many patients will be successfully treated with antibiotics alone. Future research will therefore continue to optimize our ability to more accurately ascertain the diagnosis of appendicitis and will more successfully predict the clinical course of patients treated with operative versus nonoperative approaches.

MANAGEMENT OF HEMORRHOIDS

Izi Okukhare, MD, and Robert Arnaja, MD, FACS, FRCS, FASCRS

The term *hemorrhoid* is used to describe abnormally large or symptomatic, dilated vascular cushions in the anal canal or anal verge (Fig. 1). The normal human anal canal has specialized vascular cushions that contribute to approximately 20% of the normal anal resting pressure. These vascular cushions contain submucosal blood vessels, connective tissue, and smooth muscle. Hemorrhoids are typically located in the left lateral, right posterior, and right anterior regions of the anal canal. The presence of these vascular cushions is critical to the maintenance of normal fecal continence during times of increased anal tone and increased abdominal pressure. Internal hemorrhoids are located proximal to the dentate line and covered with anoderm, whereas external hemorrhoids are located distal to the dentate line and are covered with skin. Internal hemorrhoids are classified based on the degree of prolapse.

ETIOLOGY AND SYMPTOMS

Hemorrhoids are typically caused by increased intraabdominal pressure resulting from constipation or diarrhea. Other causes of hemorrhoids include pregnancy, chronic obstructive pulmonary disorder, and hepatic dysfunction resulting in increased portal venous pressure. The increase in pressure results in abnormal dilation of the internal hemorrhoidal venous plexus and subsequent distention of the arteriovenous anastomosis and prolapse of the engorged hemorrhoidal tissue. Obtaining a complete history before the anorectal examination is crucial to identify the cause of the hemorrhoid.

Symptoms of hemorrhoids range from mild to severe and, in some rare cases, can result in life-threatening hemorrhagic shock as a result of massive rectal bleeding. Approximately 10 million people in the United States suffer from hemorrhoidal symptoms. More than 50% of patients with hemorrhoidal disease are older than 50 years. In the United States, the reported prevalence of symptomatic hemorrhoidal disease is 4.4%, with approximately 10 million people affected.

Hemorrhoidal symptoms include rectal bleeding, anal bulge, pruritus, anal pain, mucus discharge, itching, and difficulty with daily hygiene.

As a cautionary note, most patients with other anorectal maladies may present with complaints of hemorrhoids. It is crucial to evaluate for other causes of rectal bleeding such as anal fissure, rectal prolapse, and pruritus, and anorectal cancer resulting from similar presenting symptoms. Hemorrhoidal bleeding is typically described as bright red and some with bowel movement with little or no transmas. The extent of prolapse should be documented clearly to avoid misdiagnosis. A family history of colorectal cancer should be documented as well. A thorough examination of the anorectal area, including an anoscopy or proctoscopy when appropriate, should be performed in the clinical setting. Patients with atypical symptoms such as symptoms of a bowel obstruction or abdominal pain should be referred for colonoscopy as well to avoid delay of the appropriate diagnosis.

The most common symptom of internal hemorrhoidal disease is painless bleeding; however, other symptoms such as swelling, prolapse, hygiene problems, fecal incontinence, pruritus, and anal pain can also be present. Bleeding because of hemorrhoidal disease is typically bright red in color from the distal location and the arteriovenous source of bleeding. Patients also report bleeding during bowel movements with squirting of blood into the toilet during straining. Melanotic stools or blood mixed in the stool is typically indicative of a more proximal bleeding source requiring endoscopic evaluation. Prolapse of internal hemorrhoids below the dentate line may lead to compromise of the anal sphincter tone resting pressure, resulting in fecal incontinence and anal pruritus. Documentation of the presence of incontinence as well as anal sphincter tone before any surgical intervention is vital to defend against any frivolous litigation after surgical intervention if incontinence persists.

External hemorrhoids, on the other hand, typically cause severe rectal pain and discomfort when acutely thrombosed or ulcerated (Fig. 2). The pain from thrombosed hemorrhoids is quite different from that of an anal fissure. The pain from thrombosed external hemorrhoid typically subsides in 48 to 72 hours, whereas the pain from anal fissure is cyclical in nature and worsens with bowel movements. It lasts for 30 minutes to 1 hour after bowel movements. Patients describe the pain from a fissure as "passing shards of glass"; in contrast, acute pain from incarcerated ulcerated internal and external hemorrhoids usually progressively worsens and could lead to perianal sepsis. Anorectal examination of patients with severe anorectal pain can be quite challenging in the absence of sedation in the office or clinical setting due to the degree of discomfort associated with an anorectal examination. For such patients, stringent examination

pain, previous abdominal surgery, inflammatory bowel disorder, and gynecologic disease were excluded. In summary, chronic right lower quadrant pain without evidence of acute inflammation may warrant elective appendectomy in selected patients.

SUMMARY AND FUTURE DIRECTIONS

Management of appendicitis remains one of the hallmarks of a well-qualified abdominal surgeon. That said, the diagnosis can be extremely challenging, in part because of the variable anatomic location of the appendix and significant uncertainty regarding the underlying pathogenesis of the disease. Although patients who undergo prompt appendectomy can be cured successfully, those who present after a prolonged duration of symptoms can have significant morbidity resulting from untreated abdominal sepsis. For these reasons, appendicitis remains a major cause of death in underresourced environments. In otherwise stable patients, controversy exists regarding the very need for appendectomy, given that many patients will be successfully treated with antibiotics alone. Future research will therefore continue to optimize our ability to more accurately ascertain the diagnosis of appendicitis and will more successfully predict the clinical course of patients treated with operative versus nonoperative approaches.

MANAGEMENT OF HEMORRHOIDS

Izi Okukhare, MD, and Robert Arnaja, MD, FACS, FRCS, FASCRS

The term *hemorrhoid* is used to describe abnormally large or symptomatic, dilated vascular cushions in the anal canal or anal verge (Fig. 1). The normal human anal canal has specialized vascular cushions that contribute to approximately 20% of the normal anal resting pressure. These vascular cushions contain submucosal blood vessels, connective tissue, and smooth muscle. Hemorrhoids are typically located in the left lateral, right posterior, and right anterior regions of the anal canal. The presence of these vascular cushions is critical to the maintenance of normal fecal continence during times of increased anal tone and increased abdominal pressure. Internal hemorrhoids are located proximal to the dentate line and covered with anoderm, whereas external hemorrhoids are located distal to the dentate line and are covered with skin. Internal hemorrhoids are classified based on the degree of prolapse.

ETIOLOGY AND SYMPTOMS

Hemorrhoids are typically caused by increased intraabdominal pressure resulting from constipation or diarrhea. Other causes of hemorrhoids include pregnancy, chronic obstructive pulmonary disorder, and hepatic dysfunction resulting in increased portal venous pressure. The increase in pressure results in abnormal dilation of the internal hemorrhoidal venous plexus and subsequent distention of the arteriovenous anastomosis and prolapse of the engorged hemorrhoidal tissue. Obtaining a complete history before the anorectal examination is crucial to identify the cause of the hemorrhoid.

Symptoms of hemorrhoids range from mild to severe and, in some rare cases, can result in life-threatening hemorrhagic shock as a result of massive rectal bleeding. Approximately 10 million people in the United States suffer from hemorrhoidal symptoms. More than 50% of patients with hemorrhoidal disease are older than 50 years. In the United States, the reported prevalence of symptomatic hemorrhoidal disease is 4.4%, with approximately 10 million people affected.

Hemorrhoidal symptoms include rectal bleeding, anal bulge, pruritus, anal pain, mucus discharge, itching, and difficulty with daily hygiene.

As a cautionary note, most patients with other anorectal maladies may present with complaints of hemorrhoids. It is crucial to evaluate for other causes of rectal bleeding such as anal fissure, rectal prolapse, and pruritus, and anorectal cancer resulting from similar presenting symptoms. Hemorrhoidal bleeding is typically described as bright red and some with bowel movement with little or no transmas. The extent of prolapse should be documented clearly to avoid misdiagnosis. A family history of colorectal cancer should be documented as well. A thorough examination of the anorectal area, including an anoscopy or proctoscopy when appropriate, should be performed in the clinical setting. Patients with atypical symptoms such as symptoms of a bowel obstruction or abdominal pain should be referred for colonoscopy as well to avoid delay of the appropriate diagnosis.

The most common symptom of internal hemorrhoidal disease is painless bleeding; however, other symptoms such as swelling, prolapse, hygiene problems, fecal incontinence, pruritus, and anal pain can also be present. Bleeding because of hemorrhoidal disease is typically bright red in color from the distal location and the arteriovenous source of bleeding. Patients also report bleeding during bowel movements with squirting of blood into the toilet during straining. Melanotic stools or blood mixed in the stool is typically indicative of a more proximal bleeding source requiring endoscopic evaluation. Prolapse of internal hemorrhoids below the dentate line may lead to compromise of the anal sphincter tone resting pressure, resulting in fecal incontinence and anal pruritus. Documentation of the presence of incontinence as well as anal sphincter tone before any surgical intervention is vital to defend against any frivolous litigation after surgical intervention if incontinence persists.

External hemorrhoids, on the other hand, typically cause severe rectal pain and discomfort when acutely thrombosed or ulcerated (Fig. 2). The pain from thrombosed hemorrhoids is quite different from that of an anal fissure. The pain from thrombosed external hemorrhoid typically subsides in 48 to 72 hours, whereas the pain from anal fissure is cyclical in nature and worsens with bowel movements. It lasts for 30 minutes to 1 hour after bowel movements. Patients describe the pain from a fissure as "passing shards of glass"; in contrast, acute pain from incarcerated ulcerated internal and external hemorrhoids usually progressively worsens and could lead to perianal sepsis. Anorectal examination of patients with severe anorectal pain can be quite challenging in the absence of sedation in the office or clinical setting due to the degree of discomfort associated with an anorectal examination. For such patients, stringent examination

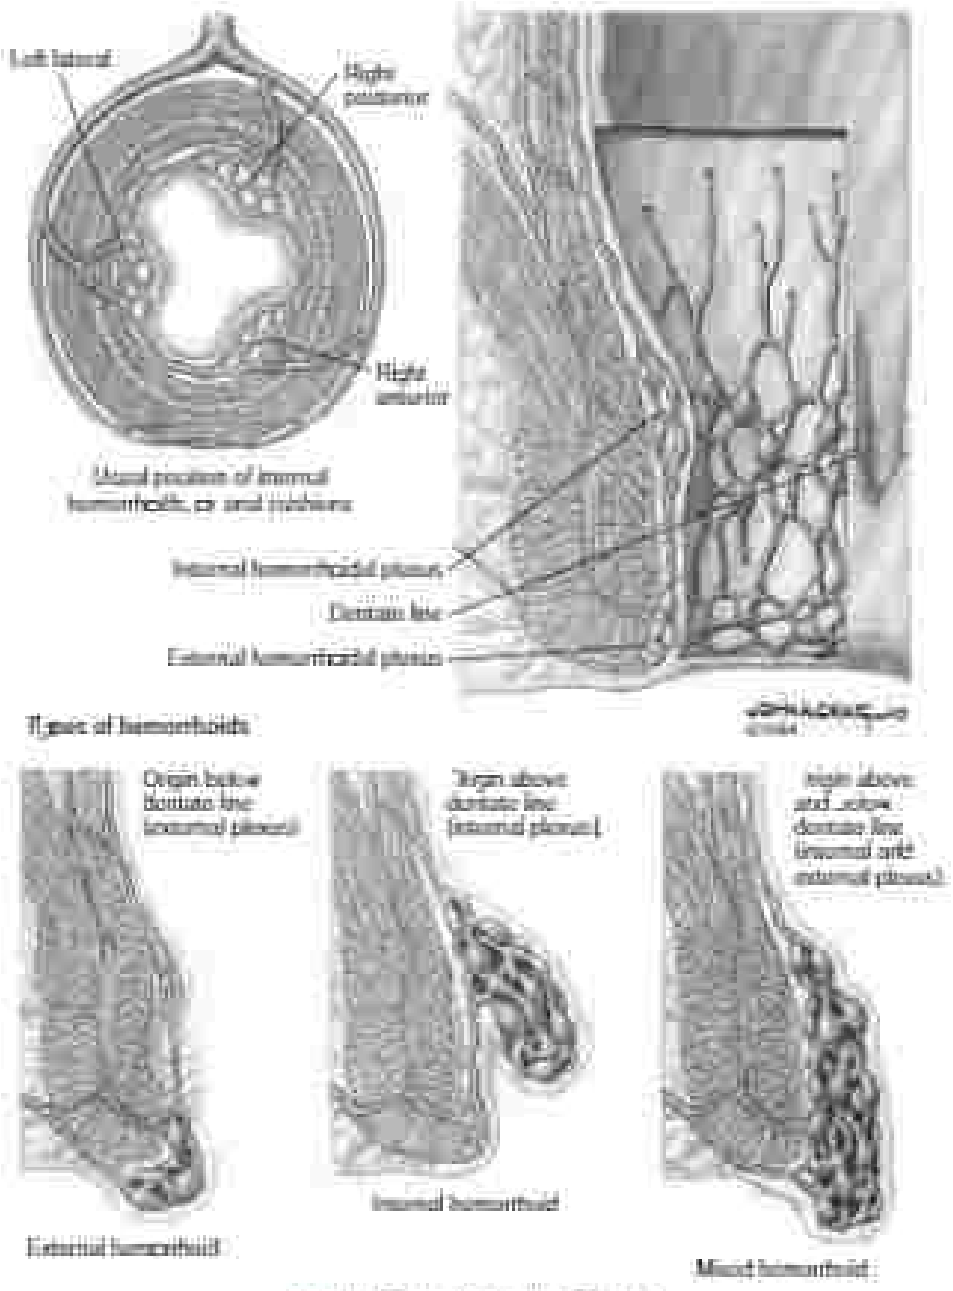

FIG. 1 Location and types of hemorrhoids.

under anesthesia with immediate treatment of the anorectal malady may be the best option for management.

CLASSIFICATION

The classification system for hemorrhoidal disease applies only to internal hemorrhoids. Internal hemorrhoids are managed based on the classification. Grades I and II can be managed nonoperatively, whereas grades III and IV often require surgical management.

Internal Hemorrhoid Classification

Grade I: Small bulge into the anal canal, no prolapse, may bleed.
Grade II: Prolapse reduces spontaneously, may have bleeding, burning or itching.
Grade III: Prolapse must be manually reduced, bleeding, itching, and mucoid drainage.
Grade IV: Prolapse not amenable to manual reduction, pain, bleeding, mucoid drainage, and may have secondary thrombosis.

TREATMENT OF HEMORRHOIDS

Medical Management

Treatment for hemorrhoidal disease typically begins with lifestyle modification as a first line therapy for most patients. Patient should be placed on fiber supplementation, increased water intake, and physical activity. Patient should be encouraged to drink at least eight glasses of water a day, except for patients with congestive heart failure. An attempt to reduce the amount of time spent while having bowel movements should be emphasized. Reading or using electronic devices while having a bowel movement should be discouraged because this prolongs the duration of straining with bowel movement, resulting in concomitant increase in the anorectal pressure from prolonged squatting.

FIG. 2 Prolapsed external and internal hemorrhoids.

A large systemic review showed that conservative therapy in patients with grade I internal hemorrhoids was sufficient enough to decrease symptomatic bleeding and prolapse. The recommended optimal medical therapy for symptomatic grades I and II hemorrhoidal disease includes warm sitz baths two to three times daily, fiber supplementation up to 24 g daily, increased water intake, and regular laxative use. Topical hemorrhoidal creams available over the counter have not been shown to consistently reduce symptoms or treat the underlying disease. After failure of medical therapy for grades I and II hemorrhoidal disease, rubber band ligation, sclerotherapy, or infrared coagulation can be used to treat patients in the office without requiring general anesthesia.

Most patients self medicate with over the counter products before seeking treatment from an experienced physician. Over the counter products include ointments, creams, suppositories, foams, and wipes. Most products contain either a single or combination of several agents including a protectant and an active ingredient. These agents either provide temporary relief from pain, itching, burning, and lubrication. Some products contain local anesthetics such as benzocaine, lidocaine, and pramoxine. Some other active agents include vasoconstricting substances such as epinephrine, phenylephrine, or ephedrine. Barrier products include dimethicone hydrous gel, cocoa butter, mineral oil, zinc oxide, starch, and petrolatum. Corticosteroids can be used as well, which provide antiinflammatory relief. Prolonged use of these products may result in thinning of the perianal skin or exacerbation of symptoms if used incorrectly for more than 4 weeks.

Rubber Band Ligation

Rubber band ligation is the most common office procedure used to treat symptomatic internal hemorrhoids (Fig. 3). It is efficacious for grade I to III hemorrhoids and does not require local anesthetics. Patients are typically placed in the jackknife position or a left lateral decubitus (Sims position). We prefer the latter position because it provides excellent exposure and is more comfortable for patients with all body types.

After careful visual examination of the perineum and anal verge, a digital rectal examination is performed before anoscopy to evaluate for any other anorectal lesions present in addition to the hemorrhoids. It is crucial to ensure that the patient does not have a full thickness rectal prolapse because placing a rubber band on prolapsed rectum will result in a solitary rectal ulcer and further bleeding. The rubber band is typically placed 2 cm above the dentate line to avoid somatic pain (Fig. 3), although suction rubber band ligator is available, this device requires the use of a pneumatic suction device. Sensation above the dentate line is tested with McGivney hemorrhoidal forceps before application of one or two rubber bands per hemorrhoidal tissue. Banding several hemorrhoids at the same sitting increases the risk of complications such as pain, fever, bleeding, thrombosis of adjacent hemorrhoidal tissue, urinary retention, and perineal sepsis. If the patient has extreme pain after placement of a rubber band, immediate removal of the rubber band is recommended using either a No. 11 blade or a suture hook. Avoidance of blood thinners for at least 7 days reduces the risk of postbanding bleed. The use of narcotics or oral antibiotics is not necessary after hemorrhoid band placement. Delayed symptoms such as fever, pelvic sepsis, and urinary retention should be addressed immediately because they may represent early signs of perineal sepsis.

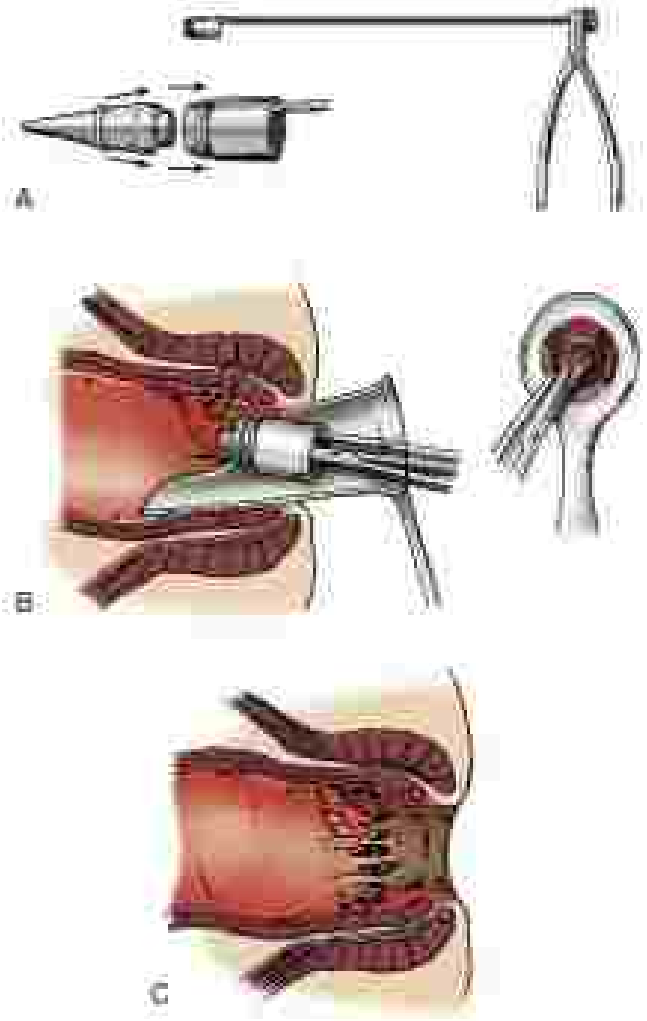

FIG. 3 Rubber band ligation of internal hemorrhoids. (A) Rubber band placed onto banding gun. (B) Hemorrhoid is grasped 2 cm above the dentate line and the band advanced over the hemorrhoid. (C) Band in correct position after ligation.

Sclerotherapy

Sclerotherapy is less commonly used for management of hemorrhoidal disease. A sclerosing agent is injected directly into the hemorrhoids, resulting in scarring, fibrosis, and fixation of the hemorrhoidal tissue. Agents typically used include hypertonic saline solution or 5% phenol

solution. The sclerosing agent is injected using a long 25-gauge needle just above the dentate line into the submucosa of the hemorrhoid. Approximately 2 to 3 mL of the sclerosing agent is injected without the aid of anesthesia. Side effects of this procedure include bleeding, injection site pain, ulceration, and sloughing of the mucosa with subsequent abscess or perirectal sepsis. Repetitive sclerotherapy can result in scarring, anal stricture, or anal fistula. Symptoms of fever, urinary retention, perineal drainage, and worsening pain should necessitate a repeat visit to the office and examination under general anesthesia if needed.

Other Office-Based Procedures (Infrared Coagulation)

Infrared photocoagulation, bipolar diathermy, and direct current electrical therapy are other office based procedures used less commonly than ligation (Fig. 4). The technique uses infrared energy to generate heat, resulting in protein coagulation and inflammatory response in the hemorrhoidal bed. The end effect is scarring and fixation of the hemorrhoid. A tungsten halogen lamp is used to generate the infrared radiation (IRC 2100, Redfield Corporation). Application of this device will yield a 4 mm^3 focus of coagulation with a 2.5-mm deep ulcer.

The HET bipolar system (Covidien) can also be used in the clinical setting without anesthesia. Using a bipolar clamp, the hemorrhoidal bundles are grasped and cauterized. This technique is used for grades I and II hemorrhoidal disease. The complications and postoperative care are very similar to that for sclerotherapy and infrared coagulation.

OPERATIVE TREATMENT

Operative hemorrhoidectomy is indicated for patients who do not respond to nonoperative management and office based procedures. It is also reserved for mixed hemorrhoids with internal and external components or grade III to IV internal hemorrhoids with bleeding. Preoperative history and physical examination as well as careful counseling about the risks, benefits, and expected results after the surgical procedure are crucial to ensuring patient satisfaction. A meticulous documentation of preoperative anal sphincter tone and presence or absence of incontinence is crucial to the defense against frivolous lawsuits in the face of the most dreaded long-term complication of incontinence after hemorrhoidectomy.

Approximately 5% to 10% of patients with hemorrhoids require hemorrhoidectomy compared with the large number of patients with hemorrhoidal symptoms. Excisional hemorrhoidectomy remains the gold standard because of the low risk of complications and its efficacy profile. The notorious postoperative pain can be ameliorated by using a standardized pain management protocol in the perioperative period. Incorporation of nonnarcotic analgesics, constipation, or diarrhea reducing regimen as well as long-acting local anesthetic remains the cornerstone of postoperative pain management after hemorrhoidectomy. The excisional hemorrhoidectomy technique can be divided into three major types discussed in the following section.

Ferguson's Hemorrhoidectomy

Ferguson's hemorrhoidectomy (closed) was first described in 1971 and is the most commonly performed hemorrhoidal procedure in United States (Fig. 5). Enemas are given before the procedure to clean out the distal rectum, and the patient is typically placed in the lithotomy position in stirrups or in the prone jackknife position with the buttocks taped apart. The patient is then given either general or regional anesthesia in conjunction with local anesthetic. We prefer to give a bilateral pudendal nerve block with long-acting local anesthetics as well as injecting the base of the hemorrhoidal bundle during the procedure. The perineal and anorectal examination with an anoscope are performed first to evaluate for any other anorectal abnormalities. The hemorrhoidal bundle is grasped using forceps and a Kelly clamp is placed at the base of the hemorrhoidal column, with care taken to avoid involvement of the internal and external anal sphincters. A ligation of the vascular pedicle of the hemorrhoidal bundle was performed at the apex of the clamp using an absorbable suture either consisting of Vicryl or chromic on a tapered needle. The hemorrhoidal bundle is then excised from the sphincter complex using either fine tip scissors or a bipolar sealing device such as the Harmonic or LigaSure device. Multiple studies have shown that the Harmonic Ace has reduced postoperative pain, bleeding, and results in a significantly faster operation than monopolar diathermy. Although the increased cost of this device is a limiting factor, the use of a bipolar sealing device should be considered in cases of complicated prolapsed thrombosed hemorrhoids and in patients receiving anticoagulation therapy. The resultant hemorrhoidal bed is then closed in a running locking fashion using absorbable sutures to reduce hemorrhage and to enhance rapid healing of the defect. We prefer to perform this procedure with the patient under general anesthesia in the lithotomy position with stirrups. A small opening is typically left distally to minimize stenosis and facilitate anal drainage of any retained fluid in the hemorrhoidal bed, reducing the risk of perirectal sepsis.

Milligan-Morgan Hemorrhoidectomy

This open technique is the most commonly used in the United Kingdom. It follows the technique described by Milligan and Morgan in 1937. The technique is identical to Ferguson's technique except that, after the apex of the hemorrhoidal bundle is suture ligated, the

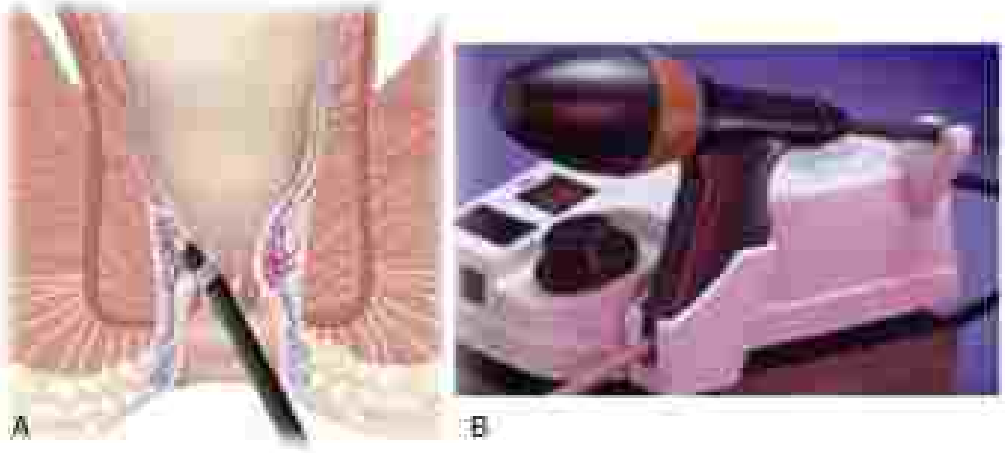

FIG. 4 Infrared coagulation of internal hemorrhoids. (A) Applicator is applied to the apex of the hemorrhoid. (B) IRC 2100 device (Redfield Corporation).

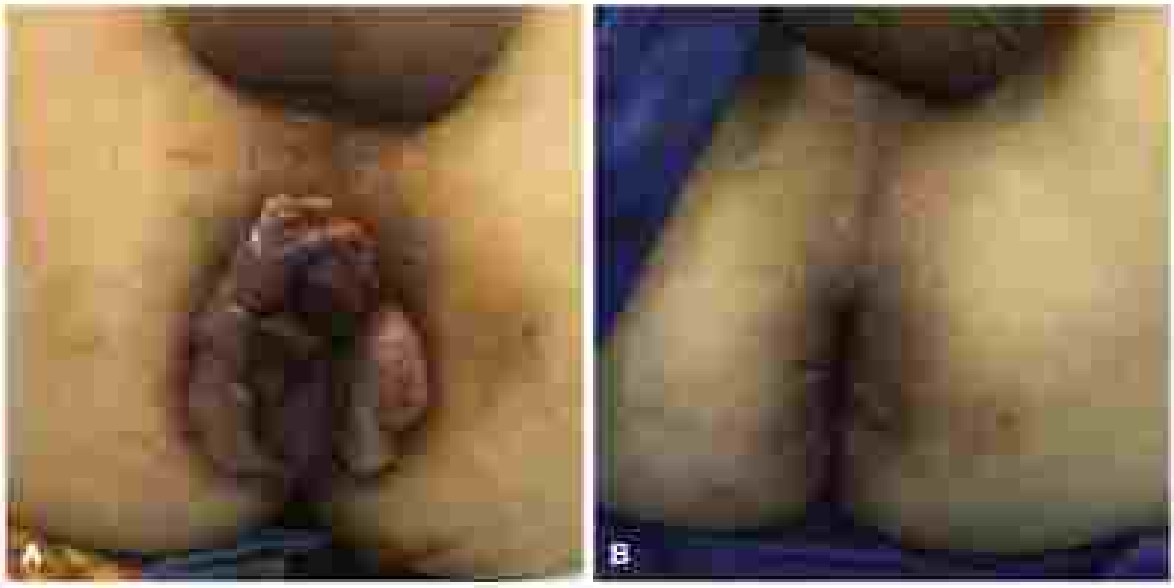
hemorrhoidal bundle is amputated and the defect is left open to granulate. The advantage of this technique includes reduced operative time and decreased pain; however, it typically presents with longer healing time compared with the closed technique. Multiple modifications of the excisional hemorrhoidal technique is available including hemorrhoidectomy, which involves suture ligation of the hemorrhoidal bundle without any removal of the hemorrhoidal tissue and can be used when necessary to prevent removal of excessive anal tissue and anal stenosis.

Circumferential Technique

The circumferential technique, also known as the whitehead hemorrhoidectomy, involves circumferential excision of the internal hemorrhoids as well as redundant mucosa just proximal to the dentate line. This technique is more commonly performed in the United Kingdom with low utilization in the United States. The drawback of this technique is the significant mucosal ectropium, also known as whitehead deformity, and high rates of anal stenosis and incontinence. This technique may have a utility in patients with significant circumferential mucosal prolapse in addition to symptomatic hemorrhoidal disease.

Transanal Hemorrhoidal Dearterialization

Doppler-guided hemorrhoidal artery ligation is a newer technique that involves using a transanal hemorrhoidal Doppler for targeted



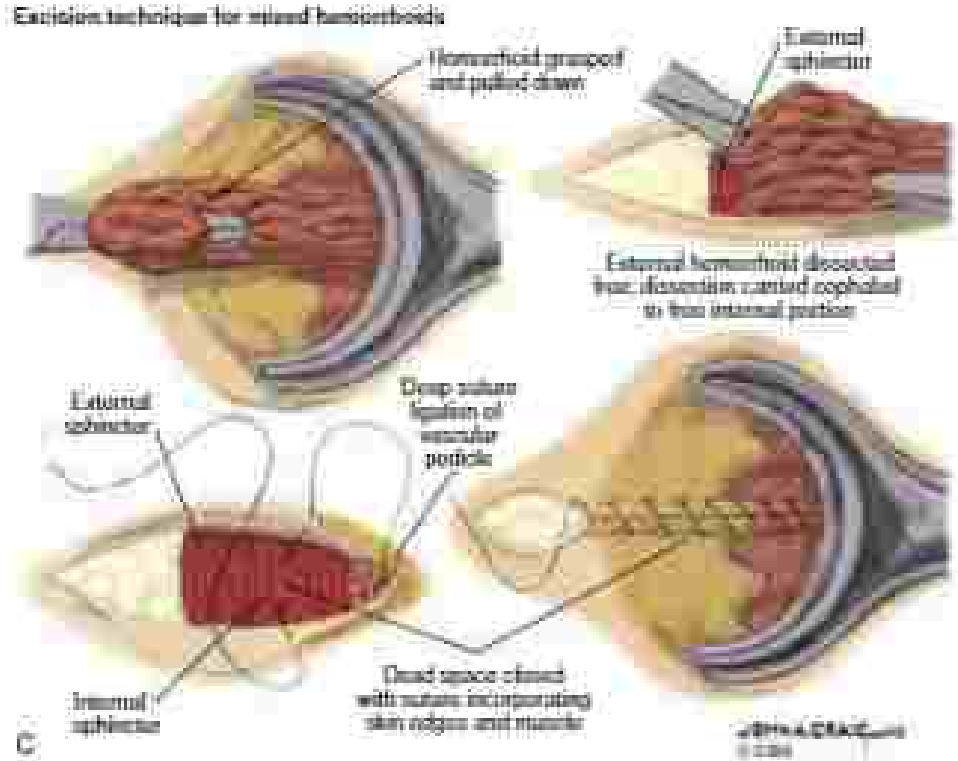


FIG. 5 (A) Before and (B) after excisional hemorrhoidectomy. (C) Ferguson's hemorrhoidectomy.

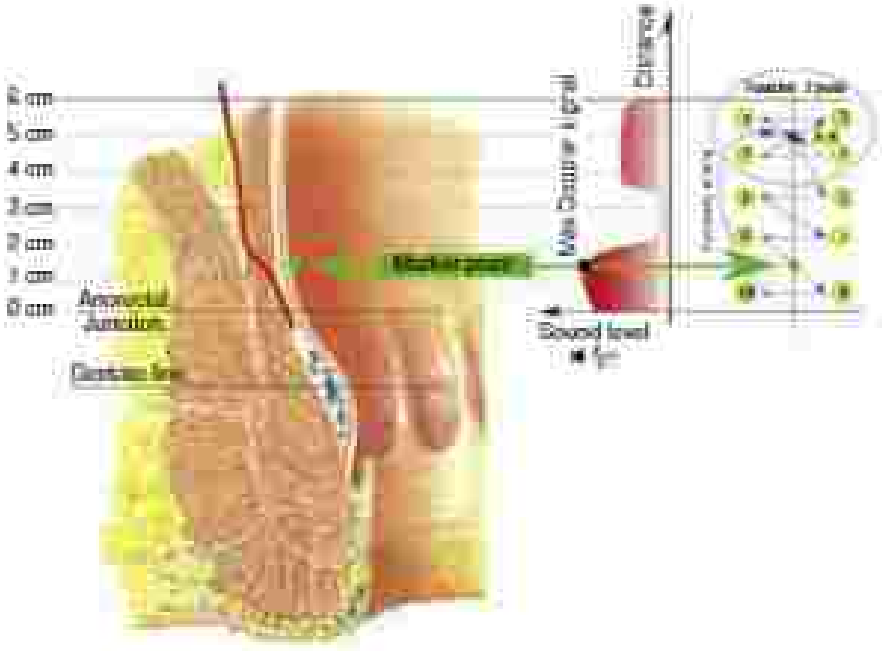

FIG. 6 Schematic of transanal hemorrhoidal dearterialization and mucopexy. Marker points denote the location of the best Doppler signal for hemorrhoidal ligation. A 2-suture is placed at the location for ligation above. For higher grade hemorrhoids, mucopexy with running sutures is performed starting proximally and encompassing the ligation point, pulling the redundant mucosa up into the rectum (right side of image). [From Kaur C, et al. Doppler guided ligation of hemorrhoidal arteries with mucopexy: a novel approach for the treatment. Ann Surg. 2004;239(5):616.]

hemorrhoidal dearterialization (Fig. 6). Doppler guidance is used to isolate hemorrhoidal arteries for ligation. This technique is typically used for grade II to III internal hemorrhoids. There is less pain and shorter operative time with this procedure. The anesthesia and patient position are similar to that of other hemorrhoidal techniques. Several targeted figure of 8 stitches are placed to ligate the hemorrhoidal vascular bundles. Four or more sutures are typically placed at a single setting. In addition, for high grade hemorrhoids such as grade III to IV hemorrhoids, mucopexy is performed; this is known as mucopexy repair. The combination of the transanal hemorrhoidal dearterialization and mucosal repair procedures in a prospective single blinded study showed a 12 month prolapse recurrence rate of 11%.

Stapled Hemorrhoidopexy EEA Stapler

Stapled hemorrhoidopexy, the procedure for prolapsing hemorrhoids first described by Longo in 1998, is typically reserved for complicated hemorrhoids with mixed internal and external components as well as grade III to IV circumferential hemorrhoids. It was developed to reduce anal pain associated with excisional hemorrhoidectomy. This technique involves the use of a specialized 33 mm end to end anastomotic circular stapler that removes mucosa and submucosa proximal to the hemorrhoids, resulting in a devascularized segment of hemorrhoidal tissue (Fig. 7). The hemorrhoidal tissue is not removed and there are no wounds below the dentate line. As a result, postoperative pain is reduced significantly compared with excisional hemorrhoidectomy. The drawback of stapled hemorrhoidectomy is that it does not adequately address any external hemorrhoidal tissue. The complication rates from stapled hemorrhoidectomy are similar to excisional hemorrhoidectomy; however, the technique has serious additional complications such as perineal sepsis, rectovaginal fistula, rectal ureteral fistulas, rectal perforations, and anal stenosis, which are often very difficult to treat. The stapled hemorrhoidectomy is performed under anesthesia. The hemorrhoidal kit contains an anal dilator, clear plastic anoscope and operating anoscope, and stapler. The anal dilator is inserted first and, circumferentially, a submucosal purse string suture using permanent suture is placed 3 to 4 cm proximal to the dentate line. The partial thickness purse string sutures are placed with care taken to not involve the vaginal wall, seminal vesicles, or the prostate anteriorly. After placement of the purse string suture, the purse string is tied around the anvil of the stapler and the stapler is fired with complete closure. The result is a specimen that contains the mucosa and submucosa of the distal rectum.

Special Situations and Other Considerations

Immunocompromised Patients

Management of hemorrhoids in this cohort of patients can be a challenge for the treating physician. Immunocompromised patients should be managed conservatively because of risk of perineal sepsis and poor wound healing after hemorrhoidectomy. Delayed and failed wound healing has been associated with AIDS. In a study by Moremadi et al., 50% of AIDS patients had incomplete healing 30 weeks after hemorrhoidectomy. For bleeding internal hemorrhoids, when absolutely necessary, sclerotherapy was described as the safer option compared to either rubber band ligation or hemorrhoidectomy.

Portal Hypertension and Hemorrhoids

Portal hypertension is another condition that can result in rectal bleeding and hemorrhoids because of the distal collateral between the inferior hemorrhoidal vein and the systemic venous drainage system. The treating physician should maintain a high index of suspicion with these patients. Rectal varices are common in patients with portal hypertension. One report showed rectal varices were found in up to 78% of patients with portal hypertension. The diagnosis of portal hypertension leading to rectal bleeding is made based on history and physical examination. Nonetheless, a flexible sigmoidoscopy, colonoscopy, and endoscopic ultrasound have been described as useful adjuncts to obtaining the correct diagnosis. Rectal varices on endoscopy are visualized as blue tinted submucosal elevations located in the rectum with direct communication with the portal venous system. Hemorrhoidal bleeding in portal hypertension should be treated conservatively. Rubber band ligation is contraindicated because of the risk of delayed bleeding. Sclerotherapy, if available, is the next treatment of choice when conservative management fails. Sclerotherapy, suture ligation of the bleeding hemorrhoidal vessel, or a stapled hemorrhoidopexy is reserved as the next line of therapy after optimal medical therapy to reduce portal pressure and transjugular intrahepatic portosystemic shunt procedure. In addition to the aforementioned armamentarium, embolization of the bleeding rectal varices has been described.

Pregnancy

The complex changes in the human physiology during pregnancy can aggravate preexisting hemorrhoids or cause new ones. Patients typically present with symptoms ranging from mild to severe. During pregnancy, hemorrhoidal symptoms worsen because of increased

FIG. 1 (A) EEA hemorrhoid and prolapse stapler with DST Series technology. (B) Stapled hemorrhoidopexy technique. Left, Purse-string sutures applied 4 cm above the dentate line. Middle, Stapler advanced into rectum and excision held on the suture. Right, Staple line after completion of procedure. (Courtesy Medtronic, Copyright 2014.)

pelvic pressure resulting from the fetus, increased blood volume, decreased venous return, constipation, and labor related straining. The prevalence of symptomatic hemorrhoid during pregnancy is between 25% and 35%. It is most common in the third trimester. Symptoms are self limiting for the most part and resolve after delivery, rarely needing intervention. Treatment is conservative unless there is strangulated gangrenous, or extensively thrombosed hemorrhoids. In one study, only 2% of pregnant women with strangulated hemorrhoids required emergent hemorrhoidectomy. This was necessary to reduce the incidence of narcotic use and premature labor.

SUMMARY

Hemorrhoidal disease is quite a common complaint in the adult population because of increased constipation and a low fiber diet. A complete history and physical examination involving a digital rectal examination and anoscopy are crucial to exclude other differential diagnoses such as anal fissure, condyloma, and pruritus, rectal prolapse, and anal cancer. Conservative management and dietary changes in addition to stool softer, laxatives, and fiber supplementation remain the mainstay of treatment for stage I to II hemorrhoidal disease. However, after failure of medical therapy and other procedures for recurrent stage III to IV hemorrhoidal disease, excisional hemorrhoidectomy can be recommended after careful counseling to provided about the risk and benefits of the procedure to adequately tailor and manage expectations. Caution should be exercised when dealing with patients in special situations to reduce the likelihood of unrest and complications.

Diagnosis, Treatment, and Surgical Management of Fissures-in-Ano

Daniel Martin, DO, Marco Ferrara, MD, and Mark K. Sullivan, MD, FACS, FASCRS

Anal pain is a common complaint for patients seeking medical consultation. Although the differential is varied, one of the primary causes are anal fissures. An anal fissure is a longitudinal tear along the sensitive epithelium of the distal anal canal. Often, patients will recall the sentinel event as severe sharp pain during and after defecation. This often leads to fear of subsequent bowel movements. Blood can be apparent on toilet paper or seen in a streak like minimal on stool. Spasms that persist for several hours after a bowel movement are not uncommon.

Although 90% of fissures are located in the posterior midline, up to 25% of fissures in females are found in the anterior midline. Fissures that veer away from the midline should prompt suspicion for other disease processes such as Crohn's disease, anal carcinoma, tuberculosis, syphilis, human immunodeficiency virus, and human papillomavirus. An acute fissure will have the appearance of a simple tear in the anoderm and is defined by symptoms of less than 6 to 8 weeks in duration. Chronic fissures are distinct with their typical hallmark physical examination findings of a distal sentinel pile, a proximal hypertrophied anal papilla, and an exposed internal anal sphincter (IAS) muscle.

The etiology for this disease is uncertain. Although classically described after passage of a large, hard stool, fissures can also be caused by anal trauma and chronic diarrhea. An elevated resting IAS tone has been demonstrated on manometric studies in patients with anal fissures, although it is uncertain if this is a cause or effect of the fissure. The anorectal angle tends to place the greatest mechanical stress in the posterior midline. Paired with the fact that this area has relatively poor perfusion and is susceptible to ischemia, this helps account for the majority of fissures occurring in this location.

Examination of a fissure can be difficult particularly if it is acute as the area can be very sensitive. Gentle skin retraction of the buttocks will often reveal the fissure (Fig. 1).

Once the fissure is confirmed, further examination of the anal canal with fingers or instrumentation is typically not required because the patient will likely not tolerate any invasive examination. If the diagnosis of a fissure is not apparent, an examination under anesthesia may be required for further evaluation to look for other diagnoses. Atypical fissures with suspicious characteristic findings such as lateral appearing, multiple locations, nonhealing, or painless warrant further evaluation and possible biopsies or cultures.

TREATMENT

Nonoperative Management

For patients who present with acute anal fissures, conservative therapy with examination should be the first line of therapy. Fiber supplementation, stool softeners, and sitz baths twice daily, with or without the addition of topical antiinflammatory creams or anesthetics will heal approximately 50% of fissures. A goal of 25 to 30 g of fiber daily for men and 20 to 25 g for women should be an. Adequate hydration with at least eight glasses of water daily is also essential. Fiber and sitz baths are effective in providing symptomatic relief in the first weeks of a developed fissure as well long term healing and recurrences (Jensen, 1986). Sitz baths or heat of any source can help alleviate spasms. A detachable shower head can also be used to apply warm water to the affected area when a bath tub is inconvenient or unavailable.

Although conservative management is quite effective for acute fissures, only approximately 25% of chronic fissures heal with the aforementioned management. Nonoperative management focuses on the hypertonicity of the IAS and ways to induced relaxation of the sphincter. Nitroglycerin and diltiazem are the most common topical solutions. Botulinum toxin (Botox) injections are an alternative to the topical solutions that promote IAS relaxation.

Topical nitroglycerin in the form of 0.2% glyceryl trinitrate (GTN) has a marked effect on healing chronic anal fissures. A recent study by Nelson and colleagues (2012) showed healing rates of 48.9% vs 35.5% in the placebo group. Recurrences at long term follow up were greater than 31% to 47% with a high noncompliance rate resulting from the side effect of headaches. Both diltiazem and nifedipine, either oral or topical, also produce similar relaxation of the IAS compared to GTN. The topical form of diltiazem seems to have the greatest effect on sphincter relaxation with added benefit of fewer side effects, particularly headaches, compared with GTN. The healing rates of fissures are similar to GTN. Rectiv (0.4% nitroglycerin) is an enteral ointment that received US Food and Drug Administration approval in 2011. It is applied twice daily for 6 to 8 weeks with a healing rate of 77% at 24 weeks (Perez-Legaz et al., 2012). Diltiazem and nifedipine, although commonly prescribed, are not US Food and Drug Administration approved for treatment of fissures and require compounding pharmacies to make a topical solution from oral formulations.

Botulinum toxin injections relax the sphincter by inhibiting the release of acetylcholine at the neuromuscular junction. The effects of the injection can produce relaxation for up to 2 to 4 months. Injections can be done in an outpatient setting depending on the patient's tolerance levels. Application dosages as well as location varies per practice with no uniform recommendations. Botox injections were found to be more effective than GTN in terms of healing and side effects, but lateral internal sphincterotomy for healing refractory fissures was 97.3% compared with 60% in the Botox group (Arroyo et al., 2004). A more recent randomized controlled trial comparing Botox injection in conjunction with topical diltiazem to have a 1 year healing rate of 65% compared with 98% with lateral internal anal sphincterotomy (Gandhiraker et al., 2015). Botox may be more beneficial for patients in which continence maybe an issue after surgery.

Operative Management

Sphincterotomy, or partial division of the internal anal sphincter, has been the mainstay therapy for failed medical management and leads to fissure healing in 88% to 100% of patients. The lateral internal sphincterotomy can be performed in an open or closed technique. The posterior midline is avoided because of the high rates of keyhole deformities that can lead to fecal incontinence and soiling. The open technique involves making a small radial incision over the intersphincteric groove, dissecting and separating the internal sphincter muscle away from the anoderm, and partially dividing the muscle. Care is taken not to divide the sphincter completely because this increases the rate of incontinence. The closed technique is performed by inserting the scalpel blade, classically a No. 11 blade, aligned with the intersphincteric groove, turning the blade medial and dividing the muscle without open exposure of the IAS.

FIG. 1 Clinical appearance of fissure-in-ano.

Incontinence is the main complication with lateral internal sphincterotomy. Up to 30% of patients can experience some form of temporary incontinence to stool, gas, or soiling (Nelson et al., 2011). When comparing the open against the closed technique for rate of incontinence and treatment failure, there was no significant statistical difference; however, the length of sphincterotomy did increase the risk for incontinence.

Fistulectomy can be included in the sphincterotomy. This involves unroofing the fissure tract, removing the hypertrophied anal papilla, and removing the external sentinel tag. Proponents for including fistulectomy state it may promote faster healing of the fissure. Fistulectomies can also be accompanied with advancement flaps. This is particularly useful when there is a risk of anal stenosis, low pressure in the sphincter, or a hypotonic anus (Kimberly et al., 2002).

SPECIAL CONSIDERATIONS

Atypical Fissures

A detailed history and physical examination can often elucidate the cause of a fissure. Even so, fissures located away from the midline should raise an index of suspicion for other disease processes. Biopsies and/or cultures may help establish a diagnosis. Fissures affect approximately one-third of Crohn's disease patients and should be suspected when a fissure presents with atypical appearances. Crohn's disease can be associated with deep ulcerations, abscesses, and fistulas. The dictum is to intervene only when necessary with fissures caused by Crohn's disease. These patients benefit from a multifaceted approach and, with appropriate medical management, can have good success rates for healing (Draught et al., 2001).

CONCLUSION

Anal fissures are a very common cause for anal pain and can often be treated successfully with conservative measures. A combination of fiber, stool softeners, and sitz baths can alleviate symptoms while awaiting more invasive procedures. Chronic fissures will likely require sphincter relaxing agents to facilitate healing. Surgery remains the most effective treatment; however, sphincterotomy does carry a risk for potential lifelong incontinence. Following a step-wise progression to fissures is paramount when treating fissures, and the clinician should always be wary of alternative diagnoses masquerading as fissures.

Management of Anorectal Abscess and Fistula

Kyle G. Cologne, MD, and Sean J. Langenfeld, MD

Approximately 100,000 patients in the United States seek care for anorectal sepsis each year. The peak age of presentation is between 20 and 40 years; males are twice as likely as females to have the condition. Cryptoglandular disease accounts for the vast majority of cases, followed by inflammatory bowel disease. Up to 50% of patients treated for an acute anorectal abscess will develop a fistula in ano, which requires further surgical treatment.

Management of anal abscess and fistula includes four basic principles: (1) control the septic process (drain the pus); (2) define the involved anatomy; (3) treat the underlying process without compromising sphincter function; and (4) minimize recurrence risk. Although most presentations are straightforward, complex and recurrent fistulas challenge even the most experienced surgeon. It is crucial for anyone managing this disease to understand the anorectal anatomy, particularly with respect to the anorectal nerve and muscle function. It is also important to treat patients in the context of their comorbid conditions (e.g., Crohn's disease) and apply the appropriate surgical technique. Improper management with unusual areas of undrained infection (e.g., the deep perianal space) can lead to unwanted sequelae such as chronic discomfort, impaired defecatory function, incontinence, or potentially life-threatening sepsis.

ANORECTAL ABSCESS

Cause and Classification

The anal glands empty into the rectum at the level of 10 to 15 crypts of Morgagni located circumferentially at the dentate line. If this drainage becomes blocked, pressure builds in the septic source grows and propagates along paths of least resistance within or through the potential space between the internal and external sphincter muscles (the intersphincteric space). Infection grows to fill one of several potential pathways of suppurative extension. These anatomic spaces of anorectal sepsis are intersphincteric, submucosal, perianal, ischiorectal, perianal (subdivided into superficial and deep by the anococcygeal ligament), and supralevator (Fig. 1).

The intersphincteric abscess, located at the site of the anal glands, tracks cranioscaudally between the sphincter layers. A submucosal abscess represents the least extensive suppurative process, located just beneath the mucosa above the dentate line. These often grow to other types of left untreated. Perianal abscesses descend through the intersphincteric space to the subcutaneous tissue around the anus and below the sphincter complex. The submucosal abscess involves a vast amount of fat in the submucosal fossa, and infection has extended either laterally via the intersphincteric space or caudally from above the external sphincter (supralevator discussed later). The vast ischiorectal fossa is a fat-filled space that encircles the external sphincter caudal to the levators and medial to the ischial tuberosities. The perianal space is located posteriorly between the levators (cranially) and the external sphincter (caudally); this space is subdivided by the anococcygeal ligament into superficial and deep spaces. Infections in the deep space are often missed because the physician must pop through this ligament to access the space during drainage procedures. The perianal space (which exists in the midline) may be solely involved, or infection may extend laterally into the ischiorectal fossa, forming the so-called horseshoe abscess. Supralevator abscesses, located above the levators as the name implies, are caused by either cranial extension of cryptoglandular sepsis or by caudal extension of an intraabdominal process, such as diverticular disease, that perforates through the peritoneum. Recent evidence suggests either of these causes are rare, with most series reporting less than 10% of overall abscesses.

Understanding the anatomic spaces of anorectal sepsis is key to deciphering the patient's presentation and planning the appropriate intervention. One attains one of the basic principles of sepsis management because complete drainage reduces subsequent complications such as systemic sepsis, recurrence, fecal incontinence, and complex fistula formation. Although the cryptoglandular etiology is believed to be responsible for the majority of anorectal abscesses, it is crucial to identify contributing conditions or alternate causes such as those displayed in Box 1, particularly if the method of presentation is atypical (multiple involved areas, edematous skin tags, red flag symptoms). The impact of these factors and causes on the nature of the disease and treatment strategy is discussed later in the chapter.

Presentation and Diagnosis

Anal pain independent of defecation is the most common complaint, which distinguishes this from anal fissure. Swelling and fever are often present. Associated symptoms and medical history suggestive of inflammatory bowel disease or immunocompromised states also should be gathered (history of rectal bleeding, diarrhea, or cramps abdominal pain). On anorectal examination, an indurated bulge with fluctuance and cellulitis near the anal verge is indicative of perianal abscess. Intersphincteric abscesses are unique in their lack of external findings but cause exquisite tenderness on attempted digital rectal examination. Ischiorectal abscesses typically have findings of induration, tenderness, and fluctuance a few centimeters away from the anal verge, but do not have the same degree of tenderness on digital rectal examination seen with intersphincteric infections.

Abscesses limited to the perianal space may have localized tenderness posterior to the anal verge, but without apparent induration or fluctuance. Bimanual examination (digital rectal examination while pinching the area next to the coccyx) will reveal the area of induration or fluctuance between the fingers. Supralevator abscesses may have no anorectal findings unless there is downward extension into another space; however, digital rectal examination may reveal findings above the puborectalis muscle sling. In this case, further evaluation with pelvic imaging should be considered to exclude their presence. Rectoscopy, proctoscopy, or flexible sigmoidoscopy can be performed to evaluate the rectal mucosa for signs of inflammatory bowel disease, but often is not tolerated and should not be pursued. Patients who cannot tolerate a digital examination should undergo an examination under anesthesia (EUA).

The majority of patients with a suggestive history and characteristic examination findings can be managed with bedside drainage or operative evaluation and treatment, particularly if the area of infection is readily visible on examination. Additional imaging, however, is useful in some acute situations. A computed tomography (CT) scan is helpful in patients with associated abdominal symptoms or findings, or with clinical suspicion of a supralevator abscess. A pelvic CT scan should not be relied on to exclude drainable anorectal infection because pendulous is often present in the absence of definitive CT findings, and bedside examination is generally more reliable. Untreated anorectal infection can lead to severe systemic infection and destruction of the anal sphincter complex itself or the nerve supply to it, resulting in varying degrees of fecal incontinence. Transanal ultrasound and magnetic resonance imaging (MRI) are not generally available or tolerated in the acute setting of an anorectal abscess. Both, however, are useful adjuncts in delineating another of the principles of management: the anatomy of complex, multiple, or recurrent fistula in ano.

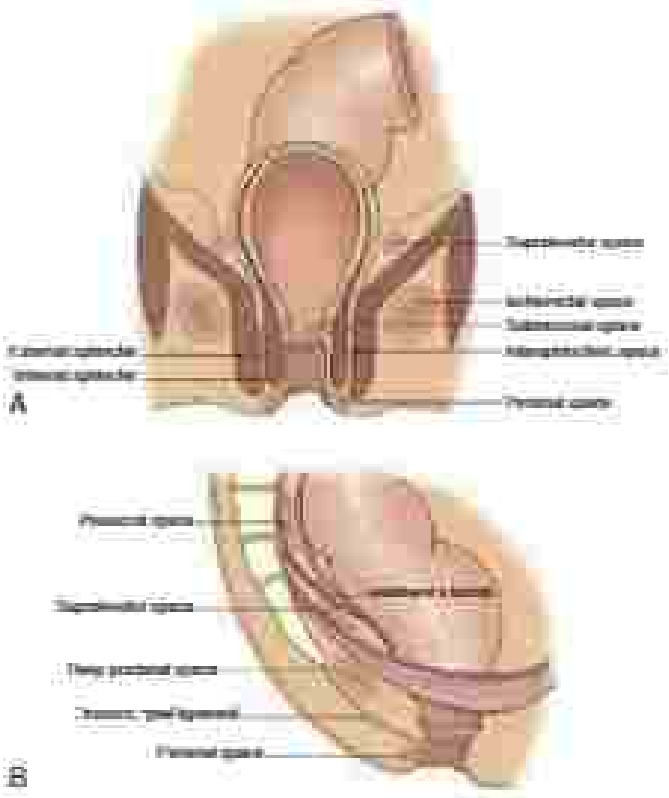

FIG. 1 Anal sepsis and fistula. Classification of anorectal abscesses by location. (A) Coronal view. (B) Sagittal view. (From Ko CJ, Lee SW, Mutinelli C. Surgery of the Alimentary Tract. 8th ed. Philadelphia: Saunders; 2013.)

BOX 1 Cause of Anorectal Abscess

- Cryptoglandular
- Iatrogenic (colorectal or genitourinary surgery)
- Perineal trauma
- Radiation injury
- Inflammatory bowel disease
- Acquired immunodeficiency syndrome
- Invasive fungal infection
- Hidradenitis suppurativa
- Pilonidal sinus
- Anal fissure
- Osteomyelitis
- Foreign body
- Malignancy (carcinoma, adenocarcinoma, hematologic malignancy)

Data from Hicks DC, et al, eds. The ASCRS Textbook of Colon and Rectal Surgery. 2nd ed. New York: Springer-Verlag; 2011.

Operative Evaluation and Drainage

Surgical drainage remains the definitive treatment of anorectal abscesses. Bedside drainage in the left lateral decubitus (or Sims) position under local anesthesia using 1% lidocaine with dilute epinephrine often is well tolerated for perianal abscesses and small submucosal abscesses. If there is concern for patient intolerance, bedside drainage can be accompanied by light sedation when available (e.g., within the emergency department) when additional healthcare providers and a monitored setting are available.

After infiltrating the area with local anesthetic, the surgeon makes a radially oriented semilunar or cruciate incision over the abscess. A critical point of this procedure is the incision should be oriented over the side of the abscess closest to the anal verge without transgression into the sphincter complex. This is done so that the subsequent fistula (which forms up to 50% of the time) is more likely to have a simple, short tract that is easier to manage. A common mistake is to drain the area over the maximum site of fluctuance or farthest away from the anal verge, which can make the subsequent fistula longer and much more difficult to treat. A hemostat or blunt probe is used to explore the wound and ensure no pockets of undrained infection remain. Usually, the outermost wall of the abscess cavity is thick and well defined and can be used as a guide. If a thinner wall is encountered, or if bimanual examination reveals additional areas of cavernous extension, these should be entered. However, care should be taken not to spread or digitally break down all fibrous tissue within the abscess because this often represents nerves, which are oriented in a radial pattern spreading outward from the anal verge. Destruction of these can result in anorectal muscle dysfunction.

A segment of skin (either an ellipse or cruciate with corners excised) at least 1 cm in size is excised to prevent premature closure of the skin. The cavity is irrigated and dry gauze is applied externally with the expectation of ongoing drainage. Dense packing is unnecessary in most cases and may only serve to damage the internal sphincters. Hemostasis can be obtained with direct pressure, cautery, the probe, silver nitrate, and the use of hibiclens with epinephrine.

Large abscesses (>5 cm), and those that must be approached externally (e.g., intersphincteric, horseshoe, and deep perianal space infections) are most appropriately done in the operating room under monitored anesthesia care or general anesthesia. The anorectal region is best exposed with the patient in the prone jack-knife position and the buttocks taped widely apart, but high lithotomy is often adequate, particularly in multiple comorbidity patients or those with a difficult airway. A headlamp or other source of good lighting is recommended. Commonly used instruments are: Hill-Ferguson, Fansler, or Pratt bivalve retractors; fistula probes and curettes; and angiocath needles with dilute hydrogen peroxide. The perianal region is inspected, noting any induration, fluctuance, or dermatologic abnormalities. A digital rectal examination is performed followed by anoscopy, looking for internal bulging or other abnormality including sphincter defects, fissures, and mucosal abnormalities. Biopsies should be performed on ulcerations, suspicious nodules, or part and lesions to exclude neoplasia. Biopsies and/or culture should be performed on recurrent abscess or fistula tracts as well to diagnose underlying inflammatory bowel disease, infections (such as tuberculosis or actinomycosis), or the rare malignancy. If the site of purulence is not obvious or deep to the skin surface, an 18-gauge needle can be used as a finder to aspirate in suspected areas. Culture data are rarely required but may be insightful in patients with recurrent infections, a history of methicillin-resistant *Staphylococcus aureus*, or patients with unaltering HIV infection in whom atypical microbes may be present.

For large ischiorectal abscess, multiloculated counterincisions can establish adequate drainage rather than a large incision that needs excising healthy tissue and prolongs healing unnecessarily. Digital examination while probing the cavity is prudent to ensure that there is no extension into the perianal space or the contralateral fossa. Packing is usually not necessary and impractical for the patient to exchange. An alternate means of drainage uses a stab incision overlying the abscess, as close to the anal verge as possible, and the insertion of a 10F to 16F malecot catheter into the cavity. The catheter is secured with an anchoring suture and left in place for a week, with regular flushing. After a week, the majority of the infection should be drained and removal leaves in place a skin tract that will allow for ongoing drainage of any residual infection. These catheters can be left in for prolonged periods in cases of large or recurrent infections.

Drainage of a perianal space abscess deserves special note because it is often a source of missed or undrained infection. A radial incision is made from the posterior anal verge toward the coccyx. Subcutaneous tissue is divided and the underlying fibers of the anococcygeal

ligament are divided in a craniocaudal direction to access the perianal space. This is a fibrous ligament and often takes a bit of force to pop through. Often, the procedure up to this point has not resulted in a lot of pus, despite preoperative imaging or palpable fluctuant disease. Once the deep space is unroofed, pus usually flows freely. If a horseshoe abscess is present, the deep space is probed laterally, where elliptical counterincisions over the involved ischiorectal fossa can be created. Penrose drains can be looped between incisions to maintain patency. Alternatively, if small, these lateral extensions can be drained with small rubber catheters cutting out from the midline posterior incision. Rarely, an anterior horseshoe can exist. If an underlying fistula to the distalmost line is noted, a seton is placed to prevent recurrent sepsis (Fig. 2). A later (staged) procedure to address the fistula can be planned.

Intersphincteric abscesses are addressed minimally. The mucosa overlying the bulging/fluctuant area within the anal canal is divided with electrocautery. The underlying internal sphincter muscle, with circumferential transversely oriented muscle fibers, is thus exposed. A hemostat is passed through the internal sphincter into the suppurative intersphincteric space and advanced cephalad. The internal sphincter is divided over the hemostat with electrocautery. Because the external sphincter is not manipulated or divided, this generally does not compromise fecal continence, but patients should be informed of that small risk as part of informed consent. An alternative but less common method involves a stab incision at the anal verge to the intersphincteric groove and insertion of a small rubber catheter into the affected intersphincteric space. The catheter is secured to the anal verge and either removed outright or tracked out slowly as intervals after sepsis has resolved.

The source of a supralevator abscess determines its treatment. Descending abdominal or pelvic sources typically are addressed with imaging guided percutaneous drainage. More complex or severe intraabdominal disease may warrant transabdominal surgery or even fecal diversion to prevent ongoing sepsis. Ascending cryptoglandular infections travel via one of two routes: either through the intersphincteric space within the bowel or through the foramen from the ischiorectal fossa (outside of the bowel wall). This is a critical difference, as the goal of treatment is to prevent formation of a complex fistula. The intersphincteric source is treated with transanal drainage through the rectal wall; an (incorrect) surgical drainage through the perineal skin and ischiorectal fossa creates an iatrogenic suprasphincteric fistula. Conversely, the supralevator abscess with an ischiorectal source should be drained via the perineal skin incision via the ischiorectal fossa. In this second scenario, transrectal drainage would be inappropriate and also create an extrasphincteric fistula (Fig. 1). Even though supralevator abscesses are rare, this is the reason imaging may help delineate the source and trajectory, which subsequently may dramatically alter the treatment approach.

Anorectal abscesses are rarely appropriate for percutaneous drainage by the interventional radiologist. Although this may temporarily eliminate the need for urgent surgery, the route of catheter drainage, which crosses the levators, can increase the complexity of the underlying fistula when present. Even if sepsis is temporarily resolved, the patient is now left with a supralevator component to the fistula, which is much more difficult to resolve for the surgeon. The only possible exception to this is for supralevator abscesses originating from an abdominal source.

Antibiotics and the Immunocompromised Patient

Most patients do not require antibiotic therapy after effective incision and drainage. In certain populations, however, antibiotics are warranted because drainage alone may not resolve the systemic inflammatory response syndrome or septic response of sepsis thereof. Patients with large areas of cellulitis, signs of systemic sepsis or shock, prosthetic heart valves, or various immunocompromised states

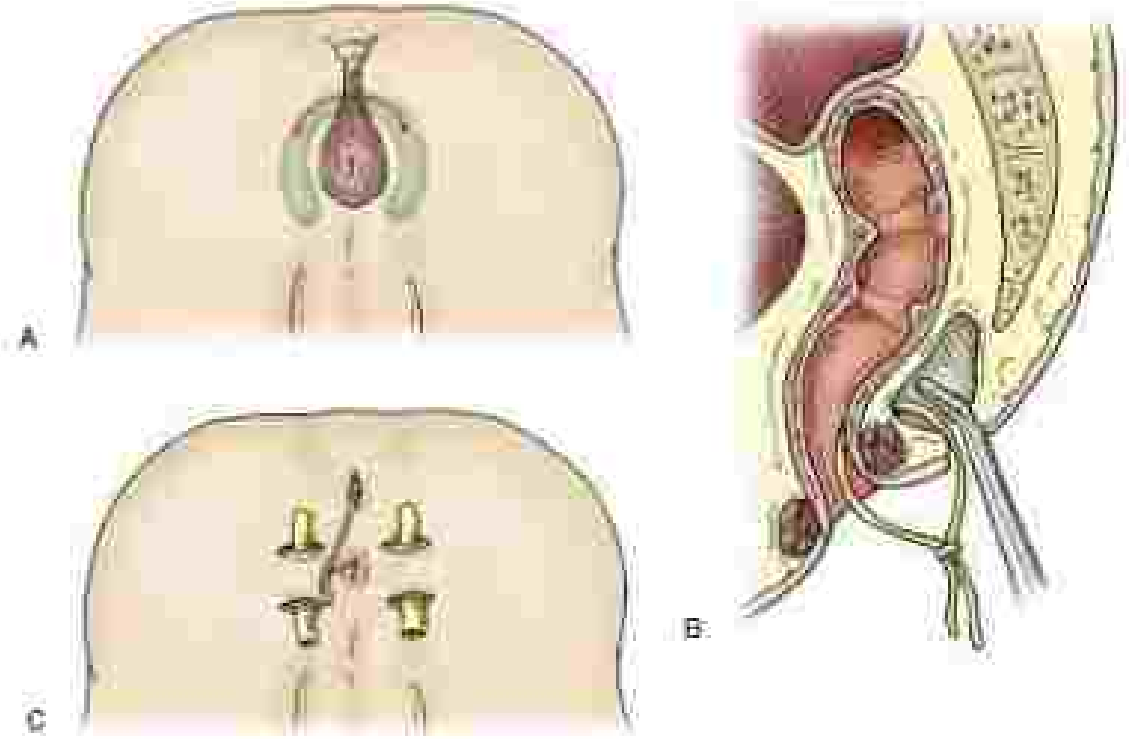

FIG. 2 (A) Horseshoe abscess shows that the deep perianal space is a window to the ischiorectal fossa bilaterally (arrows). (B) The deep perianal space is drained through a radial incision in the posterior midline. A clamp is placed in the perianal space to ensure adequate drainage. If an internal opening is identified, a seton is placed through the fistula tract, incorporating the posterior sphincter. (C) Counterincisions drain the ischiorectal fossa. Placement of Penrose drains through the cruciate incisions adequate drainage of the abscess cavities without significant soft-tissue loss. (Courtesy Cleveland Clinic, OH.)

warrant prolonged oral or parenteral antibiotics. Immunocompromised patient groups include those with diabetes mellitus, chronic corticosteroid use, AIDS, a history of bone marrow transplant, or active cytotoxic chemotherapy.

In contrast to all other patients with anorectal infection, profoundly neutropenic patients often are not addressed with surgery but are treated with antibiotics alone. Patients with absolute neutrophil counts below 500 per cubic millimeter often do not mount enough of an immune response to develop suppuration. Even with operative drainage, there is minimal pus encountered; therefore, patients with low absolute neutrophil counts and without fluctuance do not have a target for surgical drainage. Instead, prolonged, broad-spectrum antibiotics are recommended. The degree and duration of neutropenia is directly correlated with the incidence and prognosis of anorectal infection in this population. In addition, efforts to correct the neutropenia by holding chemotherapy and using pharmacologic neutrophil growth factors are employed. As the neutrophil count rises, these patients must be monitored closely because they can subsequently develop a suppurative response and require reimaging or EUS with aspiration if a drainable source develops. Progressive sepsis, obvious fluctuance, or expanding soft tissue infection is an indication for surgical evaluation, drainage, or debridement.

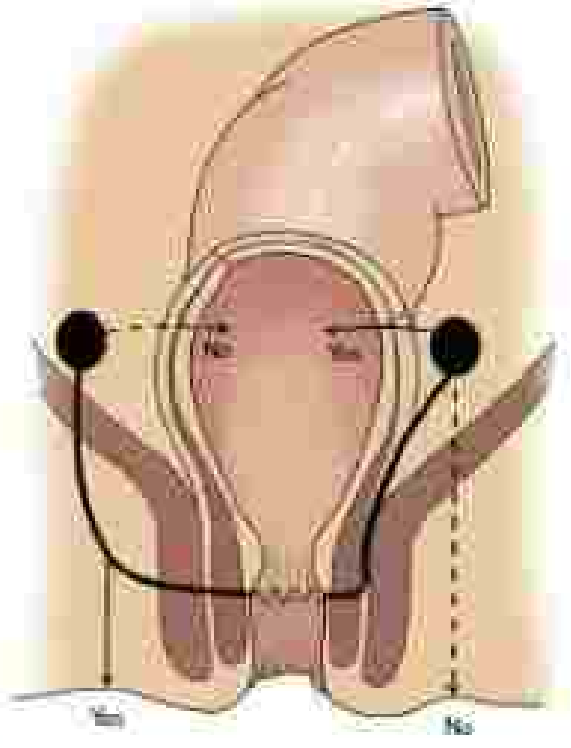

FIG 3 Drainage of a supralevator abscess (see text). On the right, the supralevator abscess is associated with a transsphincteric fistula and passage through the ischiorectal fossa; often there are associated findings of an ischiorectal abscess. This abscess is drained via the skin and ischiorectal fossa; anorectal drainage would be inappropriate because it would result in an extrasphincteric fistula. On the left, the supralevator abscess is associated with an intersphincteric fistula and should be drained transanally; drainage across the ischiorectal fossa would create a supralevator fistula. Supralevator abscesses also may be addressed via computed tomography–guided percutaneous drainage (alone or in combination with transanal transsphincteric approaches), particularly when they are due to downward extension of an intraabdominal process such as diverticulitis. (From Ky C, et al: Vital Atlas: Surgery of the Alimentary Tract, vol 7. Philadelphia: Saunders; 2007.)

Primary Fistulotomy

Fistulotomy at the time of incision and drainage of the initial anorectal abscess was once a controversial issue. Proponents argued that the presence of sepsis aided in defining the fistula tract, leaving open the tract would reduce recurrence. With increased data, however, it appears that primary or "prophylactic" fistulotomy submits a majority of patients who would never have recurrent or developed a fistula to sphincterotomy and the accompanying risks of fecal incontinence.

Primary fistulotomy should thus be considered only in the most straightforward of superficial or low transsphincteric fistulas where the fistula tract is obviously present. As a cautionary note, using fistula probes to explore abscesses can be dangerous, and care must be taken to avoid creating false passages and/or iatrogenic internal openings within the inflamed field. Such probing may not only result in persistence of the fistula but may also make subsequent fistula repair much more difficult. Primary fistulotomy is contraindicated in the elderly and in women (particularly those with previous or planned future childbirth) with anterior fistulas, as the muscle is quite thin in this area. Furthermore, it should not be done in patients with baseline fecal incontinence, Crohn's disease, AIDS, and high transsphincteric fistulas.

Necrotizing Perianal Skin Infection

Necrotizing perianal skin infections are destructive, life-threatening soft tissue infections that must be differentiated quickly from the more common anorectal abscess as the initial presentation because immediate surgical debridement offers the only chance at survival. Rapid development of severe anorectal pain that is out of proportion to physical examination is the classic harbinger of a necrotizing infection. Risk factors include diabetes, chronic renal disease, obesity, smoking, and underlying neurologic disease (such as dementia or spinal cord injury) that prevents early detection or communication of symptoms and previous anorectal infections. Tender, irregular red, violaceous, or black macules and blisters in the perianal region are early signs of this dangerous process. These types of infections may be associated with crepitus, induration, or gangrene. Septic shock and electrolyte disturbances may develop. Any anorectal infection in the presence of these severe systemic manifestations should be immediately explored in the operating room and given broad-spectrum intravenous antibiotics. Radical debridement of all nonviable tissue is necessary.

Patients will require supportive management in the intensive care setting and empiric coverage for potential flora while awaiting culture results. Multidisciplinary evaluation may also be required, depending on involvement and viability of the sphincter complex and urogenital organs. After initial debridement, if infection persists, consider transfer to a tertiary center with hyperbaric oxygen capability, which limits the growth of anaerobic and other forms of bacteria and boosts the effects of antibiotics and the immune system. The need for fecal diversion is debated but should be considered only in the subacute setting after hemodynamic stability is well established and when soft tissue wounds would be compromised by ongoing fecal spillage.

FISTULA-IN-ANO

Cause and Classification

The cryptoglandular theory suggests that the acute suppurative process of anorectal sepsis originates at 1 of 8 to 10 anal glands located at the dentate line. These glands, whose ducts penetrate the internal sphincter for varying distances into the intersphincteric space, can become blocked, thereby allowing bacteria to cause infection, which propagates along the path of least resistance out away from the blocked internal opening of the duct into the perirectal space. This process continues until an abscess forms and the growing pressure is relieved by surgical or spontaneous drainage. If the tract created by

this process seals closed. No further sequelae are noted, however, if the tract persists, an epithelialized fistula results. Although the cryptoglandular etiology is responsible for the vast majority of fistulas, Box 1 presents other causes of chronic inflammation, fistula formation, and epithelialization to the anorectum.

Fistulas are classified by their route between an internal opening in the anal canal and an external opening on the perianal skin. In 1976, Parks and colleagues published this classification system that is the most commonly used description. Fig. 4 depicts the four Parks classes of fistulas. Another type of fistula not included in this classification scheme is the superficial (or subcutaneous) fistula, which, as the name implies, does not involve the sphincter complex at all. This can be a result of scarring after recurrent infections and surgery, or another process, such as hidradenitis. Another possibility is primary, tiny skin bridging of a fissure.

Fistulas are categorized further as simple or complex. A complex fistula has features that increase the risk of recurrence and/or incontinence after intervention, either by its own anatomy or by patient factors. Table 1 defines features of complex fistulas, which include everything except subcutaneous, intersphincteric, and low transsphincteric trajectories.

Presentation and Diagnosis

Patients often have a history of an abscess that either drains spontaneously or requires surgical intervention, although the initial infection may be small and asymptomatic. Patients often have initial healing and a varying time (weeks, months, or even years) without symptoms. When a persistent tract exists, fecal material will continue to pass through the internal opening, and so patients will experience either (1) ongoing drainage through the external opening or (2) recurrent abscess as the external opening closes, blocking the exit of purulent and fecaloid material.

Because of this, patients describe intermittent anal pain, pruritus or drainage that is mucoid, bloody, purulent, or even fecaloid. Occasionally, blood per rectum occurs because of friable granulation tissue at the internal opening. Another common feature is cyclic discomfort and swelling resulting from pressure built up within the fistula tract that is relieved after spontaneous drainage.

Patients should be queried regarding gastrointestinal symptoms suggestive of inflammatory bowel disease (e.g., bloody diarrhea, crampy abdominal pain) and their current level of fecal continence. A history of anal surgery, anal infections, radiation, trauma, obstetric trauma, and systemic disease including inflammatory bowel disease,

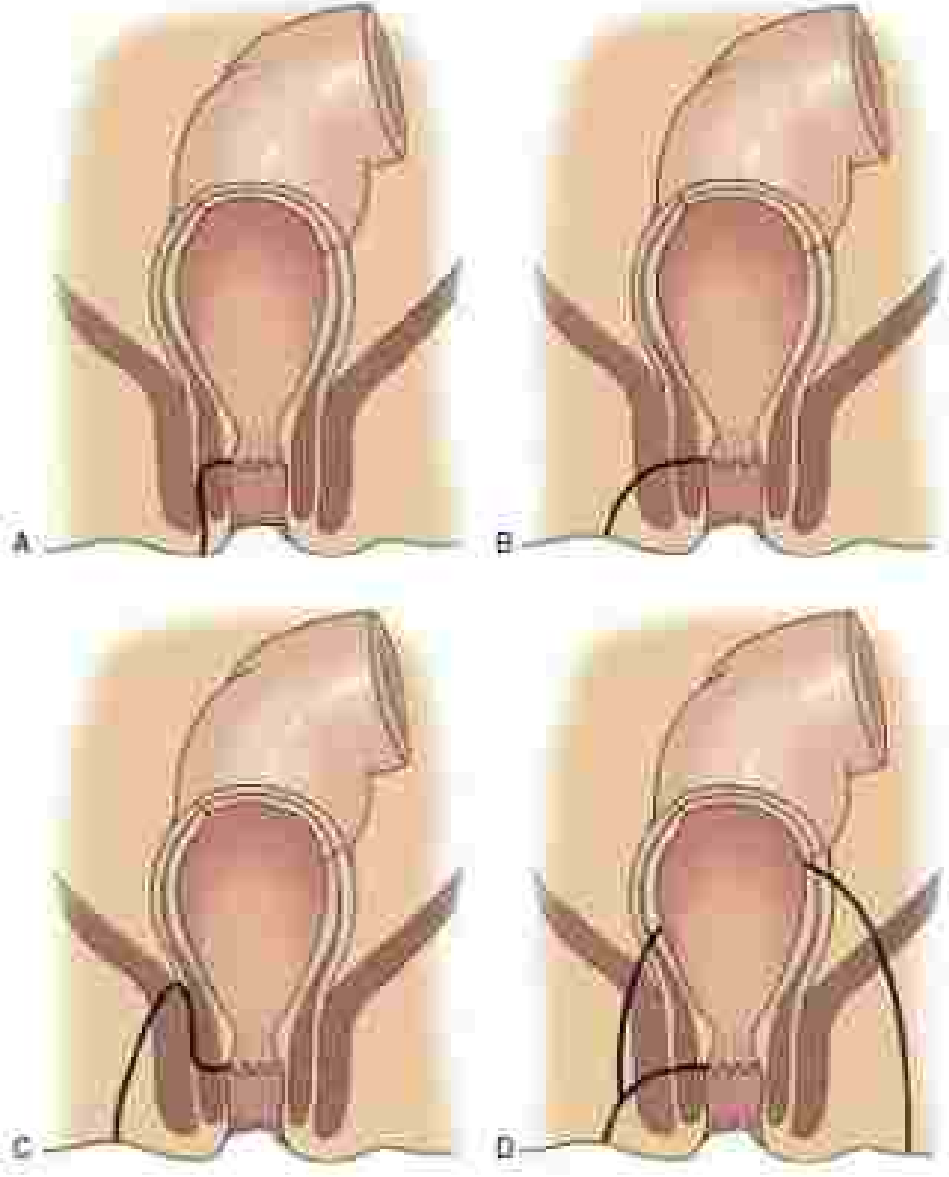

FIG. 4 Classification of anal fistula. (A) Intersphincteric: the tract remains in the intersphincteric plane. (B) Transsphincteric: the fistula tract passes from the intersphincteric plane through the external sphincter muscle. C, uncomplicated. (C) Suprasphincteric: there is an upward extension of the fistula tract in the intersphincteric plane. The tract then passes above the level of the puborectalis muscle and continues downward through the anterior/oral tract to the perianal area. (D) Extrasphincteric: there is a tract that passes from the skin of the perineum through the ischiorectal fossa and the levator muscles before entering the rectal wall. The fistula may be a consequence of an extension of a transsphincteric fistula or secondary to trauma, anorectal disease, or pelvic inflammation. (Modified from Ho D, et al. Management of Anorectal Fistulas. In: Management of Gastrointestinal Disorders. 2007.)

hematologic malignancy, or immunosuppression should be ruled because these characteristics create a high risk for nonhealing or worsening incontinence. On examination, the external opening is generally easily identifiable as an inflamed pyogenic granuloma with an associated palpable cord may adjacent to this that suggests the path of the tract. However, the external opening may be much more subtle and even closed in periods of inactivity. A fistula can usually be seen with a careful search. The internal opening occasionally can be palpated on digital rectal examination as a nodule or pit, usually at the level of the dentate line or cryptoglandular origin. Goodsall's rule states that fistulas with an external opening posterior to a transverse line across the anus drain via a curving approach to a posterior midline internal opening, whereas those with an external opening anterior to this line have short, straight (or radial) courses to the associated internal opening. This is not always accurate (particularly in females with anterior fistulas) and careful attention should be made to delineate the direction and length of any suspected fistula. Anoscopy, when tolerated, can assist in visualizing the internal opening as well as assess whether a distal proctitis is present. Further endoscopy can be considered in a patient with symptoms supportive of inflammatory bowel disease.

Surgical Treatment

There are four principles of fistula surgery: control the septic process, define the involved anatomy, treat the underlying process without compromising sphincter function, and minimize recurrence risk. Maintaining these principles is critical at each step of treatment.

1. *Control of Sepsis*

For many patients with complex fistulas or an abscess fistula at the time of operative treatment of an anorectal sepsis, a conservative, staged approach with the initial placement of a seton is most appropriate. It allows multiple future options without compromising sphincter integrity.

For a patient treated initially with a seton, a primary fistulotomy as a second stage procedure can be considered when the internal opening is less than 3 mm wide and the tract is simple, narrow, and without an associated abscess cavity. Ongoing sepsis, as evidenced by pus, cellulitis, induration, or a persistent cavity, prevents healing and closure of the tract and efforts to improve drainage (such as widening the external opening) before definitive procedure should be considered. Simple closure the fistula tract itself will likely fail, so excision or laying open of the tract is preferred, with healing by secondary intention. Complex fistulas with persistent sepsis should be assumed to harbor an undrained source of infection. Search for a high blind or circular tract. If additional treatable sources of the persistent sepsis cannot be identified or sepsis continues despite these approaches, imaging is warranted.

2. *Define Fistula Anatomy*

The anatomy of a fistula includes the internal and external openings, the course of the intervening tract(s), and the presence of any blind tracts or sinuses. Fistula anatomy can be estimated by office examination but is definitively established only by EUA. Most often, the patient can be consented for a definitive procedure, with the caveat that if a complex fistula or other unexpected findings are discovered at the time of EUA, a staged procedure may be required to preserve sphincter function. The patient is placed in prone jack-knife with the buttocks taped widely apart. It is also acceptable to use the left lateral decubitus or high lithotomy positions. When anatomy is in question, prone jack-knife may allow slightly better exposure.

The perianal region is inspected, identifying evident external openings, suspicious lesions, or scars. Digital rectal examination is performed to assess for undrained sepsis and location of the internal opening. Anoscopy is used to identify the internal opening as well as note any signs of proctitis or malignancy. A fistula probe is inserted into the external opening and gently advanced toward the anticipated internal opening with subtle redirection as resistance dictates. The fistula tract easily should accept the probe without the sensation of tissue destruction. Dilute hydrogen peroxide injected into the external opening via an angiocatheter can help identify an elusive internal opening. A false tract must not be created because it will only complicate the disease and neglect the primary tract. Once cannulated, the type of fistula is established by determining its relationship to the internal and external sphincter complex, the location, and presence of multiple fistulas or blind tracts. The percentage of sphincter complex caudal to the tract is determined by palpating the apex of the sphincter complex in relation to the probe. Low transsphincteric fistulas are defined as those with less than 30% of the external sphincter involved.

There are several troubleshooting tips to know. If the tract cannot be cannulated fully, the tract may be curved. A Kocher clamp can be used to attempt to straighten the tract. Alternatively, a partial fistulectomy or fistulotomy can be performed to follow the path of the fistula from the external opening toward the anal verge until it cannot be identified further or a draining catheter left in the external opening only. If the internal opening cannot be identified easily, the surgeon should not persist to find or make one. The internal opening may have temporarily sealed off or there may be other reasons why it is not identifiable at the time of surgery. In this circumstance, drain the infection, and re-evaluate things later. Although this approach may be associated with a higher recurrence risk, it avoids the critical mistake of making an iatrogenic internal opening at a false location. In this scenario, the identifiable portion of the fistula tract is curetted and the operation is terminated. Adjunctive imaging is performed after 3 to 6 weeks to allow for inflammation related to surgery to subside and hopefully better identify the fistula anatomy.

When a fistula is recurrent, thought to be complex, or if anatomy cannot be identified by EUA, imaging such as transanal ultrasound with contrast injection and MRI are the principal modalities applied. Both have high accuracy rates with high concordance to subsequent surgical exploration findings. Transanal (particularly three-dimensional) endosonography can also successfully predict the amount of sphincter that would be divided if primary fistulotomy is performed, as well as identify undrained sepsis, complex anatomy, and high blind tracts (Fig. 2). MRI has been shown to alter surgical approach in some cases and decrease recurrence rates, and it appears to be superior at identifying suprasphincteric or extrasphincteric tracts. CT scan lacks adequate resolution to identify fistula tracts and their relationship to the sphincters and lesions with comparable accuracy, but is highly sensitive and specific for acute abscess detection. Fistulography, in which contrast is injected into the external opening and the fistula course is traced with fluoroscopy, is rarely performed now with superior cross-sectional imaging.

TABLE 1 Features of Complex Fistulas

Anatomy	Comorbid Condition
Multiple fistulas	Compromised local continence
Suprasphincteric fistulas	Inflammatory bowel disease
Extrasphincteric fistulas	Refractory diarrhea
Associated high blind tract(s)	Anterior fistulas in women
High transsphincteric fistulas (> 30% of anal sphincter length)	Immunodeficiency or compromised wound healing History of regional radiation History of obstetric trauma Elderly patients Prior anorectal surgery

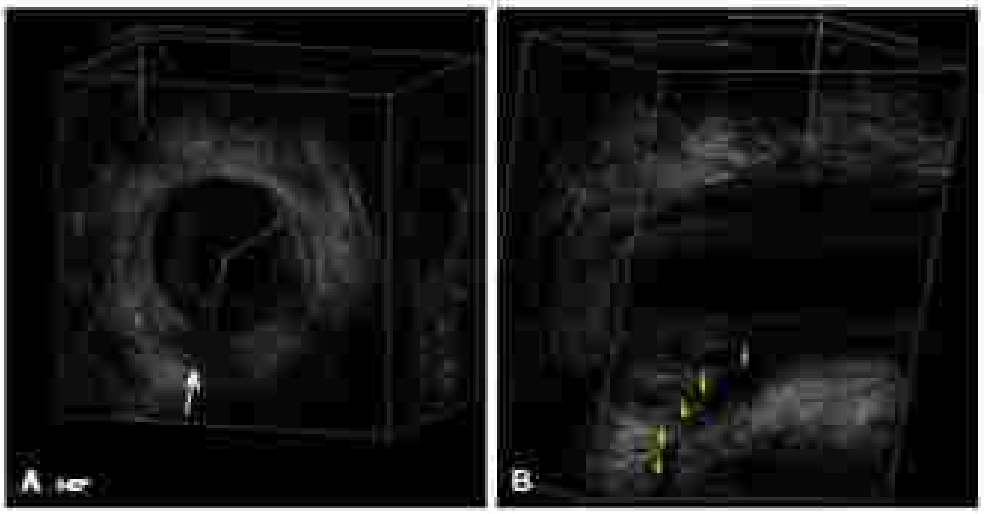

FIG. 3 Ultrasound of right posterior transsphincteric fistula. (A) Coronal view revealing a 140-degree internal sphincter defect on the left side from a previous hemorrhoidectomy. The hypoechoic ventral opening of a right transsphincteric fistula is noted by the arrow. Given the size of the internal sphincter defect, even the fistula tract, a ligation of the transsphincteric fistula tract procedure may not be feasible. (B) Angled sagittal view showing the hypoechoic transsphincteric fistula. Note the internal opening (arrow) nears half the length of the hyperechoic external sphincter; therefore, a fistulotomy would not be appropriate. (*Courtesy Amir Rezvani, Detroit, MI.*)

TABLE 2 Management Strategy by Fistula Classification

Type of Fistula	Fistulotomy	Seton*	LIFT	Advancement Flap	Fibrin Glue	Collagen Plug	Address Intersphincteral or Pelvic Sepsis
Superficial/intersphincteric	X						
Low transphincteric	X	X	X	X	X	X	
High transphincteric		X	X	X	X	X	
Suprasphincteric		X		X		X	X
Extrasphincteric						X	X

*Seton placement can be a first stage or definitive treatment option.
LIFT, Ligation of intersphincteric fistula tract.

3. Assess and Preserve Anal Sphincter Function

Although a controlled anal fistula with or without a seton can cause discomfort and problems with personal hygiene, fecal incontinence is far more disruptive to a patient's quality of life. For that reason, preservation of continence is always a priority when choosing the proper management or surgical strategy. Division of the internal sphincter usually is well tolerated without much effect on continence rates, particularly in men. Similarly, division of distal one third of the external sphincter is considered "safe" in healthy male individuals and can be considered posteriorly in females without preexisting sphincter dysfunction. The degree of sphincterotomy tolerated without affecting continence is patient dependent, and thus careful assessment and documentation of preoperative anatomy and continence rates are critical to the decision making process. Prior anorectal surgery, trauma, or childbirth as well as associated conditions that may cause diarrhea (such as colitis) or inhibit healing may increase the risk of incontinence. Women in particular are vulnerable to incontinence because of their shorter sphincter complex (or high pressure zone) and anatomic and neurologic injury to the pelvic floor sustained during childbirth (particularly when combined with normal muscle attenuation associated with aging). Great care should also be taken in patients with active inflammatory bowel disease involving the anorectum and rectovaginal fistulas because they often heal poorly and have recurrent or metachronous fistula disease. Sphincter preserving techniques are preferred in these patient populations. Table 2 provides a guide in choosing the proper surgical technique based on these and other factors.

4. Minimize Recurrence Risk

Complex fistulas are a frustrating chronic process because they are prone to recurrence despite meticulous surgical technique. Although primary fistulotomy has the lowest recurrence risk, it also is associated with the highest risk of incontinence because of inherent disruption to the sphincter complex. All other sphincter surgical procedures, although they preserve the muscular anatomy, are associated with much higher recurrence risk. This must be considered in an informed consent discussion with the patient. Although no definitive procedure has proven superiority, a surgeon's experience with any one of these described procedures may be the most important factor because reported outcomes vary widely.

Fistulotomy

Fistulotomy can be done at the time of abscess presentation, at the time of initial fistula presentation, or as a second stage procedure in appropriately selected patients. Regardless of timing, a fistulotomy is appropriate only in low risk patients with a superficial, intersphincteric, or low transphincteric fistula. Once the anatomy of the fistula is determined, the tract is cannulated and the tissue overlying the probe is divided with electrocautery. The epithelial lining of the tract

itself to fulguration with a cautic or electrocautery to remove debris and granulation tissue. The wound then heals by secondary intention. Objectively, this approach converts the fistula (or tunnel) into a valley or ditch.

For larger wounds, wound healing can be accelerated by marsupialization of the wound, which also can prevent premature epithelialization of the wound edges before the deeper areas heal (thereby creating a subcutaneous fistula). The skin or subcutaneous edges of the incision are sewn to the base of the wound with absorbable suture. Success rates are generally more than 90%, but also have the highest rates of some degree of fecal incontinence, up to 40% in some series. Hence fistulotomy is not appropriate (in most instances) for high or complex fistulas.

Seton

Two types of setons that can be used. A loose, noncutting seton allows for ongoing drainage of sepsis and prevents abscess, reformation, and shrinkage of the abscess cavity and of the fistula tract, often in preparation for a second stage procedure. The seton itself can be a thin Silastic band, vessel loop, or nonabsorbable suture (such as silk). In general, vessel loops cause less adjacent inflammation than braided sutures, and so the setons goal must be considered when choosing the material. The material is threaded through the tract and secured to a loop or omega shape so itself with several interrupted silk sutures. The noncutting (draining) setons should not be tight at the level of the skin. A hemostat should fit easily between the skin and loop without tension. The second stage procedure, either fistulotomy or a sphincter preserving operation, usually is performed 6 to 10 weeks later, though sometimes with larger or more complex fistulas, a waiting period of 3 to 4 months is advised. Setons used in this fashion for complex fistulas have success rates from 42% to 100%, depending on patient factors and the choice of the secondary procedure. For some Crohn's or other high-risk patients, draining setons can be the definitive procedure: it is left in place for prolonged periods (years) to prevent recurrent sepsis without the intention to perform a second stage procedure because of the likelihood of failure or iatrogenic incontinence. In this case, the setons are typically exchanged for a newer one when they become worn or extremely soiled (typically about once per year).

A cutting seton can be placed with the intention of slowly tightening it over time, so it pulls the fistula tract closer to the skin level under tension. In doing so, it cuts through the tissue forming a fibrous scar in the deeper layers, in theory maintaining the integrity of the sphincter complex. Cutting setons are typically tightened every 4 to 6 weeks. A critical extra step in placing these setons is the skin surface must be incised at the time of placement because it is extremely painful if placed on intact epithelium. Draining setons can be converted to cutting setons. It must be noted that cutting setons are associated with very high reported rates of fecal incontinence, and the practice has fallen out of favor in many institutions. However, it still may have a role to select cases at intermediate risk because the healing rates are relatively high and approach those of fistulotomy.

Ligation of Intersphincteric Fistula Tract

Ligation of the intersphincteric fistula tract (LIFT) procedure is a relatively new sphincter preserving technique first described in 2007. This is performed most often as a second stage procedure for a transsphincteric fistula after a mature tract has developed with or without aid of a draining seton.

With the patient in the prone jack-knife position with the buttocks taped widely apart, the fistula tract is cannulated with a probe. The external opening is widened to allow for drainage (Fig. 6). A 1- to 2-cm curvilinear incision is made with electrocautery over the palpated intersphincteric groove, and dissection is carried down to the location of the fistula tract (containing a probe for easier identification). A Lonnear retractor (Cooper Surgical) deployed along the anoderm edges provides excellent exposure. The intersphincteric plane is developed bluntly with a fine tipped hemostat. The fistula tract is isolated circumferentially with care to avoid disrupting it. The probe is removed and the two ends of the intersphincteric tract visualized within the intersphincteric incision are suture ligated with 3-0 absorbable suture. The tract is divided sharply with a scalpel. The external opening is injected with hydrogen peroxide. If there is a persistent leak, the intersphincteric opening of the external sphincter is oversewn until there is no longer a leak. Some authors test the internal opening with peroxide as well to ensure proper closure of the proximal portion of the tract. The anoderm is reapproximated with a running absorbable suture. Very high fistula tracts, or those that track long distances within the intersphincteric space may be difficult to properly isolate in the intersphincteric plane and are not good candidates for this approach.

Results of the LIFT procedure are highly varied and include several of the technical variations described previously as well as the addition of biologic mesh to the intersphincteric space. Primary healing rates vary between 47% and 95%. The impact on incontinence is not universally reported, but generally low. Success rates are comparable to those seen with endorectal advancement flap and quite superior to rates seen with glue or plugs. Tract length longer than 3 cm, prior anal fistula surgery, and obesity has been associated with LIFT failure. An interesting phenomenon is that when failure occurs, it sometimes does so at the level of the intersphincteric incision, thereby converting what was a more complex fistula into a simple, intersphincteric fistula. This phenomenon occurs if the external component of the fistula heals, but the internal opening persists. Some authors describe a subsequent primary fistulotomy to allow complete resolution of the problem.

Endorectal Advancement Flap

The endorectal advancement flap is also used as a second-stage procedure for high fistula tracts, suprasphincteric tracts, and low tracts in high-risk patients with healthy rectal mucosa (Table 1).

For lesions below the dentate line, fistulotomy or a dermal advancement flap is preferred to prevent the creation of a mucosal ectropion that can form if the rectal mucosa is brought down to the level of the anal verge. This can cause ongoing mucous drainage, pruritus, and other complaints. Patients may undergo a preoperative bowel preparation. The prone jack-knife position is preferred for most fistulas, although lithotomy position often is used to address posterior midline internal opening locations. The seton is removed and the internal opening serves to mark the apex of the flap as depicted in Fig. 7. Beginning at the internal opening, a flap is created by distal to proximal dissection with precise electrocautery, including mucosa, submucosa, and a few fibers of the internal sphincter (partial thickness). To ensure adequate perfusion, it is crucial that the base (proximal end) of the flap is wide, at least two to three times the width of the apex. Care should also be taken to prevent excessive handling of the flap, which can result in hematoma formation and tissue compromise. The internal opening itself is a good point of handling to create the necessary tension/countertension because this will subsequently be discarded. The trapezoidal shaped flap is typically 2 to 4 cm long to allow for tension free closure caudal to the level of the original internal opening. The fistula tract is debrided with a curette and the external opening is widened to allow for drainage. Absorbable suture is used to close the internal opening. Some test the integrity of the closure is tested with injection of hydrogen peroxide at the external opening, although this step can be omitted if closure is deemed adequate. The tip of the flap with the internal opening is amputated, and the flap is gently pulled distally over the natural internal opening at the level of the dentate line. Interrupted absorbable sutures are used to reapproximate the mucosal edges of the flap.

Success rates are also widely variable, with reported rates between 36.6% and 90.5%, with rates of 60% to 87% specifically for cryptoglandular disease. Factors including obesity, history of radiation, prior attempts at repair, smoking, and inflammatory bowel disease

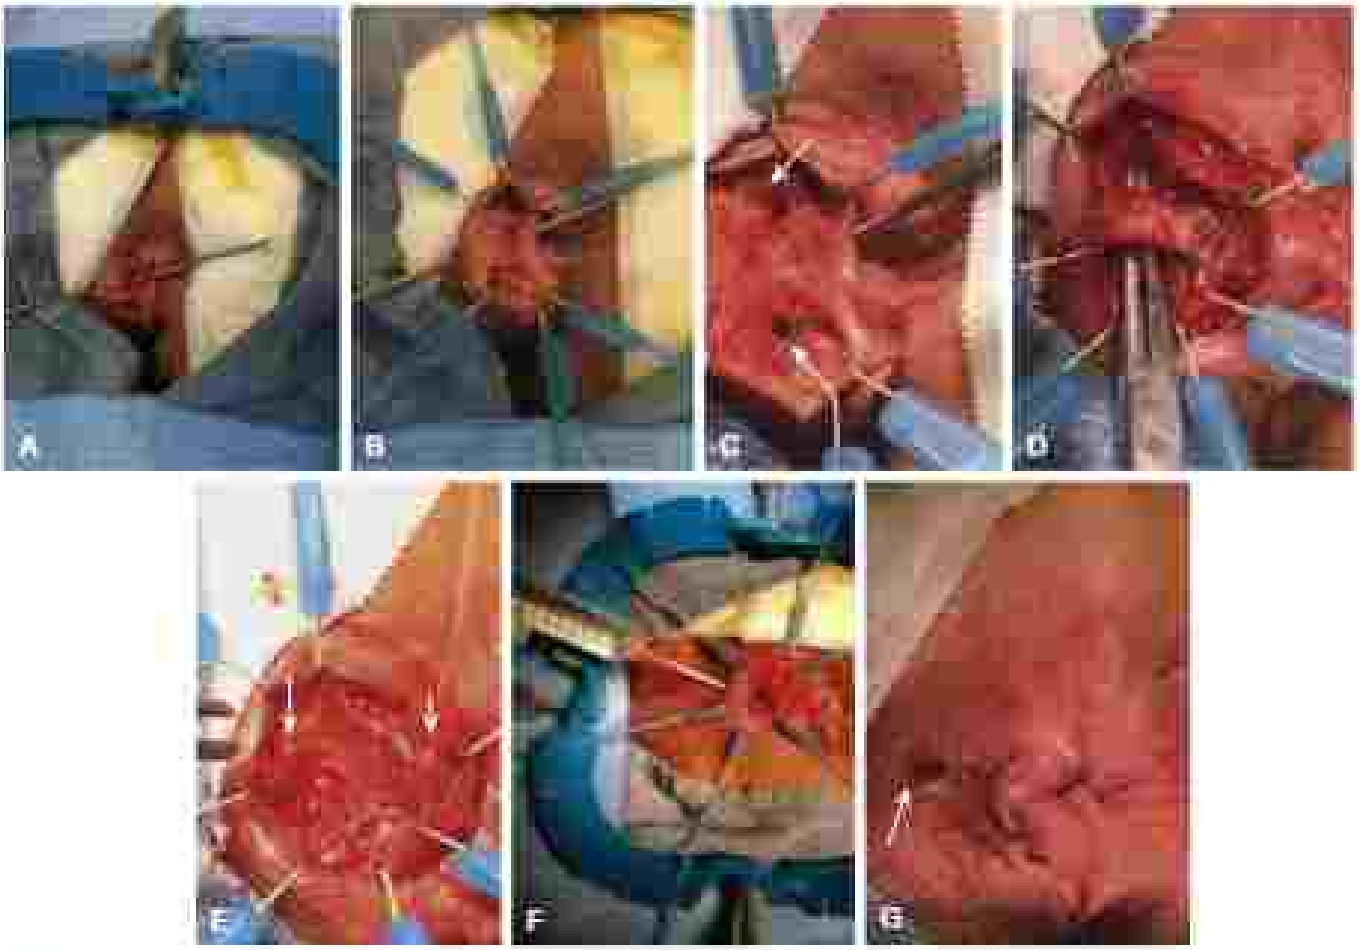

FIG. 6 (A) The fistula tract is considered. (B) A curvilinear incision is made overlying or slightly distal to the anocutaneous groove. A Lone Star retractor (Cooper Surgical) is helpful for exposure. (C) The anocutaneous pilot is developed on either side of the tract (arrows). (D) Chromic sutures ensnare the tract until it is excised. The probe is removed. (E) Dissection and ligation of fistula tract. The tract is extended with a Weitlaner (Weitlaner) tip and the tract is ligated at the border of the external anal sphincter (small arrow). If a long tract is present, it can be excised and the tract near the external anal sphincter is either ligated or imbricated with Vicryl suture (large arrow). (F) The repair is tested by injecting hydrogen peroxide into the internal and external openings. The ligated ends can also be probed to loosen sutures. If there is a leak, the fistula opening is further debrided. (G) The external opening (arrow) is slightly enlarged and the distal aspect of the tract is debrided with a curette. (Courtesy Jeffrey J. Hebrink, MD.)

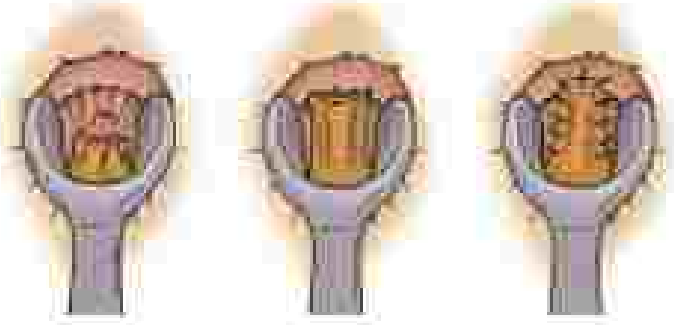

FIG. 7 Mucosal (Rowing) advancement flap. A longitudinal incision is made over the ischiorectal area to the anal canal. Proximal mucosal and anal mucosa are then undermined through a transverse incision starting at the proximal end of a previously made longitudinal incision. The flap is then sutured to the distal edge of internal anal sphincter, leaving open the most distal aspect of the wound. (From Ellsmere J, Hebrink JJ, Rosen KG, et al. New and old operations for anal fistula. Am J Surg. 2003;186:312.)

have been found to predict failure. Although the sphincter muscle is not divided, worsening of bowel continence has been reported in up to 30% of patients treated with this procedure.

Fibrin Sealant and Collagen Plug

Synthetic and biologic materials were promising new additions to the armamentarium of fistula treatment in the past 20 years. Their general principle is obliteration of the internal opening and fistula tract. Their primary benefit is a minimal risk profile because they do not involve any sphincter manipulation (and thus pose no risk to continence), are easily repeated in the case of recurrence, and do not preclude subsequent surgical management. However, low reported success rates (as low as 14%) have largely resulted in abandonment of their use. Furthermore, many insurance companies will not cover the cost of these expensive products because of low success rates.

Anorectal Stricture

Ruiqian Zhu, BS, and Yusuf Nassori, MD, FACS, FASCRS

Anal stenosis is the narrowing of the anal canal resulting from lesions, infections or inflammatory process, or the development of rigid connective tissue in place of pliable anal canal mucosa and muscles. Often, anal stenosis results in impaired bowel function and painful bowel movements. Stenosis can occur anywhere along the anal canal and, in rare cases, even involve the entire length. Because the primary focus of this chapter is the management of anatomic anal stenosis, physiologic/nonanatomic causes of anal canal narrowing, such as levator spasm and dyssynergic defecation, are not discussed. Anatomic anal stenosis may be congenital or result from secondary causes that can be iatrogenic, inflammatory, or neoplastic (Box 1). The most common cause of anal stenosis is anorectal surgery, in particular, hemorrhoidectomy. During the procedure, the excessive removal of anoderm and anorectal mucosa from the anal canal and suture/staple line dehiscence can result in scarring and the formation of chronic stricture. Therefore, the best approach to anal stenosis is prevention through the conservation of anoderm and avoidance of excessive circumferential excision and damage to the sphincter musculature during surgery. This chapter discusses the diagnosis, categorization, and nonoperative and operative treatment of anal stenosis.

DIAGNOSIS AND EXAMINATION

Symptoms of anal stenosis include constipation, obstipation, painful bowel movements, bleeding, and narrow caliber stools. Seepage and soiling may also occur as a result of sphincter damage or overflow incontinence. In an attempt to relieve symptoms, patients may resort to laxatives or digital manipulation, which can exacerbate the condition by causing more structural damage, spasm, and worsening anorectal physiology. Visual examination of the anal canal and perianal skin or digital rectal examination can confirm a diagnosis and identify the cause in most cases. By parting the gluteal folds, narrowing of the anal canal and circumferential scar formation may be observed. In addition, lesions such as anal condyloma or other infections or inflammatory conditions may be seen or present. For patients experiencing severe pain or anxiety, examination under anesthesia may be necessary. Under anesthesia, the full length of the anal canal can be evaluated, cultures and biopsies obtained, and functional and anatomic stenosis differentiated. If anal stricture is associated with fistulas or neoplasms, pelvic imaging in the form of magnetic resonance imaging can be informative. Magnetic resonance imaging of the pelvis can help delineate the extent and anatomy of related fistulae including secondary branches, and reveal extent of neoplastic involvement of surrounding tissues and organs.

CLASSIFICATION

Anorectal strictures can be classified by severity and extent of involvement of the anal canal. The categories described by Eberman and Thomas offer a comprehensive and clear description of different types of strictures.

Severity classification is as follows:

- Mild: anal canal can be examined by a lubricated index finger or medium (10F) Fergusson retractor
- Moderate: forceful dilation is necessary for the insertion of index finger or medium (10F) Fergusson retractor
- Severe: forceful dilation is required for the insertion of little finger or small (8F) Fergusson retractor

Involvement of the anal canal is described as:

- Low: more than 0.5 cm distal to the dentate line
- Middle: 0.5 cm distal and proximal to the dentate line
- High: more than 0.5 cm proximal to the dentate line

NONOPERATIVE MANAGEMENT

Stenoses that are infectious, inflammatory, or neoplastic in origin are best managed by treatment of the underlying disease (e.g., antibiotics, antivirals, biopsication, excision, or radiation). Stenoses of all severity can be managed with stool softeners, fiber supplements, and daily digital or mechanical anal dilation. Mechanical dilations can be particularly useful for patients with Crohn's disease because surgical treatment poses significant infectious complications. Generally, the first dilation is performed under anesthesia digitally or with dilators, such as Hegar dilators. For subsequent dilations, patients may self dilate with a digit or small dilator. Some patients may require multiple dilations under anesthesia. Practitioners may inject local corticosteroids following dilation to reduce stricturing scar formation. Although some patients respond well, manual dilations pose the risk of further fibrosis, worsening stenosis, and fecal incontinence as a result of damage to anal sphincter complex.

OPERATIVE MANAGEMENT

For moderate to severe stenosis, the solution to excised and perianal skin or rectal mucosa is brought in to reconstitute tissue inside the anal canal using various flap techniques. Flaps can be organized into three different categories: advancement, island, and rotational (Figs. 1 through 7). Comparison of the efficacy of different flap techniques is limited because prospective studies are difficult to conduct; therefore, technique should be selected based on the location, severity, extent of the stricture, and the surgeon's expertise. The condition of the rectal mucosa should be considered and endorectal mucosal advancement flaps avoided in patients with history of radiation therapy or Crohn's proctitis. In general, surgeons should familiarize themselves with two or three different types of flaps to appropriately tailor to most anal strictures. Procedural or technique-oriented textbooks and video clips can also provide a more in-depth insight into individual techniques.

ADVANCEMENT FLAPS

Advancement flaps have one free end that can be directly pulled into the defect. Because the survival of the flap depends on maximized

Anorectal Stricture

Ruiqian Zhu, BS, and Yosef Nasseri, MD, FACS, FASCRS

Anal stenosis is the narrowing of the anal canal resulting from lesions, infections or inflammatory process, or the development of rigid connective tissue in place of pliable anal canal mucosa and muscles. Often, anal stenosis results in impaired bowel function and painful bowel movements. Stenosis can occur anywhere along the anal canal and, in rare cases, even involve the entire length. Because the primary focus of this chapter is the management of anatomic anal stenosis, physiologic/nonanatomic causes of anal canal narrowing, such as levator spasm and dyssynergic defecation, are not discussed. Anatomic anal stenosis may be congenital or result from secondary causes that can be iatrogenic, inflammatory, or neoplastic (Box 1). The most common cause of anal stenosis is anorectal surgery, in particular, hemorrhoidectomy. During the procedure, the excessive removal of epidermis and anorectal mucosa from the anal canal and suture/staple line dehiscence can result in scarring and the formation of chronic stricture. Therefore, the best approach to anal stenosis is prevention through the conservation of epiderm and avoidance of excessive circumferential excision and damage to the sphincter musculature during surgery. This chapter discusses the diagnosis, categorization, and nonoperative and operative treatment of anal stenosis.

DIAGNOSIS AND EXAMINATION

Symptoms of anal stenosis include constipation, obstipation, painful bowel movements, bleeding, and narrow caliber stools. Seepage and soiling may also occur as a result of sphincter damage or overflow incontinence. In an attempt to relieve symptoms, patients may resort to laxatives or digital manipulation, which can exacerbate the condition by causing more structural damage, spasm, and worsening anorectal physiology. Visual examination of the anal canal and perianal skin or digital rectal examination can confirm a diagnosis and identify the cause in most cases. By parting the gluteal folds, narrowing of the anal canal and circumferential scar formation may be observed. In addition, lesions such as anal condyloma or other infections or inflammatory conditions may be seen or present. For patients experiencing severe pain or anxiety, examination under anesthesia may be necessary. Under anesthesia, the full length of the anal canal can be evaluated, cultures and biopsies obtained, and functional and anatomic stenosis differentiated. If anal stricture is associated with fistulas or neoplasms, pelvic imaging in the form of magnetic resonance imaging can be informative. Magnetic resonance imaging of the pelvis can help delineate the extent and anatomy of related fistulae including secondary branches, and reveal extent of neoplastic involvement of surrounding tissues and organs.

CLASSIFICATION

Anorectal strictures can be classified by severity and extent of involvement of the anal canal. The categories described by Eberman and Thomas offer a comprehensive and clear description of different types of strictures.

Severity classification is as follows:

- Mild: anal canal can be examined by a lubricated index finger or medium (10) Fergusson retractor
- Moderate: forceful dilation is necessary for the insertion of index finger or medium (10) Fergusson retractor
- Severe: forceful dilation is required for the insertion of little finger or small (00) Fergusson retractor

Involvement of the anal canal is described as:

- Low: more than 0.5 cm distal to the dentate line
- Middle: 0.5 cm distal and proximal to the dentate line
- High: more than 0.5 cm proximal to the dentate line

NONOPERATIVE MANAGEMENT

Stenoses that are infectious, inflammatory, or neoplastic in origin are best managed by treatment of the underlying disease (e.g., antibiotics, antivirals, biopsy/ablation, excision, or radiation). Stenoses of all severity can be managed with stool softeners, fiber supplements, and daily digital or mechanical anal dilation. Mechanical dilations can be particularly useful for patients with Crohn's disease because surgical treatment poses significant infectious complications. Generally, the first dilation is performed under anesthesia digitally or with dilators, such as Hegar dilators. For subsequent dilations, patients may self dilate with a digit or small dilator. Some patients may require multiple dilations under anesthesia. Practitioners may inject local corticosteroids following dilation to reduce stricturing scar formation. Although some patients respond well, manual dilations pose the risk of further fibrosis, worsening stenosis, and fecal incontinence as a result of damage to anal sphincter complex.

OPERATIVE MANAGEMENT

For moderate to severe stenosis, the solution to excised and perianal skin or rectal mucosa is brought in to reconstitute tissue inside the anal canal using various flap techniques. Flaps can be organized into three different categories: advancement, island, and rotational (Figs. 1 through 7). Comparison of the efficacy of different flap techniques is limited because prospective studies are difficult to conduct; therefore, technique should be selected based on the location, severity, extent of the stricture, and the surgeon's expertise. The condition of the rectal mucosa should be considered and endorectal mucosal advancement flaps avoided in patients with history of radiation therapy or Crohn's proctitis. In general, surgeons should familiarize themselves with two or three different types of flaps to appropriately tailor to most anal strictures. Procedural or technique-oriented textbooks and video clips can also provide a more in-depth insight into individual techniques.

ADVANCEMENT FLAPS

Advancement flaps have one free end that can be directly pulled into the defect. Because the survival of the flap depends on maximized

blood supply to the leading edge, the distal tip and highest tension suture areas to prone to ischemic necrosis.

Mucosal Advancements Flap

Mucosal advancement flaps are appropriate for midlevel and upper anal stenosis. This technique, also used to treat anal fistulas, is the primary technique that uses outward advancement of rectal mucosa. First, the scarred tissue is excised and a rectal mucosal flap created with a transverse incision at the dentate line. The flap usually involves

BOX 1 Classification of Anal Stenosis

Iatrogenic
Hemorrhoidectomy
Fistulectomy
Fissurectomy
Trans anal mass excision
Low anterior resection with coloanal anastomosis
Intersphincteric resection
Ileal pouch–anal anastomosis
Sphincteroplasty
Gracilis transposition
Excision of perianal skin tumor

Inflammatory
Crohn's disease
Anal fistula
Hidradenitis suppurativa
Tuberculosis
Schistosomiasis
Actinomycosis
Lymphogranuloma venereum
Acquired granuloma
Herpes simplex
Toxic epidermal necrolysis

Neoplastic
Condyloma acuminata
Bowen's disease
Paget's disease
Anal squamous cell carcinoma
Rectal adenocarcinoma

Miscellaneous
Radiation therapy
Perineal/anorectal trauma
Hot water enemas
Mucosal anti-inflammatory suppositories
Chronic laxative abuse
Chronic diarrhea

the mucosal and submucosal layers and small portion of underlying sphincter muscle complex. The tissue is then advanced past the excision area while maintaining blood supply through submucosal vascular plexuses. Last, the flap is sutured at the distal edge of the internal sphincter near the anal verge. Distal overextension of the flap or suture to the anal verge may cause ectropion, the outward turning of the anal mucosa into the anodermal junction or perianal skin.

V-Y Flap

V-Y advancement flaps are best suited for low stenosis and should not be used for strictures situated above the dentate line. The V-Y flap is example of an advancement flap that involves toward advancement of anoderm. First, a Y-shaped incision is made with the excision of the scar tissue constituting the vertical stroke of the Y. Then, a V-shaped flap (corresponding to the lip of the Y) with vascularized fatty subdermal tissue is made with the wide base facing away from the dentate line. Finally, the narrow tip of the V-shaped flap is sutured to the dentate line to form the final Y shape.

ISLAND FLAPS

Advancement transfer flaps are suitable for long strictures because they reduce the risk of tissue necrosis. Flaps are incised to the depth of the subcutaneous fat and the pedicle maintained to ensure the viability of the tissue island. The flaps should be loose enough to pull into the anal canal without tension. Flaps can be performed unilaterally or bilaterally based on the amount of tissue necessary to cover the excision area.

V-Y Flap

The V-Y flap is suitable for low, severe strictures. Following excision of the scar, a V-shaped incision with the wide base facing the dentate line is performed to form an isolated island of tissue that is slid over the excised area. The donor site is closed as a straight line.

Diamond Rhomboid Flap

Diamond flaps are suited for moderate to severe long strictures. Following the excision of the fibrous tissue, a diamond-shaped flap is created from healthy anoderm and pulled into the anal canal. The flap is then aligned with the defect and sutured to the edges. Finally, the original donor site is closed as a straight line.

House Flap

Because of its length, the house flap is capable of covering the entire length of anal canal and is suitable for long strictures or strictures above the dentate line. The fibrous tissue is excised, followed by the creation of a house-shaped flap in anoderm. The "roof" of the house faces away from the dentate line and the length of the "walls" matches the lengths of the scar tissue excision. The base of the house is sutured to the proximal end of the excision area.

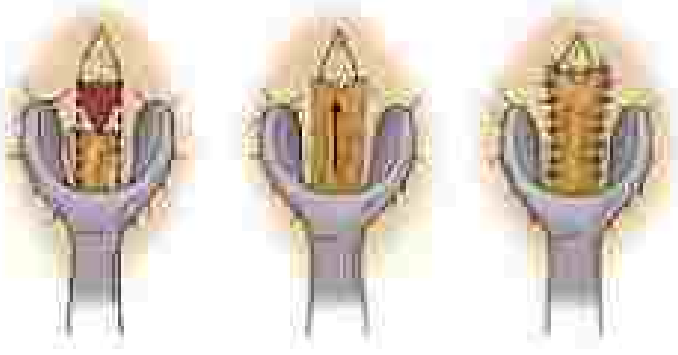

FIG. 1 Mucosal advancement flap. [From Hardiman JW. Mucosal advancement flaps. In: Beck DE, Wexner SD, editors. Fundamentals of Anorectal Surgery. 3rd ed. London: Saunders; 2006.]

U Flap

As with diamond and house flaps, U flaps are suitable for moderate to severe stricture. U flaps begin with a U-shaped incision distal to the scar tissue excision. The resulting oval flap of tissue is pulled down to the anal canal to cover the excision area. Although the flap is anatomically in place, the donor site is left open and is commonly left to granulate.

[illegible] FLAP

Extensive stenosis where a large amount of skin is necessary for coverage can be approached with the V rotational flap. A rotational flap optimally maintains tension and maintains blood supply. After the excision of scarred tissue, bilateral full-thickness diagonal flaps are made based on the pedicle arising from the anterior limit of the base of the V. The length should be as great as the length of the flaps are then rotated to an anatomical position. However, rotational flap techniques are generally used over V rotation as the latter are more complex and result in longer hospital stays.

POSTOPERATIVE CARE

Single and limited excisions can be performed in the outpatient setting. For more extensive procedures, hospital admission may be necessary. During the initial 2 to 3 weeks following surgery, patients should be placed on a short-stay regimen and must adhere to strict measures of wound management that decrease the flap risk of the postoperative complications such as contamination and infection. Sitz baths with dilute saline or mild soaps are encouraged over standard toilet paper. Such should be used for severe or hemorrhoidal patients. Additionally, it is recommended for patients to apply ice over areas of incision for the first 24 hours to reduce inflammation and swelling. Ice daily to the buttocks to alleviate associated spasm and discomfort. Patients should avoid excessive wiping after bowel movements and shower as an alternative to maintain hygiene. Potential complications include infection, suture line dehiscence, flap necrosis, incontinence, and exuberant granulation tissue development in open donor sites. Patients should be instructed to report excessive pain, diminish evacuations, ongoing bleeding, urinary retention, fever, or chills.

OUTCOMES

Outcomes of flap procedures in the literature are variable and difficult to assess because they are mostly retrospective reports of small patient series with variable follow-up times. The following discussion of a few noteworthy studies provides a brief overview. In their review of literature from 1972 to 2008, Brisinda et al. compiled retrospective data and case series to report outcomes of various flaps with a minimum follow-up of 3 months. With the exception of the V-Y flap, all flaps discussed in this chapter were reported to have a 90% or greater healing rate. Since the Brisinda review, Farid and colleagues conducted a prospective study randomizing 60 patients to either house diamond, or V-Y flap. Despite longer operative times, house flaps, when compared with diamond and V-Y flaps, had the lowest recurrence rate (3% vs 20% and 13%, respectively), lowest complication rate (13% vs 53% and 40%, respectively) and greatest anal caliber at 1-year follow-up. The house flap was also associated with greatest quality of life improvement and patient satisfaction. More recently, Boone et al. published their data on nine anal stenosis patients treated with the diamond flap. During the mean follow-up, all patients reported significant improvement in their symptoms and were able to pass bowel movement without difficulty.

SUMMARY

Anal stenosis is the narrowing of the anal canal and is most commonly associated with scarring after anorectal surgery. While nonoperative methods fail to provide adequate symptom relief, surgical treatment has been shown to be effective and provide good outcomes. While various flap techniques are available to address different types and severities of strictures, preventative measures to reduce iatrogenic injury during anorectal procedures should be emphasized.

MANAGEMENT OF PRURITUS ANI

Nathalie Massilla, MD, and Jean R. Cl[illegible]

Pruritus ani is a skin condition characterized by itching or a burning sensation of the perianal region. The causes are multifactorial, and patients typically present after attempting home remedies and over-the-counter medications, compounded by embarrassment to discuss these symptoms with healthcare professionals. Undoubtedly, pruritus ani is an unpleasant sensation that can greatly affect the quality of life of affected patients. The estimated incidence in the general population is up to 5%, with a male:female ratio of 4:1. Patients are often diagnosed in the fourth to sixth decades of life, with a slow progression of symptoms that worsen, particularly at night and in warm weather, because of excessive moisture of the perianal area. Pruritus ani can be localized or diffusely involve the perianal skin, and can be classified into primary or idiopathic cases, or secondary to certain disorders. Multiple conditions have been implicated in the etiology of pruritus ani, perianal soiling being the most common cause.

PATHOPHYSIOLOGY AND ETIOLOGY

The differential diagnosis of pruritus ani is composed of a long list of conditions that can be grouped into infectious, inflammatory, and neoplastic. Primary or idiopathic pruritus ani accounts for more than one-half of cases (Shelley, 1959), and although a variety of factors have been implicated in the pathophysiology (anatomic, dietary, hygienic, psychogenic, local irritants, and medications), fecal contamination and local skin irritation seem to be the common promoting factors. This phenomenon occurs by the activation of unmyelinated C fibers in the epidermis and subdermis; however, the neurophysiologic mechanisms behind the symptoms are much more complex. Unexpectedly, scratching can temporarily alleviate the itching sensation, but is thought to produce inadequate feedback to inhibit further symptoms (pruritoceptive itching). Avoiding scratching is key in the interruption of the vicious cycle of skin trauma, which is an additional stimulus for itching.

A number of foods have been associated with the production of perianal itching and are commonly excluded from the diet as part of the initial management. These prurigenic foods include coffee, colas, citrus fruits, chocolate, tea, energy drinks, alcoholic beverages, tomato, and spicy foods. They act as irritants of the perianal skin, and have also been implicated in altering bowel habits, stool consistency, and facilitating seepage. A detailed history and physical examination are critical in narrowing the diagnosis because in many cases both primary and secondary etiologies can be found. Secondary pruritus should be considered in cases in which an identifiable cause is found. The etiologies in this group are very broad and can be classified into five categories: infectious, dermatologic, systemic disease, benign and malignant anorectal diseases, and miscellaneous (Box 1).

Infectious

Among the infectious agents, sexually transmitted diseases are common causes of anal pruritus, particularly in patients practicing anoreceptive intercourse. The most common pathogens are *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Treponema pallidum*. Genital herpes infections, molluscum contagiosum, and condyloma acuminatum (human papillomavirus infection) are also encountered (Fig. 1). *Shigella* lesions are typically painful ulcers with associated perianal burning sensation that after rupture can leave superficial skin ulcerations (Fig. 2). Symptoms usually resolve after appropriate treatment. Pinworm infection is the most common cause of perianal dermatitis in children, whereas *Candida albicans* is frequently implicated in refractory dermatitis in adults. *Streptococcus pyogenes* is usually the causative agent of erysipelas, a superficial infection of the intertriginous skin often seen in warm weather. Fungal infections account for 10% to 15% of secondary anal pruritus, with *Candida albicans* being the most common fungi identified. Parasitic perianal infections are rare, but common parasites identified include *Ancylostoma duodenale* or *Necator americanus* (hookworm), *Strongyloides stercoralis*, and pediculosis pubis. Nocturnal and postdefecation pruritus ani in children is a characteristic symptom of pinworm infection.

Dermatologic

A wide variety of conditions have been associated with pruritus ani; therefore, a detailed history and physical examination are crucial. Perianal eczema is the most common dermatologic condition responsible for anal pruritus. Frequently, it originates as contact dermatitis to hygiene products or medications used to treat other anorectal conditions, such as over-the-counter hemorrhoidal ointments, deodorants, scented wipes or toilet paper, or soaps. Inquiry about anal hygiene habits and products used must be part of the history. These patients are more likely to have a history of other atopic conditions including asthma. Atopic dermatitis is another common cause of pruritus ani, with an estimated frequency of 1.4% to 2.8% of the population. Psoriasis is another skin problem associated with perianal pruritus, and although not as common, reports in the literature vary from 3% to 50%. Other less common dermatologic conditions that cause pruritus ani include seborrheic dermatitis, lichen planus, lichen sclerosus, and

MANAGEMENT OF PRURITUS ANI

Nathalie Massella, MD, and Jose R. Cintron, MD

Pruritus ani is a skin condition characterized by itching or a burning sensation of the perianal region. Most cases are multifactorial, and patients typically present after attempting home remedies and over-the-counter medications, compounded by embarrassment to discuss these symptoms with healthcare professionals. Undoubtedly, pruritus ani is an unpleasant sensation that can greatly affect the quality of life of affected patients. The estimated incidence in the general population is up to 5%, with a male/female ratio of 4:1. Patients are often diagnosed in the fourth to sixth decades of life, with a slow progression of symptoms that worsen, particularly at night and in warm weather, because of excessive moisture of the perianal area. Pruritus ani can be localized or diffusely involve the perianal skin, and can be classified into primary or idiopathic cases, or secondary to certain disorders. Multiple conditions have been implicated in the etiology of pruritus ani, perianal eczema being the most common cause.

PATHOPHYSIOLOGY AND ETIOLOGY

The differential diagnosis of pruritus ani is composed of a long list of conditions that can be grouped into infectious, inflammatory, and neoplastic. Primary or idiopathic pruritus ani accounts for more than one half of cases (50%–90%), and although a variety of factors have been implicated in the pathophysiology (anatomic, dietary, hygienic, psychogenic, local irritants, and medications), fecal contamination and local skin irritation seem to be the common promoting factors. The phenomenon occurs by the activation of unmyelinated C fibers in the epidermis and subdermis; however, the neurophysiologic mechanisms behind the symptoms are much more complex. Consequently, scratching can temporarily alleviate the itching sensation, but is thought to produce inadequate feedback to inhibit further symptoms (pruritus-scratch-itching). Avoiding scratching is key in the interruption of the vicious cycle of skin trauma, which is an additional stimulus for itching.

A number of foods have been associated with the production of perianal itching and are commonly excluded from the diet as part of the initial management. These pruritogenic foods include coffee, colas, citrus fruits, chocolate, tea, energy drinks, alcoholic beverages, tomato, and spicy foods. They act as irritants of the perianal skin, and have also been implicated in altering bowel habits, stool consistency, and facilitating seepage. A detailed history and physical examination are critical in narrowing the diagnosis because in many cases both primary and secondary etiologies can be found. Secondary pruritus should be considered in cases in which an identifiable cause is found. The etiologies in this group are very broad and can be classified into five categories: infectious, dermatologic, systemic disease, benign and malignant anorectal diseases, and miscellaneous (Box 1).

Infectious

Among the infectious agents, sexually transmitted diseases are common causes of anal pruritus, particularly in patients practicing anoreceptive intercourse. The most common pathogens are *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Treponema pallidum*, but herpes infections, molluscum contagiosum, and condyloma acuminatum (human papillomavirus infection) are also encountered (Fig. 1). Herpetic lesions are typically painful vesicles with associated perianal burning sensation that after rupture can leave superficial skin ulcerations (Fig. 2). Symptoms usually resolve after appropriate treatment. β Hemolytic streptococci is the most common cause of perianal dermatitis in children, whereas *Staphylococcus aureus* is frequently implicated in refractory dermatitis in adults. *Corynebacterium minutissimum* is the causative agent of erythrasma, a superficial infection of the intertriginous skin often seen in warm weather. Fungal infections account for 10% to 15% of secondary anal pruritus, with *Candida albicans* being the most common fungi identified. Parasitic perianal infections are rare, but common parasites identified include *Enterobius vermicularis* (pinworm), *Sarcoptes scabiei* (scabies), and pediculosis pubis. Nocturnal anal pruritus are in children is a characteristic symptom of pinworm infection.

Dermatologic

A wide variety of conditions have been associated with pruritus ani; therefore, a detailed history and physical examination are crucial. Perianal eczema is the most common dermatologic condition responsible for anal pruritus. Frequently, it originates as contact dermatitis to hygiene products or medications used to treat other anorectal conditions, such as over-the-counter hemorrhoid ointments, deodorants, scented wipes or toilet paper, so soaps. Inquiry about anal hygiene habits and products used must be part of the history. These patients are more likely to have a history of other atopic conditions including asthma. Atopic dermatitis is another common cause of pruritus ani, with an estimated frequency of 15% to 20% of the population. Psoriasis is another skin problem associated with perianal pruritus, and although not as common, reports in the literature vary from 1% to 30%. Other less common dermatologic conditions that cause pruritus ani include seborrheic dermatitis, lichen planus, lichen sclerosus, and

lichen simplex chronicus. A high index of suspicion is necessary for an adequate diagnosis and treatment.

Systemic Disease

Multiple systemic diseases have been associated with pruritus ani. Although the underlying triggering mechanisms are not known, treating the primary problem appears to alleviate the symptoms. Diabetes mellitus is one of the common diseases associated with anal pruritus, followed by liver disease (cholestasis), leukemia, lymphoma, chronic renal failure, uremic pruritus, pellagra, iron deficiency anemia, vitamin A and ^{1} deficiency, and hyperthyroidism.

Anorectal Disease

Pruritus ani is commonly found in patients with numerous benign anorectal conditions such as external and internal hemorrhoids (Fig. 3), anal fissures and fistulas (Fig. 4), hidradenitis suppurativa, perianal Crohn's disease, anal skin tags, and pilonidal disease. Symptoms can be caused by the disease itself or from local skin irritation associated with fecal soiling, prolapsing tissue, mucus discharge, and chronic drainage. Perianal disease commonly interferes with local hygiene, leading to skin irritation from residual fecal material. Management of the perianal condition is necessary and may improve symptoms, as it has been seen to patients with hemorrhoids after rubber band ligation or hemorrhoidectomy.

Malignant anorectal processes can also provoke pruritus ani and should be considered and ruled out when appropriate. Among these diseases are anal canal and anal margin cancer (Fig. 5), low rectal cancer, Bowenoid disease, or perianal squamous cell carcinoma in situ (i.e., ^{4}), and Paget's disease or cutaneous adenocarcinoma in situ. In patients with premalignant perianal lesions such as anal intraepithelial neoplasia caused by human papilloma virus infection, pruritus ani can be caused by the anal condyloma itself rather than the presence of dysplasia. The most common extramammary area affected by Paget's disease is the perianal region, occurring more frequently in white women in the sixth decade of life. In these cases, further evaluation of the gastrointestinal, urinary, and gynecologic systems is warranted, attributable to the high incidence of associated malignancy (33%–36%).

Miscellaneous

Radiation-induced perianal dermatitis is an undesired side effect of cancer treatments. Multiple grading systems have been used to grade skin damage from radiation. Regardless of the stage of dermatitis,

from dry desquamation to breakdown and ulceration of the skin; a large number of patients experience anal pruritus. Excessive moisture of the perianal skin from urinary incontinence or vaginal discharge is also associated with skin irritation and consequent pruritus ani.

EVALUATION AND DIAGNOSIS

Clinical History

Because a specialist often sees patients with pruritus ani after other treatments have failed, establishing a diagnosis can be challenging and frustrating. A detailed clinical history including presenting and associated symptoms, disease progression, comorbidities, allergies, and medications is warranted. Specifics about diet, sexual contact, bowel habits, hygiene products and behaviors, and prior use of local agents should be part of the initial clinical encounter. History of atopy, urogenital disorders or surgeries, and sexually transmitted diseases, among others, can aid narrowing the differential diagnoses.

Physical Examination

Inspection of the perianal area, perineum, and genitalia should be the first step of the physical examination. The examiner should look for erythema, fibrosis, ulcerations, maceration of the skin, residual

TABLE 1 Washington Hospital Staging Criteria

	Physical Findings

Stage I	Erythematous and inflamed perianal skin
Stage II	White, lichenified perianal skin
Stage III	Lichenified skin with coarse ridges and ulceration

local material, drainage, and scratch marks. If creams or ointments have been applied, they must be gently cleansed to expose the area for proper evaluation. Frequently, no obvious abnormality is found on the initial evaluation. A digital anorectal examination followed by anoscopy should be performed to rule out anal canal conditions.

The Washington criteria, developed at the Washington Hospital Center, are commonly used to classify the severity of the pruritus ani based on clinical findings (Table 1). In patients with stage I disease, erythematous inflamed skin may be the only finding. In stage II, there is lichenified perianal skin as a result of excessive itching and scratching or rubbing of the skin, resulting in thick leathery appearing skin. In addition to these changes, stage III patients exhibit the presence of coarse ridges and ulceration of the affected skin. These staging criteria should be documented during clinic encounters because it is useful for follow up and evaluation of the response to treatment.

Microbiology testing should be performed based on index of suspicion and clinical findings. To avoid misleading results, appropriate sample collection and specimen manipulation is essential. For example, when feasible, drainage or secretions should be aspirated with a syringe and placed in a sterile container, and viral cultures should be kept on ice for transportation. In patients with diarrhea, bacterial stool cultures as well as ova and parasites testing must be considered.

When considered appropriate, a more extensive endoscopic examination can be performed, including examination under anesthesia, flexible sigmoidoscopy, and colonoscopy with tissue sampling for biopsies and cultures. Nonhealing skin lesions despite appropriate treatment are indications for a biopsy to rule out malignancy.

MANAGEMENT

The initial goal of treatment of patients with pruritus ani should be directed to relief of symptoms, healing of impaired skin, and protection and prevention of additional damage. Once a causative agent is identified (e.g., allergen, local irritant), further contact with the perianal skin must be avoided. Ultimately, management treats or controls the underlying condition after making a diagnosis in cases of secondary pruritus.

Education and Lifestyle Modifications

Particularly important in the management of idiopathic pruritus, a set of general strategies and recommendations should be implemented on the initial consultation. These changes are intended to reestablish the integrity of the perianal skin and prevent further damage, when there is no underlying condition responsible for the symptoms. Patients should be instructed to avoid applying any home remedies, over the counter products, perfumed wipes, powders, lotions, or soaps. "mild cleaning of the perianal area with water and unscented hypoallergenic soaps, followed by total air-drying the area or by dabbing with toilet paper. Avoiding excess moisture of the perianal area is paramount. This can be achieved by placing a cotton ball or a makeup removal pad after cleaning, which will aid to keep the area dry. Patients should also avoid tight fitting underclothing and synthetic fabrics, especially in warm climates. Maintaining regular bowel habits is very important, by controlling stool consistency, which may reduce the chances of stool leakage and soiling. There is significant

BOX 1 Food Products That Contribute to Pruritus Ani Symptoms

Caffeine containing products
- Colas
- Coffee
- tea
- Energy drinks

Tomato
Beer
Spicy and acidic foods
Refined carbohydrates
Nuts

value in the dietary recommendations for patients affected by pruritus ani; the elimination of problematic foods from the diet has shown significant improvement of symptoms in up to 60% of patients after 2 weeks (Box 2).

Topical Agents

If there is persistent symptomatology after 2 weeks of uninterrupted treatment, special attention should be placed on excluding other etiologies of secondary pruritus. Only after infectious causes have been eliminated from the differential diagnosis should topical steroids be considered. Low potency topical steroids such as hydrocortisone 1% are used as first line treatment with good results, decreasing symptoms and improving the quality of life. Duration of therapy should not exceed 8 weeks because prolonged therapy or the use of potent steroids is associated with skin atrophy and worsening of anal pruritus. Substance P is a neuropeptide that triggers itching and burning pain; capsaicin decreases its levels, successfully treating the symptoms in up to 70% of patients when compared with placebo. Topical steroids and capsaicin should be applied in the morning after cleaning, and at night. After completion of therapy, this topical preparation should be replaced by a zinc oxide–based skin protectant such as Calmoseptine.

In rare cases of idiopathic pruritus ani, symptoms may persist and become intractable, despite all treatment strategies and after secondary causes have been excluded. For this small subset of patients, intradermal injection of methylene blue has been described with acceptable success. The alleged mechanism of symptomatic relief is thought to be destruction of nerve terminations in the perianal area. The technique description including concentration and combination of drugs varies slightly among reports. Full-thickness skin necrosis is a complication of this treatment.

SUMMARY

Pruritus ani is a common anorectal condition that can become debilitating and frustrating for patients who suffer from it. A detailed clinical history and physical examination are of utmost importance to establish a diagnosis. When secondary pruritus is identified, the treatment should be tailored to the underlying condition. Biopsies, cultures, and other special testing methods should be performed when appropriate. The majority of the cases improve with education and lifestyle modifications such as cleaning habits and removing offending agents.

Surgical Management of Fecal Incontinence

Evgeny R. [illegible], MD, and Amir [illegible] M. Rafi [illegible], MD, FACS, FASCRS

Fecal incontinence is defined as the involuntary loss of fecal contents (feces, gas) through the anal canal and the inability to postpone an evacuation until socially convenient. For practical reasons, the definition only applies to individuals older than age 4 years who have reached mental and developmental capacity or who previously achieved continence. Fecal incontinence is not a diagnosis but a debilitating symptom that results from an imbalance in a complex pathway regulating fecal control.

Fecal incontinence is much more frequent than acknowledged and is underreported because of its negative stigma. Obtaining accurate rates of prevalence depends on the cohort and methodology but seems to range from 1.4% to 11.5% in the general population. The quality of life of affected individuals and involved caregivers is severely diminished. In the United States, patients residing in nursing facilities are disproportionally affected (18%), and incontinence is in fact one of the leading immediate causes for institutionalization. As such, it generates a substantial financial and logistical burden to health care and society. In absence of any perfect treatment, goal-oriented management is important and may not infrequently be tasked to the practicing general surgeon.

Normal fecal control depends on various factors. Under normal circumstances, the combination of factors should allow to store (ideally formed) stool for a prolonged period. A functional unitimity with a sufficient and adjustable rectal outlet resistance is crucial. An intact, properly innervated, and responsive anal sphincter complex and pelvic floor musculature (e.g., puborectalis sling) provide the dynamic sphincter tone at rest and on demand (squeeze), but the hemorrhoidal cushions add a fine tuning seal of the anal canal. Assessing the various components depends on a complex network of central and peripheral nervous system pathways which allow for both awareness of rectal distention and coordination of the pelvic floor muscles and sphincter complex for timely and complete evacuation. Other factors relevant for fecal control should not be overlooked; a proper stool consistency as well as the sufficiently spacious rectal reservoir with normal elasticity are equally important.

There are numerous conditions that negatively affect this complex balance at various points and ultimately contribute to fecal incontinence (Table 1). Functional incontinence may result when a normal anatomy is (1) disrupted by psychological and habit deconditioning or (2) overwhelmed/exhausted by diarrhea (e.g., from irritable bowel syndrome, inflammatory bowel disease, dietary intolerances, laxative abuse) or by constipation with fecal impaction and paradoxical diarrhea or overflow incontinence. Such causes are very common and must be investigated and explored during the evaluation. Morphologic alterations may affect the macrostructure (e.g., rectal prolapse, cloaca, fistulae), or represent more hidden sphincter defects or pudendal nerve injury. Sphincter damage, as endured from obstetrical or anorectal surgical trauma (e.g., hemorrhoidectomy, hemorrhoidectomy), may clinically remain compensated for a substantial period (years) before coping mechanisms start to fail and fecal incontinence develops decades later. For example, up to 35% of women after vaginal delivery are found to have a sphincter defect, however, the symptoms of fecal incontinence are often delayed until years later (e.g., onset of menopause), and the presence of a defect alone may not correlate with the incontinence symptoms.

DIAGNOSTIC EVALUATION AND WORKUP

Patients presenting with fecal incontinence require a respectful but thorough and methodological history and physical examination. The purpose of the interview is to translate the patient's genuine complaints into a detailed understanding of the type and extent of incontinence, awareness of incontinence episodes (urge vs passive incontinence), timing and frequency of symptoms, stool characteristics and habits, and other associated symptoms (e.g., prolapse, drainage, urinary or sexual dysfunction). A detailed obstetrical and surgical history is essential. Underlying disease processes such as diabetes, stroke, inflammatory bowel disease, malignancy, or specific medications may contribute to fecal incontinence and should be documented. The examination is not limited to defining the sphincter tone at rest and during squeezing and Valsalva maneuvers, but should evaluate for the presence of pelvic organ prolapse, masses, surrounding skin irritation, hemorrhoids, fissures, hemorrhoids, or perianal/rectovaginal fistulas. The perianal and rectal sensation are assessed, and the clinical integrity and function of the sphincter complex and accessory muscles determined on physical examination.

Various patient-reported scoring systems are used to quantify patients' degree of fecal incontinence in a standardized fashion. The Cleveland Clinic Fecal Incontinence Score (Wexner) is one of

Surgical Management of Fecal Incontinence

Gregory K. Lee, MD, and Andreas M. Kaiser, MD, FACS, FASCRS

Fecal incontinence is defined as the involuntary loss of rectal contents (feces, gas) through the anal canal and the inability to postpone an evacuation until socially convenient. For practical reasons, the definition only applies to individuals older than age 4 years who have respective mental and developmental capacity or who previously achieved continence. Fecal incontinence is not a diagnosis but a debilitating symptom that results from an imbalance in a complex pathway regulating fecal control.

Fecal incontinence is much more frequent than acknowledged and is underreported because of its negative stigma. Obtaining accurate rates of prevalence depends on the cohort and methodology but seems to range from 1.4% to 11.5% in the general population. The quality of life of affected individuals and involved caregivers is severely diminished. In the United States, patients residing in nursing facilities are disproportionally affected (18%), and incontinence is in fact one of the leading immediate causes for institutionalization. As such, it generates a substantial financial and logistical burden to health care and society. In absence of any perfect treatment, goal-oriented management is important and may not infrequently be tasked to the practicing general surgeon.

Normal fecal control depends on various factors. Under normal circumstances, the combination of factors should allow to store (ideally formed) stool for a prolonged period. A functional unitarity with a sufficient and adjustable rectal outlet resistance is crucial. An intact, properly innervated, and responsive anal sphincter complex and pelvic floor musculature (e.g., puborectalis sling) provide the dynamic sphincter tone at rest and on demand (squeeze), but the hemorrhoidal cushions add a fine tuning seal of the anal canal. Generating the various components depends on a complex network of central and peripheral nervous system pathways which allow for both awareness of rectal distention and coordination of the pelvic floor muscles and sphincter complex for timely and complete evacuation. Other factors relevant for fecal control should not be overlooked; a proper stool consistency as well as the sufficiently spacious rectal reservoir with normal elasticity are equally important.

There are numerous conditions that negatively affect this complex balance at various points and ultimately contribute to fecal incontinence (Table 1). Functional incontinence may result when a normal anatomy is (1) disrupted by psychological and habit deconditioning or (2) overwhelmed/exhausted by diarrhea (e.g., from irritable bowel syndrome, inflammatory bowel disease, dietary intolerances, laxative abuse) or by constipation with fecal impaction and paradoxical diarrhea or overflow incontinence. Such causes are very common and must be investigated and explored during the evaluation. Morphologic alterations may affect the macroanatomy (e.g., rectal prolapse, cloaca, fistulae), or represent more hidden sphincter defects or pudendal nerve injury. Sphincter damage, as endured from obstetrical or anorectal surgical trauma (e.g., hemorrhoidectomy, hemorrhoidectomy), may clinically remain compensated for a substantial period (years) before coping mechanisms start to fail and fecal incontinence develops decades later. For example, up to 35% of women after vaginal delivery are found to have a sphincter defect, however, the symptoms of fecal incontinence are often delayed until years later (e.g., onset of menopause), and the presence of a defect alone may not correlate with the incontinence symptoms.

DIAGNOSTIC EVALUATION AND WORKUP
