Second-Line Therapy and Beyond Second-line therapy for advanced NSCLC was almost never recommended until a seminal study in 2000 showed that docetaxel improved survival compared to supportive care alone. Little progress had been made in the second-line setting for NSCLC patients until the introduction of immunotherapy agents (see below) with only pemetrexed and docetaxel available as FDA-approved agents, and erlotinib recommended in patients with EGFR mutation–positive NSCLC who did not receive a first line EGFR TKI. Ramucirumab is a recombinant human IgG1 monoclonal antibody that targets VEGFR-2 and blocks the interaction of VEGF ligands and VEGFR-2. A phase III trial demonstrated a significant improvement in progression-free survival and overall survival when ramucirumab was combined with docetaxel as second-line therapy in patients who had progressed on platinum-based chemotherapy. Contrary to bevacizumab, ramucirumab was safe in patients with both squamous and nonsquamous NSCLC and is approved regardless of histology.

Immunotherapy Immune checkpoint inhibitors are a novel class of agents that have significantly improved the quality of life and survival for a group of patients with advanced NSCLC. Immune checkpoint inhibitors work by blocking interactions between T cells and antigen presenting cells (APCs) or tumor cells that lead to T-cell inactivation. By inhibiting this interaction, the immune system is effectively upregulated and T cells become activated against tumor cells. Several large randomized phase III trials demonstrated superior overall survival for both the anti-PD1 antibodies, nivolumab and pembrolizumab and the anti-PD-L1 antibody atezolizumab compared to second-line docetaxel in patients with NSCLC who have progressed on platinum-based chemotherapy **(Table 74-13)**. Nivolumab and atezolizumab are approved as second-line therapy in patients who have progressed following platinum-based chemotherapy regardless of the presence of PD-L1 while pembrolizumab is approved in patients with tumors positive for PD-L1 expression in ≥1% of tumor cells. Pembrolizumab demonstrated superior efficacy to first-line platinum-based chemotherapy in patients with tumors expressing PD-L1 in greater than 50% of tumor cells, as assessed with immunohistochemistry. A similarly designed study did not show efficacy when nivolumab was compared to chemotherapy; however, in this study patients with tumors expressing PD-L1 in greater than 1% of tumor cells were enrolled. Pembrolizumab is approved as first-line therapy in patients with tumors that are positive for PD-L1 expression in ≥50% of tumor cells. While PD-L1 has been identified as a biomarker that can predict response to immune checkpoint inhibitors, responses are observed in patients who do not appear to express the biomarker and not all PD-L1 positive patients respond to checkpoint inhibition. Complicating matter is that each checkpoint inhibitor is being developed in conjunction with its own antibody to assess PD-L1 expression and a large effort is underway to compare these tests. Further evaluation of these agents in both NSCLC and SCLC is ongoing in combination with already approved chemotherapy and targeted agents as well as other checkpoint inhibitors.

TABLE 74-13 Results of Phase III Trials Comparing Chemotherapy and Immunotherapy in Patients with NSCLC

STUDY	THERAPY	NO. OF PATIENTS	OS (MONTHS)	PFS (MONTHS)
Checkmate 017	Docetaxel	137	6.0	2.8
Squamous	Nivolumab	135	9.2	3.5
Checkmate 057	Docetaxel	290	9.4	4.2
Nonsquamous	Nivolumab	292	12.2	2.3
Keynote 10	Docetaxel	212	8.5	4.0
PD-L1 ≥1%	Pembrolizumab 2 mg/kg	259	10.4	2.9
	Pembrolizumab 10 mg/kg	255	12.7	2.9
OAK	Docetaxel	425	10.3	2.8
	Atezolizumab	425	12.6	4.0
Keynote 24	Platinum-chemotherapy	116	NR	6.0
PD-L1 ≥50%	Pembrolizumab	73	NR	10.3
Checkmate 26	Platinum-chemotherapy	212	13.2	5.9
PD-L1 ≥1%	Nivolumab	211	14.4	4.2

Abbreviations: OS, overall survival; PFS, progression-free survival; Platinum-chemotherapy refers to first-line platinum-doublet chemotherapy.

Supportive Care No discussion of the treatment strategies for patients with advanced lung cancer would be complete without a mention of supportive care. Coincident with advances in chemotherapy and targeted therapy was a pivotal study that demonstrated that the early integration of palliative care with standard treatment strategies improved both quality of life and mood for patients with advanced lung cancer **(Chaps. 9 and 65)**. Aggressive pain and symptom control is an important component for optimal treatment of these patients.

TREATMENT

Small-Cell Lung Cancer

The overall treatment approach to patients with SCLC is shown in Fig. 74-5.

SURGERY FOR LIMITED-DISEASE SMALL-CELL LUNG CANCER

SCLC is a highly aggressive disease characterized by its rapid doubling time, high growth fraction, early development of disseminated disease, and dramatic response to first-line chemotherapy and radiation. In general, surgical resection is *not* routinely recommended for patients because even patients with LD-SCLC still have occult micrometastases. However, the most recent American College of Chest Physicians Evidence-Based Clinical Practice Guidelines recommend surgical resection over nonsurgical treatment in SCLC patients with clinical stage I disease after a thorough evaluation for distant metastases and invasive mediastinal stage evaluation (grade 2C). After resection, these patients should receive platinum-based adjuvant chemotherapy (grade 1C). If the histologic diagnosis of SCLC is made in patients on review of a resected surgical specimen, such patients should receive standard SCLC chemotherapy as well.

CHEMOTHERAPY

Chemotherapy significantly prolongs survival in patients with SCLC. Four to six cycles of platinum-based chemotherapy with either cisplatin or carboplatin plus either etoposide or irinotecan has been the mainstay of treatment for nearly three decades and is recommended over other chemotherapy regimens irrespective of initial stage. Cyclophosphamide, doxorubicin (Adriamycin), and vincristine (CAV) may be an alternative for patients who are unable to tolerate a platinum-based regimen. Despite response rates to first-line therapy as high as 80%, the median survival ranges from 12 to 20 months for patients with LD and from 7 to 11 months for patients with ED. Regardless of disease extent, the majority of patients relapse and develop chemotherapy-resistant disease. Only 6–12% of patients with LD-SCLC and 2% of patients with ED-SCLC live beyond 5 years. The prognosis is especially poor for patients who relapse within the first 3 months of therapy; these patients are said to have *chemotherapy-resistant disease*. Patients are said to have *sensitive disease* if they relapse more than 3 months after their initial therapy and are thought to have a somewhat better overall survival. These patients also are thought to have the greatest potential benefit from second-line chemotherapy **(Fig. 74-7)**. Topotecan is the only FDA-approved agent for second-line therapy in patients with SCLC. Topotecan has only modest activity and can be given either intravenously or orally. In one randomized trial, 141 patients who were not considered candidates for further IV chemotherapy were randomized to receive either oral topotecan or best supportive care. Although the response rate to oral topotecan was only 7%, overall survival was significantly better in patients receiving chemotherapy (median survival time, 26 weeks vs 14 weeks; $p = 0.01$). Moreover, patients given topotecan had a slower decline in quality of life than did those not receiving chemotherapy. Other agents with similar low levels of activity in the second-line setting include irinotecan, paclitaxel, docetaxel, vinorelbine, oral etoposide, and gemcitabine. Clearly novel treatments for this all too common disease are desperately needed.

THORACIC RADIATION THERAPY

Thoracic radiation therapy (TRT) is a standard component of induction therapy for good performance status and limited-stage SCLC patients. Meta-analyses indicate that chemotherapy combined with chest irradiation improves 3-year survival by ~5% as compared with chemotherapy alone. The 5-year survival rate, however, remains disappointingly low at ~10–15%. Most commonly, TRT is combined with cisplatin and etoposide chemotherapy due to a superior toxicity profile as compared to anthracycline-containing chemotherapy regimens. As observed in locally advanced NSCLC, *concurrent* chemoradiotherapy is more effective than *sequential* chemoradiation but is associated with significantly more esophagitis and hematologic toxicity. Ideally TRT should be administered with the first two cycles of chemotherapy because later application appears slightly less effective. If for reasons of fitness or availability, this regimen cannot be offered, TRT should follow induction chemotherapy. With respect to fractionation of TRT, twice-daily 1.5-Gy fractioned radiation therapy has been shown to improve survival in LD-SCLC patients but is associated with higher rates of grade 3 esophagitis and pulmonary toxicity. Although it is feasible to deliver once-daily radiation therapy doses up to 70 Gy concurrently with cisplatin-based chemotherapy, there are no data to support equivalency of this approach compared with the 45-Gy twice-daily radiotherapy dose. Therefore, the current standard regimen of a 45-Gy dose administered in 1.5-Gy fractions twice daily for 30 days is being compared with higher-dose regimens in two phase III trials, one in the United States and one in Europe. Patients should be carefully selected for concurrent chemoradiation therapy based on good performance status and adequate pulmonary reserve. The role of radiotherapy in ED-SCLC is largely restricted to palliation of tumor-related symptoms such as bone pain and bronchial obstruction.

PROPHYLACTIC CRANIAL IRRADIATION

Prophylactic cranial irradiation (PCI) should be considered in all patients with either LD-SCLC or ED-SCLC who have responded well to initial therapy. A meta-analysis including seven trials and 987 patients with LD-SCLC who had achieved a complete remission after upfront chemotherapy yielded a 5.4% improvement in overall survival for patients treated with PCI. In patients with ED-SCLC who have responded to first-line chemotherapy, a prospective randomized phase III trial showed that PCI reduced the occurrence of symptomatic brain metastases and prolonged disease-free and overall survival compared to no radiation therapy. Long-term toxicities, including deficits in cognition, have been reported after PCI but are difficult to sort out from the effects of chemotherapy or normal aging.

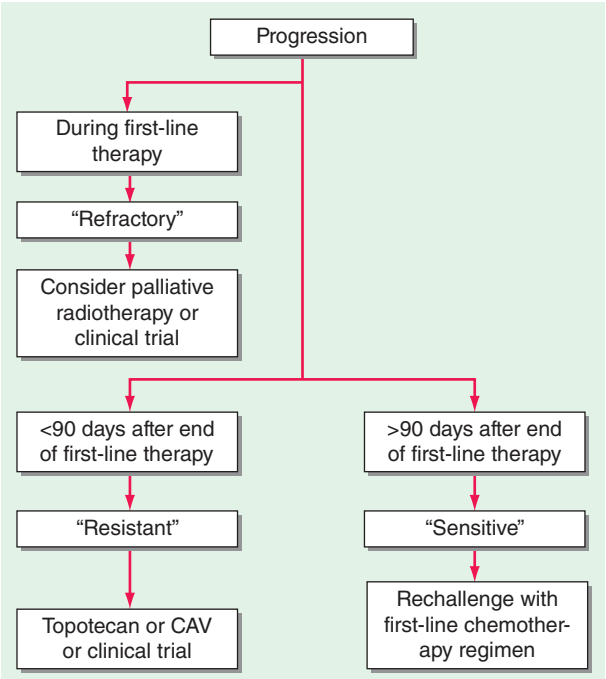

FIGURE 74-7 Management of recurrent small-cell lung cancer (SCLC). CAV, cyclophosphamide, doxorubicin, and vincristine. *(Adapted with permission from JP van Meerbeeck et al: Lancet 378:1741, 2011.)*

THYMIC TUMORS

Thymic tumors are rare malignancies accounting for 0.5–1.5% of all malignancies in the United States with a higher incidence among Asian populations. They are particularly rare among children and young adults with incidence peaking in the fifth decade of life. There is no difference between sexes and no clear risk factors have been identified.

CLINICAL MANIFESTATIONS

The majority of thymic tumors occur in the anterior mediastinum. Approximately 40% of patients with mediastinal masses will be asymptomatic with an incidental finding on chest imaging. In patients presenting with an anterior mediastinal mass, if appropriate, serum beta-HCG (human chorionic gonadotropin) and α fetoprotein (AFP) should be sent to rule out a germ cell tumor. A patient with a sign or symptom of thymoma or thymic carcinoma may present with chest pain, dyspnea, cough or superior vena cava syndrome secondary to effects on adjacent organs or a paraneoplastic syndrome, most commonly myasthenia gravis, pure red cell aplasia or hypogammaglobulinemia. More rare paraneoplastic syndromes include limbic encephalitis, aplastic anemia, hemolytic anemia, and autoimmune disease such as Sjogrens syndrome, polymyositis, rheumatoid arthritis, ulcerative colitis among others.

STAGING

Given the rarity of the tumor, patients with suspected thymoma should be evaluated by a multidisciplinary team including a surgeon, medical

TABLE 74-14 Staging Thymic Tumors

MASAOKA STAGE	DEFINITION
I	Grossly and microscopically encapsulated
IIA	Microscopic transcapsular invasion
IIB	Macroscopic invasion into surrounding tissue excluding pericardium, lung, and great vessels
III	Macroscopic invasion into neighboring organs of the lower neck or upper chest
IVA	Pleural or pericardial dissemination
IVB	Hematogenous or lymphatic dissemination to distal organs
WHO	
A	Tumor with few lymphocytes
AB	Tumor with features of type A and foci rich in lymphoctyes
B1	Tumor with features of normal epithelial cells with vesicular nuclei and distinct nucleoli and an abundant population of lymphocytes. Also known as cortical thymoma, lymphocyte-rich thymoma
B2	Thymoma with no or mild atypia with round or polygonal shaped cells with small component of lymphocytes
B3	Well differentiated thymic carcinoma with mild atypia
C	Thymic carcinoma with high atypia

and radiation oncologist as well as pathologist with experience in treating the disease. A CT scan of the chest with contrast is recommended to determine if the mass is resectable based on relationship to surrounding structures. An MRI with contrast may be performed if clinically indicated. A PET scan may be useful in the evaluation of a patient with thymic tumors although may be less useful in the staging of thymoma compared to thymic carcinoma. A core needle biopsy is considered standard of care for obtaining a histological diagnosis of an anterior mediastinal tumor. This may be obtained via CT or ultrasound imaging. However, in some circumstances a mediastinoscopy or open biopsy may be required.

Thymomas are commonly staged using the Masaoka system or the World Health Organization (WHO) staging system as described in Table 74-14. WHO type A, AB, and B1 tend to be more well-differentiated, type B2 and B3 are moderately differentiated, and C are poorly differentiated.

TREATMENT

Surgical resection is the mainstay of treatment for patients with Masaoka type I and II thymic tumors. In patients with type III and IV who are potentially resectable thymic tumors, neoadjuvant chemotherapy may be given to decrease the tumor size and allow for a resection with negative margins. Surgery remains controversial and provides a limited role in the treatment of stage III and IV disease. No additional therapy may be required in patients with type I who have a resection with negative margins. Postoperative radiation therapy may be recommended based on extracapsular extension and the presence of positive margins in patients with type II or III thymic tumors or histological evaluation WHO B3 and C. Radiation therapy may be beneficial in patients with locally advanced disease (type III or IV) or in patients with symptoms secondary to compression of surrounding structures. Chemotherapy with cisplatin, doxorubicin, and cyclophosphamide (CAP) remains the mainstay of therapy in the neoadjuvant and adjuvant setting as well as first-line therapy in patients with metastatic thymoma, while carboplatin and paclitaxel are often employed in patients with thymic carcinoma. Limited additional agents are recommended based on small phase II trials as second-line therapy and beyond.

SUMMARY

The management of NSCLC has undergone major change in the past decade. To a lesser extent, the same is true for SCLC and thymic tumors. For patients with early-stage disease, advances in radiotherapy and surgical procedures as well as new systemic therapies have greatly improved prognosis in all diseases. For patients with advanced lung cancer, major progress in understanding tumor genetics and tumor immunology has led to the development of rational targets and specific inhibitors which have documented efficacy in specific subsets of NSCLC. Furthermore, increased understanding of how to activate the immune system to drive antitumor immunity has proven to be a successful therapeutic strategy for a subset of patients with advanced lung cancer. In Fig. 74-8, we propose an algorithm of the treatment approach for patient with stage IV NSCLC. However, the reality is that only a small subset of patients responds to immune checkpoint

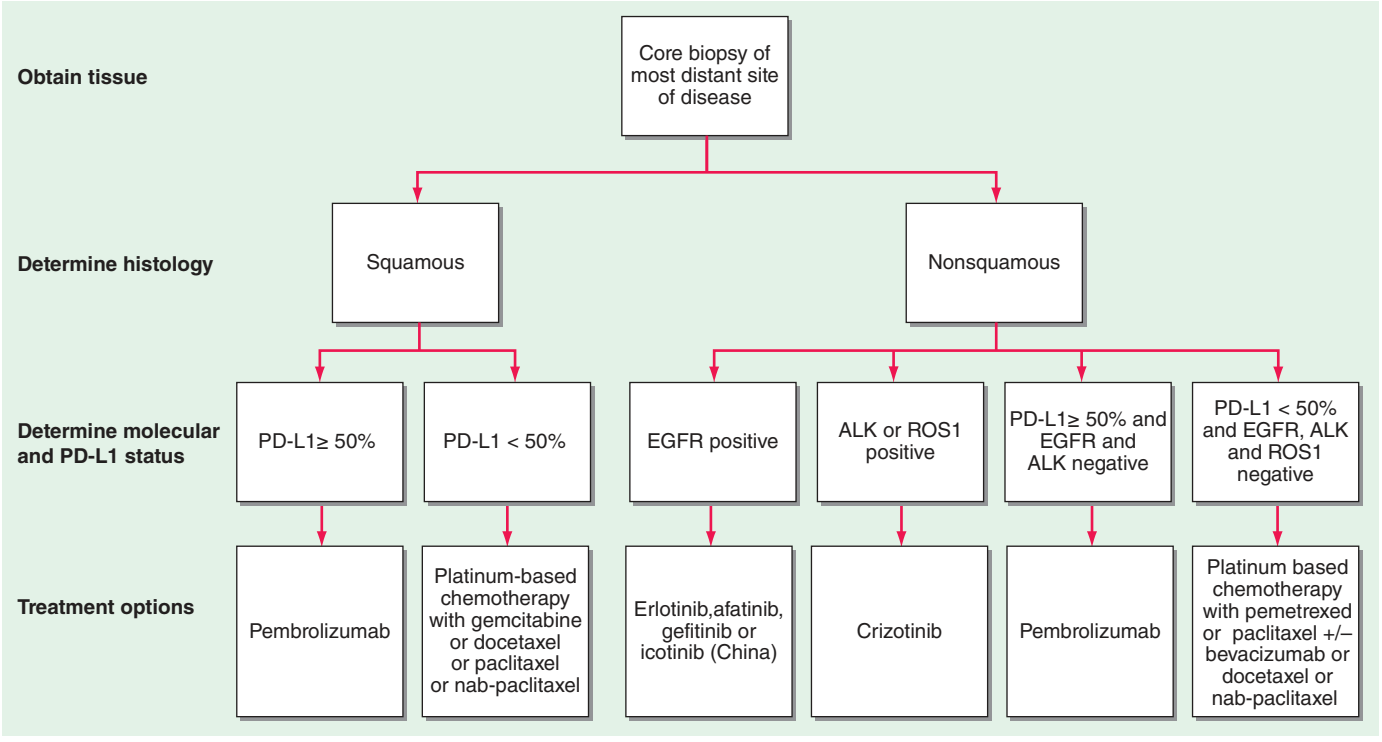

FIGURE 74-8 Approach to first-line therapy in a patient with stage IV non-small-cell lung cancer (NSCLC).

inhibitors and the majority of patients treated with targeted therapies or chemotherapy eventually develop resistance, which provides strong motivation for further research and enrollment of patients onto clinical trials in this rapidly evolving area.

75 Breast Cancer

Daniel F. Hayes, Marc E. Lippman

Breast cancer is a malignant proliferation of epithelial cells lining the ducts or lobules of the breast. In the year 2017, ~247,000 cases of invasive and 61,000 cases of in situ breast cancer and 41,000 deaths will occur in the United States. In addition, ~2000 men will be diagnosed with breast cancer. Epithelial malignancies of the breast are the most common cause of cancer in women (excluding skin cancer), accounting for about one-third of all cancer in women. As a result of improved treatment and earlier detection, the mortality rate from breast cancer has begun to decrease very substantially in the United States. This chapter does not consider rare malignancies presenting in the breast, such as sarcomas and lymphomas, but focuses on the epithelial cancers.

EPIDEMIOLOGY AND RISK FACTORS

Breast cancer is principally a disease of older women. Seventy-five percent of all breast cancers occur in women aged >50 years. The female-to-male ratio is ~150:1. It is also a hormone-dependent disease. Women without functioning ovaries, or who experience an early menopause, and who never receive combination estrogen/progesterone replacement therapy, are much less likely to develop breast cancer than those who have a normal menstrual history. A log-log plot of incidence versus age for breast cancer shows two components: a straight-line increase with age but with a decrease in slope beginning at the age of menopause. Length of menstrual life—particularly the fraction occurring before first full-term pregnancy—is a substantial component of the total risk of breast cancer. Breast cancer risk is increased in women with early menarche, late first full-term pregnancy, and late menopause. These three factors account for 70–80% of the variation in breast cancer frequency in different countries. Also, duration of maternal nursing correlates with substantial risk reduction independent of either parity or age at first full-term pregnancy.

International variation and immigration statistics of incidence provide insight into hormonal carcinogenesis. A woman living to age 80 years in North America has one chance in nine of developing invasive breast cancer. Asian women have traditionally had only 1/5th to 1/10th the risk of breast cancer of women in North America or Western Europe. However, with shifts from agrarian to industrialized economic systems, and in immigrant populations, Asian women living in modern, Western-style environments have risks identical to those of their Western counterparts.

Presumably, these differences are secondary to menstrual, and associated intrinsic estrogen exposure, histories. However, differences in diets have also been implicated, although the role of diet in breast cancer etiology is controversial. While there are associative links between total caloric and fat intake and breast cancer risk, the exact role of fat in the diet is unproven and may actually intersect with menstrual history and estrogenic exposure.

Central obesity is both a risk factor for occurrence and recurrence of breast cancer. Moderate alcohol intake also increases the risk by an unknown mechanism. Folic acid supplementation appears to modify risk in women who use alcohol but is not additionally protective in abstainers. Recommendations favoring abstinence from alcohol must be weighed against other social pressures and the possible cardioprotective effect of moderate alcohol intake. Chronic low-dose aspirin use is associated with a decreased incidence of breast cancer. Depression is also associated with both occurrence and recurrence of breast cancer.

Exogenous use of female hormones also plays a role in breast cancer incidence. Oral contraceptive use causes a small increased risk of breast cancer. However, this risk is more than balanced by avoidance of an undesired pregnancy and a substantial protective effect against ovarian epithelial and endometrial cancers.

Hormone replacement therapy (HRT) with conjugated equine estrogens plus progestins increases the risk of breast cancer and adverse cardiovascular events, but decreases the risk of bone fractures and colorectal cancer. On balance, there appear to be more negative events with HRT; 6–7 years of HRT nearly doubled the risk of breast cancer. Of note, administration of conjugated estrogens alone (estrogen replacement therapy in women who have had hysterectomies) produces no significant increase in breast cancer incidence. Thus, there are serious concerns about long-term HRT, especially in combination with progestins, in terms of cardiovascular disease and breast cancer. No comparable safety data are available for other less potent forms of estrogen replacement, such as bioequivalent estrogen found in soy, and they should not be routinely used as substitutes. Rapid decrease in the number of women on HRT has already led to a coincident decrease in breast cancer incidence. HRT in women previously diagnosed with breast cancer, especially of the subtype that expresses estrogen receptors, increases recurrence rates.

In addition to the other factors, radiation is a risk factor in younger women. Women who have been exposed before age 30 years to radiation in the form of multiple fluoroscopies (200–300 cGy) or treatment for Hodgkin's disease (>3600 cGy) have a substantial increase in risk of breast cancer, whereas radiation exposure after age 30 years appears to have a minimal carcinogenic effect on the breast.

GENETIC CONSIDERATIONS

The genetics of breast cancer require an understanding of the distinction between inherited, germline genetic differences among individuals and acquired, somatic genetic changes within cancers. The former, often called single nucleotide polymorphisms (SNPs), if deleterious, may lead to higher susceptibility to developing cancer and/or to a patient's response to or toxicity from a given treatment (pharmacogenetics). Somatic genetic changes that are not inherited, including mutations, amplifications, deletions, translocations, and others, are responsible for the malignant behavior of a cancer, including

unrestrained proliferation, as well as extravasation from one site and migration and establishment of metastases into another.

In this regard, human breast cancer is a clonal disease. One or more transformed cells, which arise due to a combination of inherited germline susceptibility and environmentally driven somatic changes, are eventually able to express full malignant potential. Thus, breast cancer may exist for a long period as either a noninvasive disease or an invasive but nonmetastatic disease. These facts have significant clinical ramifications, including overdiagnosis of biologically nonmalignant but anatomically apparent cancers.

Germline Genetic Susceptibility Although family history is an important risk factor, for most women the increased risk associated with a family member who has had breast cancer appears to be related to both a weak, and probably multi-gene germline susceptibility and/or similar exposure to environmental/life style risk factors. Not >10% of human breast cancers can be linked directly to single germline SNPs. However, when they are present, the relative and absolute risk for that individual's developing breast, and other, cancers in her lifetime are extraordinary.

Of these, the *BRCA1* and *2* genes are the best characterized and have the greatest clinical importance. *BRCA1* has been identified at the chromosomal locus 17q21; this gene encodes a zinc finger protein, and the protein product functions as a transcription factor and is involved in gene repair. Women who inherit a mutated allele of this gene from either parent have at least a 60–80% lifetime chance of developing breast cancer and about a 33% chance of developing ovarian cancer. The cancers that arise within a *BRCA1*-mutated patient are almost exclusively negative for estrogen and progesterone receptors (ER, PgR) and for human epidermal receptor 2 (HER2) (so-called "triple negative" breast cancers), and ~20% of women with triple negative breast cancers will be positive for deleterious germline BRCA1 SNPs. Nonetheless, the risk of breast cancer penetrance is variable within the *BRCA1*-affected population and is higher among women born after 1940, presumably due to promotional effects of hormonal factors. Men who carry a mutant allele of the gene have an increased incidence of prostate cancer and breast cancer.

BRCA2, which has been localized to chromosome 13q12, is also associated with an increased incidence of breast cancer in women. It should be noted that cancers that arise in *BRCA2* contexts are more likely to be ER positive, compared to those in *BRCA1* families, in which they are almost universally negative for ER, PgR, and HER2 expression. Of interest, men with *BRCA2* deleterious SNPs also have a higher risk of breast cancer, although most male breast cancer cases do not occur in *BRCA2*-mutated men, and the risk of breast cancer in men who do carry the *BRCA2* mutation is lower than that in women with this genetic abnormality.

Germline mutations in *BRCA1* and *BRCA2* can be readily detected in blood tests of normal circulating leucocytes. However, most experts do not recommend testing all women, since the rate of germline SNPS in this gene in the general population is quite low (well below 1%) and the tests are not 100% accurate. Further, it is not infrequent to identify variants of unknown significance (VUS) that may increase patient anxiety without a clear-cut set of recommendations about management. Consensus guidelines on who should be tested include any patient with a triple negative breast cancer and any patient with contralateral breast cancer or who has a first-degree relative (mother, father, or sister) with breast cancer. Further, any man with breast cancer should also be tested. Some guidelines suggest testing any patient with breast cancer who is of Ashkenazi descent, since the incidence in this population of a specific founder *BRCA1* mutation (substitution of adenine for guanine at position 185) is ~2%. Patients with these mutations should be counseled appropriately.

Over the last 5 years, panels of germline genes have been offered in addition to *BRCA1* and 2. These include genes that are known to be risk factors for breast cancer if the individual harbors deleterious SNPs, including *p53*, *PTEN*, and *PALB1*. However, several of the other genes included in these panels are less well-studied, and therefore it is less clear how to counsel affected individuals.

Somatic Genetic Changes in Breast Cancer Abnormalities in these and other genes can also be acquired, leading to breast cancer and its specific behavior. The specific causes of these mutations in breast cancer are generally unknown. A *p53* mutation is present in ~40% of human breast cancers as an acquired defect. Acquired mutations in *PTEN* occur in ~10% of the cases. *BRCA1* mutation in sporadic primary breast cancer has not been reported. However, decreased expression of *BRCA1* messenger RNA (mRNA) (possibly via gene methylation) and abnormal cellular location of the BRCA1 protein have been found in some breast cancers. Loss of heterozygosity of *BRCA1* and *BRCA2* suggests that tumor-suppressor activity may be inactivated in sporadic cases of human breast cancer.

Approximately 80% of all breast cancers overexpress ER. Many of these cancers respond to antiestrogen treatments. Likewise, increased expression of the dominant oncogene *erbB2*, often due to amplification, occurs in approximately one-quarter of human breast cancer cases. The product of this gene, HER2, contributes to transformation of human breast epithelium. HER2 is the target of effective systemic therapy in adjuvant and metastatic disease settings.

A series of other acquired "driver" mutations has been identified in sporadic breast cancer by major sequencing consortia. Of interest, activating mutations in the gene that encodes for ER (*ESR1*) have been reported in ~20% of metastatic breast cancers after prior endocrine treatment, but almost never in untreated primary cancers. Similarly, activating mutations in *erb2* are reported in 3–5% of breast cancers. Both these findings may have therapeutic implications. Multiple academic and commercial entities are offering exon sequencing for these and many other possible mutations on either tumor biopsies or on circulating DNA shed from tumors. Unfortunately, most occur in no more than 5% of cases. Further, they are either not associated with any known targeted therapeutic agents, or the abnormalities are associated with response to an agent in another disease, but at present not in breast cancer. Therefore, while appealing, "personalized medicine" is for now more of a dream than a reality.

PREVENTION OF BREAST CANCER

One major reason to determine risk would be to develop and apply effective prevention strategies. These might either be lifestyle changes or surgical or pharmacologic interventions. At present, although diet and exercise are certainly recommended approaches to healthy living, none has been proven to specifically decrease a woman's risk of breast cancer. Avoidance of combined estrogen/progestin HRT avoids their associated increased risk of breast cancer.

Prophylactic removal of the breasts is an effective, albeit usually unacceptable, preventive strategy. Retrospective and prospective registries have demonstrated that bilateral prophylactic mastectomies reduce the risk of breast cancer incidence and mortality by more than 95%. Because breasts are not encapsulated organs, some normal breast tissue is always left behind, and therefore women who elect to have prophylactic mastectomies should be counseled that they still have some risk of developing a new breast cancer. Because of its obvious adverse effect on sexuality, cosmesis, and breast-feeding, this approach is not considered appropriate for a woman of average risk.

As noted, cessation of menses and/or other means of reducing estrogen exposure, such as aromatase inhibition in postmenopausal women, and use of the selective estrogen receptor modulators (SERMs) tamoxifen and raloxifene are effective methods to lower breast cancer risk. So-called chemoprevention with SERMs or aromatase inhibition lowers risk of ER-positive breast cancer by approximately one-third to one-half, although it has no effect on the more lethal ER-negative breast cancers. Of interest, prophylactic bilateral oophorectomy and salpingo-oophorectomy, which is often performed in women with high genetic risk (such as those with inherited *BRCA1/2* deleterious SNPs), also reduces breast cancer risk.

SCREENING FOR BREAST CANCER

A recent review by the American Cancer Society (ACS) supports the perception that screening mammography reduces breast cancer mortality by one-quarter to one-third in women aged ≥50 years. The data for

a relative reduction in breast cancer mortality for women between ages 40 and 50 years are almost as positive; however, since the incidence of breast cancer is much lower in younger women, the number of women whose lives are saved is much lower than in older women, and because they have denser breasts, and therefore there are more false-positive findings and the positive predictive factor is lower.

Further, screening mammography and early detection are more likely to identify tumors at a stage more appropriate for conservative local therapy. Better technology, including digitized mammography, routine use of magnified views, and greater skill in mammographic interpretation, have all improved the accuracy of mammography. Newer diagnostic techniques (magnetic resonance spectroscopy [MRI], positron emission tomography [PET], etc.) appear to have higher sensitivity, but their specificity is often lower. Further, many authors have raised concern about diagnosis of anatomically defined cancers that may be biologically insignificant, raising the specter of overdiagnosis and treatment. Since none of these newer technologies has been shown to be superior to mammography in regards to mortality reduction, screening of women with standard risk by any technique other than mammography is not recommended.

Screening with more sensitive but less specific techniques, in particular MRI, is recommended for women with genetic risk, such as *BRCA1* or *BRCA2* carriers or those with Li-Fraumeni, Cowden's, or Bannayan-Riley-Ruvalcaba syndromes; untested first-degree relatives of women with cancer; women with a history of radiation therapy to the chest between ages 10 and 30 years; or women with a lifetime risk of breast cancer of at least 20%. In these women, the positive predictive value of MRI is higher because of the higher incidence of cancer, and, furthermore, many of them are considering prophylactic mastectomy as an alternative, and therefore the lower specificity and risk of a false positive finding has been considered more acceptable.

Research does not show a clear benefit of individual self-examination or by physical breast examinations done by a health professional. Because of this lack of evidence, regular clinical breast examination and breast self-examination are not recommended. Still, all women should be familiar with how their breasts normally look and feel and report any changes to a health care provider right away. Moreover, because the breasts are a common site of potentially fatal malignancy in women, examination of the breast is an essential part of the physical examination. Although breast cancer in men is unusual, unilateral lesions should be evaluated in the same manner as in women, with the recognition that gynecomastia in men can sometimes begin unilaterally and is often asymmetric.

EVALUATION OF BREAST MASSES IN MEN AND WOMEN

Virtually all breast cancer is diagnosed by biopsy of a nodule detected either on a mammogram or by palpation. Algorithms have been developed to enhance the likelihood of diagnosing breast cancer and reduce the frequency of unnecessary biopsy.

THE PALPABLE BREAST MASS

If a patient brings a breast abnormality to the attention of a health care giver, or if a lesion is appreciated during routine examination, proper attention needs to be given to ensure appropriate evaluation and treatment. Lesions with certain features are more likely to be cancerous. These include enigmatically, painless masses, and, more importantly, hard, irregular masses, especially if tethered or fixed to the underlying chest wall. In contrast, those that are cystic appearing on physical examination or are associated with pain, are less likely malignant. However, none of these is a terribly accurate positive or negative finding. Likewise, a negative mammogram in the presence of a persistent lump in the breast does not exclude malignancy. Any concerning, and persistent, breast finding should be referred to an experienced breast diagnostician.

In premenopausal women, lesions that are either equivocal or nonsuspicious on physical examination should be reexamined in 2–4 weeks, during the follicular phase of the menstrual cycle. Days 5–7 of the cycle are the best time for breast examination. A dominant mass in a postmenopausal woman or a dominant mass that persists through a menstrual cycle in a premenopausal woman should be referred to an experienced breast diagnostician for further evaluation, including biopsy if appropriate.

Several points are essential in pursuing these management decision trees. First, risk-factor analysis is not part of the decision structure. No constellation of risk factors, by their presence or absence, can be used to exclude biopsy. Second, fine-needle aspiration should be used only in centers that have proven skill in obtaining such specimens and analyzing them. The patient and physician must be aware of a 1% risk of false negatives. Third, additional technologies such as MRI, ultrasound, and sestamibi imaging cannot be used to exclude the need for biopsy; although in unusual circumstances, they may provoke a biopsy.

THE ABNORMAL MAMMOGRAM

Diagnostic mammography, which is performed after a palpable abnormality has been detected, should not be confused with *screening mammography*, which is performed in an asymptomatic woman with no prediscovered abnormalities. Diagnostic mammography is aimed at evaluating the rest of the breast before biopsy is performed or occasionally is part of the triple-test strategy to exclude immediate biopsy.

Subtle abnormalities that are first detected by screening mammography should be evaluated carefully by compression or magnified views. These abnormalities include clustered, heterogeneous, linear, and branching microcalcifications; densities (especially if spiculated); and new or enlarging architectural distortion. For some nonpalpable lesions, ultrasound may be helpful either to identify cysts or to guide biopsy. If there is no palpable lesion and detailed mammographic studies are unequivocally benign, the patient should have routine follow-up appropriate to the patient's age. If a nonpalpable mammographic lesion has a low index of suspicion, mammographic follow-up in 3–6 months is reasonable. However, it cannot be stressed too strongly that in the presence of a breast lump a negative mammogram does not rule out cancer, and if it persists or enlarges during follow-up, the patient should be referred to an experienced breast diagnostician.

BREAST MASSES IN THE PREGNANT OR LACTATING WOMAN

During pregnancy, the breast grows under the influence of estrogen, progesterone, prolactin, and human placental lactogen. Lactation is suppressed by progesterone, which blocks the effects of prolactin. After delivery, lactation is promoted by the fall in progesterone levels, which leaves the effects of prolactin unopposed. The development of a dominant mass during pregnancy or lactation should never be attributed to hormonal changes. A dominant mass must be treated with the same concern in a pregnant woman as any other. Breast cancer develops in 1 in every 3000–4000 pregnancies. Stage for stage, breast cancer in pregnant patients is no different from premenopausal breast cancer in nonpregnant patients. However, pregnant women often have more advanced disease because the significance of a breast mass was not fully considered and/or because of endogenous hormone stimulation. Persistent lumps in the breast of pregnant or lactating women *cannot* be attributed to benign changes based on physical findings; such patients should be promptly referred for diagnostic evaluation.

BENIGN BREAST MASSES

Only ~1 in every 5–10 breast biopsies leads to a diagnosis of cancer, although the rate of positive biopsies varies in different countries and clinical settings. These differences may be related to interpretation, medico-legal considerations, and availability of mammograms. The vast majority of benign breast masses are due to "fibrocystic" changes, a descriptive term for small fluid-filled cysts and modest epithelial cell and fibrous tissue hyperplasia. The subset of women with ductal or lobular cell proliferation (~30% of patients), particularly the small fraction (3%) with atypical hyperplasia, have a fourfold greater risk of developing breast cancer than those women who have not had a biopsy. The increase in the risk is about nine-fold for women in this category who also have an affected first-degree relative. Thus, careful follow-up of these patients is required. By contrast, patients with a

benign biopsy without atypical hyperplasia are at little risk and may be followed routinely.

STAGING

Correct staging of breast cancer patients is of extraordinary importance. Not only does it permit an accurate prognosis, but in many cases, therapeutic decision making is based largely on the TNM (primary tumor, regional nodes, metastasis) classification. Comparison with historic series should be undertaken with caution, as the staging has changed several times in the past 20 years. The current staging is complex and results in significant changes in outcome by stage as compared with prior staging systems.

NONINVASIVE BREAST CANCER

Breast cancer develops as a series of molecular changes in the epithelial cells that lead to ever more malignant behavior. Increased use of mammography has led to more frequent diagnoses of noninvasive breast cancer. These lesions fall into two groups: ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (lobular neoplasia or LCIS). The management of both entities is controversial.

Ductal Carcinoma In Situ Proliferation of cytologically malignant breast epithelial cells within the ducts is termed *ductal carcinoma in situ* (DCIS). Atypical hyperplasia may be difficult to differentiate from DCIS. At least one-third of patients with untreated DCIS develop invasive breast cancer within 5 years. However, many low-grade DCIS lesions do not appear to progress over many years; therefore, many patients are overtreated. Unfortunately, there is no reliable means of distinguishing patients who require treatment from those who may be safely observed.

For many years, the standard treatment for DCIS was mastectomy. Although no studies have compared breast-preserving therapy to mastectomy, the ~100% ten year survival rates with the former suggest that it is a satisfactory strategy. Breast-preserving surgery alone may also be acceptable. However, although survival was identical in the two arms of a randomized trial comparing wide excision plus or minus irradiation, the latter caused a substantial reduction in the local recurrence rate as compared with wide excision alone. Addition of tamoxifen or an aromatase inhibitor (AI) to any DCIS surgical/radiation therapy regimen further improves local control. However, in the largest trial comparing the two in DCIS, anastrozole did not improve distant disease-free or overall survival compared to tamoxifen.

Several prognostic features may help to identify patients at high risk for local recurrence after either lumpectomy alone or lumpectomy with radiation therapy, and therefore might provide an indication for mastectomy. These include extensive disease; age <40; and cytologic features such as necrosis, poor nuclear grade, and comedo subtype with overexpression of *erbB2*. In summary, it is reasonable to recommend breast-preserving surgery for patients who have a localized focus of DCIS with clear margins followed by breast irradiation and tamoxifen or anastrozole. For patients with localized DCIS, axillary lymph node dissection is unnecessary.

More controversial is the question of what management is optimal when there is any degree of invasion. Because of a significant likelihood (10–15%) of axillary lymph node involvement even when the primary lesion shows only microscopic invasion, it is prudent to do at least a sentinel lymph node sampling for all patients with any degree of invasion. Further management is dictated by the presence of nodal spread.

Lobular Neoplasia Proliferation of cytological malignant cells within the lobules is termed *lobular neoplasia* (LCIS). Nearly 30% of patients who have had adequate local excision, or incidentally discovered LCIS, or just a biopsy a needle biopsy of a suspicious area develop a subsequent breast cancer (usually infiltrating ductal carcinoma) over the next 15–20 years. Ipsilateral and contralateral cancers are equally common. Therefore, LCIS may be considered a premalignant condition with associated elevated risk of subsequent breast cancer, rather than a form of malignancy itself, and aggressive local management seems unreasonable. Management options include careful observation with routine mammography or chemoprevention with either a SERM or an AI (for postmenopausal women) for 5 years as well as concurrent and subsequent annual mammography and semiannual physical examinations. A third option, although no more effective and associated with substantial cosmetic, and perhaps emotional, morbidity is bilateral prophylactic mastectomy.

TREATMENT

Breast Cancer

BIOLOGICAL CONSIDERATIONS

One of the most important advances in our understanding of breast cancer has been the appreciation that it can be classified by gene expression patterns into a series of subtypes.

1. **Luminal:** Luminal breast cancers are almost always positive for ER and negative for HER2 amplification. They are divided into two groups:
   - **Luminal A:** Luminal A tumors have the highest levels of ER expression as well as of downstream ER-dependent genes, such as PgR. They are almost universally negative or low in HER2, and they have low proliferative thrust. They are usually low grade, are most likely to respond to endocrine therapy, and have a favorable prognosis. They appear to be less responsive to chemotherapy.
   - **Luminal B:** Luminal B breast cancers are also of luminal epithelial origin, but with a gene expression pattern distinct from luminal A. They tend to be PgR negative and have evidence of higher proliferative activity. They also tend to express HER2, but not to the level of the so-called "HER2 amplified" cancers. Their grade is more often higher than luminal A cancers. Prognosis is somewhat worse. They may be more sensitive to chemotherapy.
2. ***HER2* amplified:** These tumors have amplification of the *HER2* gene on chromosome 17q and frequently exhibit coamplification and overexpression of other genes adjacent to *HER2*. Historically the clinical prognosis of such tumors was poor. However, with the advent of trastuzumab and other targeted therapies, the clinical outcome of *HER2* positive patients is markedly improved compared to 20 or more years ago.
3. **Basal:** These ER/PgR–negative and *HER2*-negative tumors (so-called triple negative) are characterized by markers of basal/myoepithelial cells. They tend to be high grade, and express cytokeratins 5/6 and 17 as well as vimentin, p63, CD10, α-smooth muscle actin, and epidermal growth factor receptor (EGFR). Patients with *BRCA1* mutations also fall within this molecular subtype. They also have stem cell characteristics.
4. **Normal breast-like:** These tumors have a gene expression profile reminiscent of nonmalignant "normal" breast epithelium. Prognosis is similar to the luminal B group. This subtype is somewhat controversial and may represent contamination of the sample by normal mammary epithelium.
5. **Claudin-low:** These cancers are often triple negative but they have low expression of cell-cell junction proteins including E-cadherin. They are frequently associated with lymphocytic infiltration.

GENERAL TREATMENT CONSIDERATIONS

Treatment of breast cancer depends on whether the patient does or does not have evidence of distant (meaning outside the breast, chest wall, and regional lymph nodes) metastases, as detected by scintigraphic or radiologic imaging and biopsy. For patients with no evidence of detectable distant metastases, the goal of therapy is cure, or at least substantial survival prolongation, and is divided into primary and systemic considerations. Primary therapies consist of surgical and radiation treatments directed toward the breast and locoregional lymph nodes. These approaches are designed to excise and eliminate the cancer and sterilize unaffected breast tissue as appropriate. Adjuvant systemic

treatments, consisting of antiestrogen (or endocrine), anti-HER2, and/or chemotherapies, are given to treat micrometastases that may have already escaped to distant sites but are not yet detectable.

All treatments for breast cancer are based on prognostic and predictive factors. Prognostic factors provide an indication of how likely a cancer will recur, either locally or in distant organs, in the future if a patient is not treated with the respective treatments. Predictive factors are used to determine if a given treatment is likely to work or not, assuming the patient's prognosis justifies treatment (or further treatment assuming the patient has been treated in some manner already).

Prognostic features guide both whether and what type of primary and adjuvant systemic treatments should be pursued. Anatomic prognostic features include visual and physical examination findings of locally advanced breast cancer (T4 lesions: skin erythema ["inflammatory"] or edema ["peau d'orange"], nodules, or ulceration or tumor fixation to the chest wall). In patients without any of these findings, the most important prognostic features are tumor size and lymph node status (TN in the staging system). As discussed below, biologic features, such as histologic tumor grade as well as ER, PgR, and HER2, are also prognostic. Over the last decade, several multiparameter tests based on gene expression have been developed to determine prognosis in patients who have node-negative, ER-positive, and HER2-negative disease.

Predictive features are usually used to guide systemic therapies. These include ER for endocrine treatments and HER2 for anti-HER2 therapies, such as trastuzumab. There are no established predictive factors to predict response to radiation treatment. The issue of chemoresistance in luminal A cancers is under large-scale investigations.

EARLY-STAGE BREAST CANCER

Primary Therapies Prior to 1980, the Halsted radical mastectomy, in which the breast, chest wall muscles, and complete axillary nodal contents were removed, was the standard treatment of choice for women with newly diagnosed breast cancer. In the 1980s, prospective randomized trials demonstrated that recurrence and survival rates were the same with the less disfiguring modified radical mastectomy, in which the chest wall muscles were preserved and only a sampling of axillary lymph nodes were removed.

In the same decade, breast-conserving treatments, consisting of the removal of the primary tumor by some form of surgical excision (designated as lumpectomy, quadrantectomy, or partial mastectomy), were shown to result in equal, if not slightly superior, to that associated with mastectomy. Several of these trials also demonstrated that the in-breast recurrence rate was quite high in the absence of breast radiation, while it was reduced substantially if radiation was provided. Therefore, for women undergoing breast conservation, postlumpectomy radiation is usually indicated, although it may be less necessary and withheld in older women with ER-positive, node-negative breast cancer, since their risk of subsequent in-breast recurrence is quite low with surgery and endocrine therapy only. When lumpectomy with negative tumor margins is achieved and radiation is delivered appropriately, breast conservation is associated with a recurrence rate in the breast of ≤5%.

Not all patients are candidates for breast-conserving therapy. Contraindications include large tumor to breast ratio, inability to achieve clear margins with adequate cosmesis after extensive surgery, multifocal cancers, extensive four-quadrant DCIS, and inability to receive radiation. The latter issue arises in women with dermal autoimmune disease (such as lupus erythematosus), prior radiation to the site, and/or lack of available radiation treatment facilities. Further, although not contraindicated, breast-conserving therapy may be less cosmetically acceptable than mastectomy with reconstruction if the nipple-areolar complex is involved with cancer and must be sacrificed. This is a personal choice, and some women prefer mastectomy, especially those with high genetic risks for second breast cancers.

For patients who do undergo mastectomy, postoperative chest wall and regional nodal radiation is also associated with an improvement in survival if they have a high risk of local-regional recurrence, such as tumors ≥5 cm, four or more positive axillary lymph nodes, or postoperative positive margins. Postmastectomy radiation is not indicated in women with cancers <2 cm, negative lymph nodes, and negative margins. It is considered for women who fall into the areas between these (2–5 cm, one to three positive nodes, or close margins), and is usually recommended if a patient has one to three involved axillary lymph nodes.

At present, nearly one-third of women in the United States are managed by lumpectomy, and recent data suggest that the fraction of women treated with breast-conserving therapy is decreasing. It appears that many women still undergo mastectomy who could safely avoid this procedure and probably would if appropriately counseled.

Axillary node sampling or dissection is unnecessary in many cases. Sentinel lymph node mapping and biopsy (SLNB) is generally the standard of care for women with localized breast cancer and clinically negative axilla. If SLNB is negative, more extensive axillary surgery is not required, avoiding much of the risk of lymphedema following more extensive axillary dissections. Even in the presence of sentinel lymph node involvement, further axillary surgery may not be required for selected patients, such as older women and those with ER-positive cancers.

The survival of patients who have recurrence in the breast after proper treatment (adequate surgery and radiation if indicated) is somewhat worse than that of women who do not, but it is not worse than those who suffer local-regional recurrence after mastectomy. Thus, local-regional recurrence is a negative prognostic variable for long-term survival but not the *cause* of distant metastasis. Most patients should consult with a radiation oncologist before making a final decision concerning local therapy. However, a multimodality clinic in which the surgeon, radiation oncologist, medical oncologist, and other caregivers cooperate to evaluate the patient and develop a treatment plan is usually considered a major advantage by patients.

Adjuvant Systemic Therapies The concept of adjuvant systemic therapy is based on the observation that cancer is a condition of genetic instability, and with increasing generations of cellular replication, genetic abnormalities accumulate. Although these occur randomly, and therefore may lead to sensitivity or resistance to therapies, the latter is of greater concern. Thus, as a consequence of accumulation of mutations to resistance, almost all patients with metastatic breast cancer are destined to die with, if not of their cancer.

However, treatment with the same therapies administered earlier, in the setting of micrometastatic disease only, has been repeatedly shown to be more effective than waiting until symptomatic, documented metastases occur. Put simply, the use of systemic therapy as an adjuvant to local management of breast cancer substantially improves survival. More than half of the women who would otherwise die of metastatic breast cancer remain disease-free and experience considerable survival advantaged when treated with the appropriate adjuvant systemic regimen. These data have grown more and more impressive with longer follow-up and more effective regimens.

PROGNOSTIC VARIABLES As noted, prognostic factors help define who most likely needs, or perhaps more importantly does not need, adjuvant systemic therapy. The most important prognostic variables are provided by *tumor staging: tumor size (T), lymph node status (N) and detectable distant metastases (M)* **(Table 75-1)**. *Histologic classification* of the tumor has also been used as a prognostic factor. Tumors with a

poor nuclear grade have a higher risk of recurrence than tumors with a good nuclear grade. Semiquantitative measures such as the Elston score improve the reproducibility of this measurement. Importantly, there is no need to perform imaging for distant metastases in a patient with no signs or symptoms of widespread disease and who has a T3 or less tumor and fewer than four involved axillary lymph nodes.

Adjuvant systemic therapy may not be needed at all for patients with very small (<1 cm) tumors and negative lymph nodes. However, there is no patient with invasive breast cancer who does not have some risk of subsequent distant metastases, and therefore who might not benefit at all. This consideration raises two issues: (1) the differences in odds of benefit and odds of toxicities of the various types of therapies and (2) the judgment between the patient and her caregiver regarding the calculated absolute benefit-risk ratio for specific types of adjuvant systemic treatments.

There are three types of adjuvant systemic therapies: (1) chemotherapy; (2) endocrine; and (3) anti-HER2 therapies. The decision whether to apply each of these depends on prognostic and predictive features as well as the combined judgment of the patient and caregiver. For example, a patient might be much more likely to accept endocrine therapy for a very small potential benefit than she would accept chemotherapy for the same calculated advantage, since the former is much less often associated with either life-taking, life-threatening, or permanently life-changing toxicities than the latter. Thus, one has to consider prognostic and predictive factors for each type of therapy, separately.

The greatest controversy concerns the recommendation for adjuvant *chemotherapy*, since there is no good predictive factor for this class of treatments, and the decision must be made on prognosis alone. Large overview analyses suggest that chemotherapy reduces the risk of recurrence over the 10 years subsequent to primary diagnosis by approximately one-third. For patients with positive lymph nodes and/or features that render the cancer T4, the risk of distant recurrence (and thus not being cured) over that decade is 50% or higher. Therefore, a one-third reduction of at least 50% means that 15–20%, or more, women will be cured who would not have been in the absence of adjuvant chemotherapy. The life-taking, life-threatening, or permanently life-changing toxicities of adjuvant chemotherapy are ~1–2%, and therefore almost all medical oncologists would recommend adjuvant chemotherapy in this setting.

In contrast, there is rarely justification for adjuvant chemotherapy in most women with tumors <1 cm in size whose axillary lymph nodes are negative. However, this decision is very much weighed by the expression of ER and HER2. For example, the risk of recurrence of such a patient whose tumor is negative for ER, PgR, and HER2 (so-called triple-negative breast cancer) over the succeeding 10 years without any adjuvant is ~15%. If chemotherapy reduces this risk by approximately one-third or more, which is what large overview analyses suggest, then 5%, or perhaps even higher, of patients will be cured who would otherwise be destined to die of their disease. Likewise, a patient with ER and PgR-negative, but HER2-positive, disease has a slightly worse prognosis (risk of recurrence over 10 years is ~20%), and will benefit not only from the adjuvant chemotherapy but from anti-HER2 therapy as well, so that her potential absolute benefit is even higher. Many, but not all, clinicians would recommend adjuvant chemotherapy for such patients.

On the other hand, patients with ER-positive disease have a better prognosis than those with ER-negative breast cancer, and adjuvant endocrine therapy will further reduce the odds of recurrence by approximately one-half. Therefore, the same patient in the example above (<1 cm, node negative) but who has an ER-positive and HER2-negative cancer has a lower initial risk of recurrence (~10% over 10 years). Given the relatively low life-taking, life-threatening, or permanently life-changing toxicities, she is very likely to accept adjuvant endocrine therapy, further lowering her estimated risk of recurrence to ~5%. If chemotherapy reduces this risk by approximately one-third, no more than 1–2% of patients will benefit. This potential benefit is approximately the same as the number of patients who will suffer life-taking, life-threatening, or permanently life-changing toxicities. Thus, in this case, most clinicians would recommend adjuvant endocrine, but not chemotherapy.

These examples represent extremes. In the screening era, up to 30% of newly diagnosed patients have T2-3, node-negative, ER-positive cancers. These patients have an intermediate risk between the two extremes, and the calculated absolute benefit of adjuvant chemotherapy is ~3–5%. It is unclear if this small but real benefit is sufficient to justify adjuvant chemotherapy. Detection of breast cancer cells either in the circulation or bone marrow is associated with an increased relapse rate. However, the finding of bone marrow micrometastases only portends a slightly worse prognosis, especially in node negative patients, and bone marrow biopsies are not recommended in patients with early stage disease.

The most exciting development in this area is the use of gene expression arrays to analyze patterns of tumor gene expression, especially for node-negative, ER-positive cancers. Several groups have independently defined gene sets that reliably predict disease-free and overall survival far more accurately than any single prognostic variable. The Oncotype DX® Recurrence Score (RS) analysis of 21 genes was the first such assay to be adopted. A number of retrospective and more recently prospective studies have documented its utility in identifying patients with node-negative, ER-positive breast cancer whose prognosis, assuming adequate adjuvant endocrine therapy, is so good that they can forego adjuvant chemotherapy. Basically, the 30–50% of patients with ER positive, node negative, but low RS, appear to have luminal A breast cancers, and they do not need chemotherapy, whereas those with high RS appear to have luminal B cancers and the benefits of adjuvant chemotherapy clearly outweigh the risks. For those with intermediate RS, the answer is still unclear and has been the focus of now completed, but as yet unreported, prospective trials.

More recently, other assays, including the Prosigna,® EndoPredict,® and Breast Cancer Index® have also been shown to have clinical utility in this setting. Only one of these tests should be ordered for a single patient, since they do not always give the same results and there are no data to determine which, in the case of discordance, might be "correct." Also, the use of such standardized risk assessment tools such as Adjuvant! Online (*www.adjuvantonline.com*) is very helpful. These tools are highly recommended in otherwise ambiguous circumstances.

Several *measures of tumor growth rate* correlate with early relapse, but their use is problematic due to analytical variability. Of these, assessment using immunochemical assays for the proliferation marker, Ki67, is the most widespread. However, there is substantial lab-to-lab variability and disagreement regarding optimal cut points. At present, in standard practice outside of a highly skilled laboratory, use of Ki67 is not recommended to make clinical decisions.

Molecular changes in the tumor are also useful. Tumors that overexpress *erbB2* (HER2/neu) have a worse prognosis, but expression of this gene for prognosis is most important in patients with ER-positive, node-negative disease. Indeed, patients with HER2-positive breast cancer are so likely to have a high RS that it is not recommended that the Oncotype DX,® or for that matter any of the other multiparameter assays, be ordered. HER2 should be performed on every breast cancer biopsy, however, because of its predictive role for anti-HER2 therapies.

Predictive Factors to Choose Adjuvant Systemic Therapy

The decision to recommend AST is also based on predictive factors; those that provide a prediction of the likelihood that a given class, or even specific drug within a class, will have activity or not. The two important predictive factors, which should be ordered in all breast cancer biopsies (primary or metastatic), are ER and HER2.

There is no detectable benefit in patients with ER-poor, or -negative, cancers, whereas adjuvant endocrine therapy reduces the risk of recurrence by one-half or more in patients with ER-rich cancers. ER is most commonly measured by counting the percent of positive cells within the cancer after immunohistochemical (IHC) staining. Endocrine therapy is recommended for any patient with ≥10% positive cells, whereas it is not for those whose cancers only have 0–1% staining. The evidence supporting benefit in 1–9% cases is weak, but given the potential benefit and relatively low toxicities of endocrine therapy, it is recommended for patients in this circumstance, with a low threshold for discontinuation if side effects are intolerable.

HER2 is the target for anti-HER2 therapies. Adjuvant trastuzumab therapy reduces the risk of distant recurrence by one-third or more, with associated substantial risk of dying of breast cancer. Most, if not all, of the large adjuvant trastuzumab trials have been performed in patients with HER2-"positive" breast cancer. HER2 status is determined using either IHC staining for protein overexpression, or fluorescent in situ hybridization (FISH) for gene amplification. IHC staining of 3+ (on a scale of 0–3+) is considered positive, whereas 0–1+ is considered negative. For cases with 2+ staining, reflex FISH analysis is recommended. FISH can either be used as the initial evaluation, or for additional evaluation in IHC 2+ cases. FISH results are considered positive if the ratio of HER2 to centromere signal on chromosome 17 is ≥2.0. There is no reason to do FISH if IHC is 3+ or 0–1+, nor is there reason to order IHC testing if FISH is ≥2.0. If note, preclinical studies and retrospective analyses of a few selected cases from the prospective randomized trials have suggested that perhaps trastuzumab might be effective in cases with IHC 1–2+ results. A large prospective randomized clinical trial addressing this issue is completed but not yet reported.

There are no reliable predictive factors for chemotherapy, in general or for specific types of chemotherapies. It has been hypothesized that chemotherapy may be more active in ER-negative and/or HER2-positive cancers. More recently, this issue has evolved to imply that luminal B cancers may be more chemosensitive, whereas luminal A cancers are perceived to be relatively chemoresistant. At present, none of the tests for intrinsic subtype should be used to determine whether to give chemotherapy or not, based on *prediction* of resistance in patients with poor *prognosis*, such as those with T4 or node-positive disease. Attempts to identify reliable predictive factors for individual classes of chemotherapeutic agents (such as anthracyclines, alkylating agents, or taxanes) have been unsuccessful. The platin salts (carbo-, cis -platin) may have higher activity in patients with triple-negative breast cancer and perhaps in patients with HER2-positive disease.

Adjuvant Regimens If chemotherapy is indicated, it should include multiple agents, either in combination or as sequential single agents. If indicated, anti-HER2 therapy should include at least 1 year of trastuzumab, and preliminary data have supported addition of pertuzumab for at least three months. Endocrine therapy should be administered to patients with ER-positive breast cancer following completion of chemotherapy and administered for at least 5 years, and probably longer.

Endocrine Therapy There are two proven endocrine therapy strategies: the SERM, tamoxifen, or estrogen ablation. In addition to being effective in preventing new cancers and reducing the risk of local-regional recurrences in patients with DCIS, tamoxifen reduces the risk of distant recurrence and death due to invasive breast cancer by ~40% over the decade following diagnosis. It is equally effective in pre- and postmenopausal women, although it may be slightly less effective in very young (<40 years) patients. Because tamoxifen is a SERM, it has mixed ER antagonism (in the breast and brain) and agonism (in the bone, liver, and uterus). Therefore, it is active against breast cancer in the prevention, adjuvant, and metastatic settings, but frequently causes hot flashes. The agonistic effect results in reduction of osteopenia/osteoporosis, especially in postmenopausal women, but it increases thrombosis and endometrial cancers due to this effect in the liver and uterus, respectively.

Estrogen depletion can be achieved surgically in premenopausal women by oophorectomy or ovarian suppression with a gonadotropin-releasing hormone super-agonist (GnRH agonist), such as goserelin, that results in tachyphylaxis of the pituitary. However, women with nonfunctioning ovaries, whether induced or by natural menopause, still produce small amounts of estrogen. Estrogen production in these women occurs by adrenal synthesis of estrogen precursors (testosterone, dehydroepiandrosterone [DHEA]) that are converted to estradiol and estrone by aromatase activity in peripheral fat and possible cancer cells. In postmenopausal women, circulating estrogen can be reduced to nearly imperceptible levels with the use of oral AIs. There are three such agents available (anastrozole, letrozole, and exemestane). Although there is no perceptible difference in activity or toxicity among the three AIs, they are all slightly more effective than tamoxifen.

It is recommended that all postmenopausal women with ER-positive breast cancer be treated for at least 3–5 years with an AI, unless there is a contraindication. The most common concern is the presence of severe osteoporosis, since this is the most frequent life-taking or life-threatening toxicity of the AIs. Likewise, ~15–20% of patients cannot tolerate the AIs due to musculoskeletal symptoms mimicking osteoarthritis and arthralgias. For both these groups of women, tamoxifen is a reasonable therapy, again assuming no contraindications exist. The most important of these is a past history of thrombosis, or high risk of cerebrovascular disease.

For premenopausal women, the decision of optimal endocrine therapy depends on prognosis and patient choice. Complete estrogen depletion is slightly more effective than tamoxifen alone, but it may also be associated with more bothersome side effects, such as hot flashes, vaginal dryness, and sexual dysfunction. Recent studies have suggested that complete estrogen depletion, consisting of either oophorectomy or chemical suppression of gonadotropins coupled with an AI, is indicated for women with worse prognosis, in particular node positivity. For those with more favorable prognosis, tamoxifen alone may be preferable. The AIs should not be administered to women with functioning, or dormant, ovaries, since the negative hypothalamic-pituitary feedback can result in a rebound hyperestrogenic production effect.

The duration of adjuvant endocrine treatment is unclear. Until recently, the standard recommendation was at least 5 years of therapy. Several studies have now demonstrated that although 5 years of adjuvant endocrine treatment clearly reduces the risk of recurrence during that time and for a few years after discontinuation, the annual risk of distant recurrence during the subsequent 15 years is 0.5–3%, depending on the initial T and N status. Further, so-called extended adjuvant endocrine therapy with either tamoxifen or an AI, for at least years 6–10, continues to reduce this late risk of relapse. The decision of whether to continue adjuvant endocrine therapy or not after 5 years must therefore take into consideration initial risk (T, N, grade), current side effects and potential cumulative toxicities, and the patient's perception of the relative and absolute benefits and risks.

Chemotherapy If adjuvant chemotherapy is indicated, as discussed above, one must consider the optimal regimen. Several studies, and a combined overview analysis, have demonstrated that multiple-agent chemotherapy is more effective than single agent. However, at least two studies have shown that sequential single-agent chemotherapy is as effective, and may be slightly less toxic, than simultaneous combination chemotherapy although it requires longer total duration to deliver. Administration of four to six cycles of chemotherapy appears to be optimal; one cycle is less effective than six, but more than six have generally increased toxicity without further efficacy.

Several chemotherapeutic agents have activity in the adjuvant setting. These include alkylating agents, (principally cyclophosphamide), anthracyclines (doxorubicin, epirubicin), antimetabolites (5-fluorouracil [5FU], capecitabine, methotrexate), and the taxanes (paclitaxel, docetaxel). Within classes, randomized trials have failed to demonstrate superiority of one agent versus another (e.g., doxorubicin vs epirubicin, or paclitaxel vs docetaxel). Dose escalation above an optimal dose is not more effective. The advantage of more frequent scheduling for most individual agents is unclear, but weekly or every other week paclitaxel is superior to every 3-week infusion, while, enigmatically, the opposite is true for its cousin, docetaxel. However, one benefit of a "dose dense" regimen (e.g., every 2 weeks with cytokine support vs every 3 weeks) is earlier completion of therapy.

These agents are usually combined within a single regimen. The oldest of these is cyclophosphamide, methotrexate, and 5FU (CMF) Addition of an anthracycline, or substitution of an anthracycline for the antimetabolite, improves outcomes slightly, albeit with slightly increased risk of heart failure and secondary leukemia. Addition of a taxane to an anthracycline-based regimen further reduces the chances of distant recurrence and death, albeit only modestly. Recent studies have suggested that addition of an anthracycline to a taxane-based

regimen is also modestly more effective than a taxane plus cyclophosphamide alone.

Which regimen is appropriate for a patient must be individualized based on prognosis, comorbid conditions, and the perspective of the patient. For example, the modest relative improvement of giving an anthracycline, cyclophosphamide, and a taxane (AC-T) may not transfer to a sufficiently large absolute improvement in survival in a patient with a relative small (T2) tumor and negative nodes, whereas that same relative reduction in death may translate to a sufficiently large absolute benefit in a patient with a worse prognosis. Therefore, the former patient might best be served with a taxane/cyclophosphamide (TC) regimen alone, while the latter might wish to accept the added risk of congestive heart failure and leukemia associated with the anthracyclines.

Neoadjuvant treatment involves the administration of adjuvant systemic therapy, most commonly chemotherapy, before definitive surgery and radiation therapy. The objective partial and complete response rates of patients with breast cancer to neoadjuvant chemotherapy exceed 75%. Thus, many patients will be "downstaged" by neoadjuvant chemotherapy. In this circumstance, patients with locally advanced, inoperable cancers may become candidates for surgery, and a small fraction of patients who are not considered eligible for breast-conserving surgery may become so due to shrinkage of their cancer. However, overall survival has not been improved using this approach as compared with the same drugs given postoperatively.

Patients who achieve a pathologic complete remission after neoadjuvant chemotherapy have a substantially improved survival compared to those who do not. It is unknown if this observation implies that the latter group did not benefit, or just had a worse initial prognosis, yet still gained some benefit. Although it is appealing to consider treating patients who have not had a pathologic complete response with even more chemotherapy, no studies have demonstrated that doing so improves overall survival. It is possible that these patients have chemoresistant disease, and therefore more chemotherapy will not be of value. However, it is essential that all patients, regardless of response to neoadjuvant chemotherapy, receive adjuvant endocrine therapy if they have an ER-positive breast cancer and adjuvant anti-HER2 therapy if their cancer is HER2 positive.

The neoadjuvant setting also provides an appealing opportunity for the evaluation of new agents. For example, a second HER2-targeting antibody, pertuzumab, has been shown to provide increased rates of pathologic complete response when combined with trastuzumab in the neoadjuvant setting. However, this approach is controversial; it is not clear that demonstration of higher response rates in the neoadjuvant setting will translate into better overall survival. For example, neoadjuvant trials demonstrated that combination trastuzumab and lapatinib resulted in higher pathologic complete responses than trastuzumab alone, yet a classically performed adjuvant trial failed to demonstrate improved survival for this regimen.

Chemotherapy is associated with nausea, vomiting, and alopecia in ~100% of patients, although the former two are well controlled with modern antiemetics. More importantly, chemotherapy causes neutropenia and fever, with a risk of infection of ~1%. The neutropenia can be prevented in most patients with appropriate use of the growth factor filgrastim. Secondary myelodysplasia and leukemia occur in ~0.5–1% of patients treated with anthracyclines as well as with high cumulative doses of cyclophosphamide, usually occurring within 2–5 years of treatment. The anthracyclines cause cumulative dose-related congestive heart failure, which occurs in ~1% of patients treated with standard four to five cycles at 60 mg/m^2. Peripheral neuropathy is the major dose-limiting and life-changing toxicity of the taxanes. Neuropathy occurs during treatment in ~15–20% of patients, and permanent, chronic neuropathy persists in 3–5%.

Anti-HER2 Therapy The emergence of therapies directed toward HER2 has been one of the great success stories of all oncology. Several trials have demonstrated that the humanized monoclonal antibody, trastuzumab, decreases both risk of recurrence and mortality in early-stage breast cancer. While trastuzumab administered after chemotherapy is effective, the accumulated evidence suggests that it is optimally delivered concurrently with chemotherapy, particularly in association with a taxane. However, concurrent treatment with an anthracycline is generally avoided, since the main toxicity of trastuzumab is cardiac dysfunction, which appears more often when the agent is delivered simultaneously with doxorubicin. Therefore, if an anthracycline is to be used, it is most commonly given prior to administration of trastuzumab—for example as AC for four cycles followed by a taxane plus trastuzumab. In patients with reasonably favorable prognosis (T1 or 2, node negative), single-agent paclitaxel plus trastuzumab appears to be an adequate regimen.

Twelve months of trastuzumab therapy is optimal. Randomized trials have demonstrated no additional benefit beyond 12 months, whereas 6 months has been shown to be inferior to 12. Trastuzumab is administered intravenously weekly or every 3 weeks.

Other, anti-HER2 treatments that are effective in the metastatic setting are appealing candidates for adjuvant therapies. As noted, neoadjuvant studies have demonstrated that chemotherapy with the combination of trastuzumab and pertuzumab results in higher pathologic complete responses than trastuzumab alone. The U.S. Food and Drug Administration (FDA) has granted this combination with accelerated approval, but final approval for the combination is pending more clinically meaningful results (disease-free, overall survival) from now-completed, classic adjuvant trials. Although lapatinib did not add to trastuzumab therapy and single-agent adjuvant lapatinib is inferior to single agent trastuzumab, another anti-HER2 tyrosine kinase inhibitor, neratinib, is superior to no anti-HER2 therapy. Neratinib has not been compared to trastuzumab, either as a single agent or in combination. Ado-trastuzumab emtansine, an antibody-drug conjugate, has activity in the metastatic setting even in patients who have progressed on trastuzumab and is now being tested in the adjuvant setting.

Skeletal Strengthening Agents Bone-strengthening agents that are commonly used to treat osteoporosis appear to have some, but limited, activity in preventing recurrent breast cancer, particularly in postmenopausal women. In an overview analysis of all trials addressing bisphosphonate therapy, improvement in overall survival was not significantly associated with any specific bisphosphonate class, treatment schedule, ER status, nodal status, tumor grade, or concomitant chemotherapy. No differences were seen in nonbreast cancer mortality. Bone fractures were reduced (relative risk [RR] 0.85, 95% confidence interval [CI] 0.75–0.97; 2 p = 0.02). At present, there is no clear consensus regarding routine use of bisphosphonates as an adjuvant therapy, although patients with advancing osteopenia or confirmed osteoporosis should be treated accordingly.

Novel Adjuvant Systemic Agents Other exciting adjuvant strategies are being tested, such as poly–ADP ribose polymerase (PARP) inhibitors in patients with known germline *BRCA1* or *BRCA2* mutations or those with triple-negative cancers that share similar defects in DNA repair in their etiology. The remarkable results of immune checkpoint inhibitors in other cancers have led to studies of this approach in both metastatic and post-neoadjuvant chemotherapy settings but are still considered highly investigational.

Recommendations for adjuvant therapy are found in **Table 75-2**.

STAGE III BREAST CANCER

Between 10 and 25% of patients present with so-called locally advanced, or stage III, breast cancer at diagnosis. Many of these cancers are technically operable, whereas others, particularly cancers with chest wall involvement, inflammatory breast cancers, or cancers with large matted axillary lymph nodes, cannot be managed with surgery initially. As noted, neoadjuvant compared may be no more effective than postsurgical adjuvant chemotherapy in prolonging survival, but the advantages of downstaging and therefore facilitating local therapy are accepted. Radiotherapy either to the chest wall after mastectomy or to the breast after tumor excision is almost always recommended, as is regional lymph node treatment. Adjuvant anti-HER2 and endocrine therapies are also used, as appropriate. These patients should be managed in multimodality clinics to coordinate surgery, radiation

TABLE 75-2 Suggested Approaches to Adjuvant Systemic Therapy[a]

NODAL STATUS	TUMOR SIZE	ER	HER2	MULTI-PARAMETER ASSAY	MENSTRUAL STATUS	CHEMOTHERAPY	ENDOCRINE THERAPY	ANTI-HER2 THERAPY
Positive	Any	Neg	Neg	Not indicated	Any	Multidrug	None	None
		Pos			Prem		Ovarian ablation + AI	
					Post		AI	
		Any	Pos		Any			Trastuzumab X12 mos; pertuzumab X12 weeks
Negative	<1 cm	Neg	Neg	Not indicated	Any	Consider multidrug	None	None
	≥1 cm	Neg	Neg		Any	Multidrug	None	None
	1–5 cm	Pos	Neg	Low RS	Prem	None	Tam	None
					Post		AI	None
				Intermed	Any	Consider multidrug	Tam (pre) or AI (post)	None
				Hi	Any	Multidrug	As for node pos	None
		Any	Pos	Not indicated	Any	Single-agent paclitaxel	As for node pos	Trastuzumab X12 mos

[a]Meant for guidance only. Each patient should be considered independently based on tumor and comorbidity status.

therapy, and systemic chemo-, endocrine, and anti-HER2 therapies, as indicated. Such approaches produce long-term disease-free survival in ~30–50% of patients.

BREAST CANCER SURVIVORSHIP ISSUES

The odds of surviving breast cancer have increased dramatically over the last 35 years due to a combination of early detection and more effective therapies. Although detection bias improves case fatality rates, age-adjusted mortality rates (mortality/100,000 women in society/year) have declined by >30%. Therefore, while ~40,000 American women will die of metastatic breast cancer in 2016, >60,000 would have suffered breast cancer mortality without these advances. Thus, all clinicians, not just oncologists, need to be aware of survivorship issues in patients with previously diagnosed and treated breast cancer.

No special follow-up procedures, such as serial circulating tumor biomarkers or systemic radiographic/scintigraphic imaging, are indicated in an asymptomatic patient with no physical findings of recurrence. Although randomized trials have demonstrated slightly higher incidence of detection of metastases with lead times of 3–12 months by screening asymptomatic patients compared to no special follow-up, there is no evidence of improved overall survival. If anything, one of these studies suggested a worse quality of life due to higher anxiety levels associated with the testing, and toxicities associated with earlier treatment in patients who were otherwise doing well at that time. These recommendations are summarized in Table 75-3.

It is important to carefully assess and evaluate new symptoms, considering whether they might be due to the cancer, the treatment, or an unassociated condition. Judgment needs to be used to decide if blood tests or imaging are required, in order to avoid missing a lesion for which appropriate treatment would improve the patient's quality of life but to diminish overtesting, with associated inconvenience, anxieties, false positives, and cost. Serial echocardiography should be performed every 3 months for patients on adjuvant trastuzumab, but not after it is discontinued.

Likewise, there is no role for serial monitoring for long-term, life-threatening toxicities associated with chemotherapy, such as myelodysplastic syndromes or congestive heart failure, since these are quite uncommon and likely to cause obvious symptoms requiring proper evaluation if they occur.

For patients on endocrine therapy, quality-of-life issues may be critical, including hot flashes, sexual difficulties, musculoskeletal complaints, and risk of osteoporosis. Although estrogen therapy, given orally, transdermally, or transvaginally, effectively reduces these side effects, it should not be given to these patients, since it may counteract the efficacy of the endocrine therapy. Nonhormonal treatments, such as selected antidepressants for hot flashes and musculo-skeletal symptoms, and counseling and water-based lubricants for sexual issues can be quite helpful. It is important to screen bone density in patients on an AI more frequently than is recommended for the average postmenopausal woman, since total estrogen depletion results in enhanced risk of osteoporosis and fracture. All women should be counseled to take daily calcium and vitamin D replacement, and if osteoporosis is present or osteopenia is worsening, bone strengthening agents should be administered.

THERAPY OF METASTATIC DISEASE

About 15–20% of patients treated for localized breast cancer develop metastatic disease in the subsequent decade after diagnosis.

TABLE 75-3 Surveillance Guidelines for Breast Cancer Patients after Primary and Adjuvant Therapy during Routine Follow-up

TEST	FREQUENCY
Recommended	
History; eliciting symptoms; physical examination	q3–6 months × 3 years; q6–12 months × 2 years; then annually
Breast self-examination	Monthly
Mammography	Annually
Pelvic examination	Annually as per age-appropriate guidelines (particularly for patients on SERMs)
Patient education about symptoms of recurrence	Ongoing
Coordination of care	Ongoing
Assessment of side effects if on endocrine therapy	Ongoing
Echocardiography if on trastuzumab	Every 3 months; discontinue when trastuzumab therapy complete
Not Recommended (if asymptomatic)	
Complete blood count	
Serum chemistry studies	
Chest radiographs	
Bone scans	
Ultrasound examination of the liver	
Computed tomography of chest, abdomen, or pelvis	
Tumor markers CA 15-3, CA 27-29, CEA, CTC	
Transvaginal endometrial ultrasonography	

Abbreviations: CA, cancer antigen; CEA, carcinoembryonic antigen; CTC, circulating tumor cell; SERM, selective estrogen receptor modulator.

Source: Recommended Breast Cancer Surveillance Guidelines, ASCO Education Book, Fall, 1997. From J Clin Oncol 15:2149, 1997; with permission.

Soft tissue, bony, and visceral (lung and liver) metastases all account for approximately one-third of sites of initial relapses. However, by the time of death, most patients will have bony involvement. Recurrences can appear at any time after primary therapy, but at least half occur >5 years after initial therapy. This observation is particularly true in patients with ER-positive disease, for whom the risk of distant recurrence remains constant for as long as 20 years and is the basis for recommendation of extended adjuvant endocrine therapy. It is now clear that a variety of host factors can influence recurrence rates, including depression and central obesity, and these diseases should be managed as aggressively as possible.

For patients with no prior history of metastases, a biopsy of suspicious physical or radiographic lesions should be performed, both for confirmation that the lesion does, indeed, represent recurrent cancer and to reevaluate ER and HER2, which can differ between the primary and metastatic lesions in up to 15% of cases. One should not assume that an apparent abnormality is a breast cancer metastasis. Many benign conditions, such as tuberculosis, gallstones, sarcoidosis, or other nonmalignant diseases, can mimic a recurrent breast cancer and are of course treated much differently.

Although treatable, metastatic disease is rarely if ever cured. The median survival for all patients diagnosed with metastatic breast cancer is <3 years, but with remarkable variability depending on intrinsic subtype and effective treatments. Patients with triple-negative metastatic breast cancer have the shortest expected survival, while those with ER-positive disease can expect to live the longest. HER2 positivity was initially found to be a very poor prognostic factor in metastatic breast cancer, but the availability of several effective treatments has improved the expected survival rates to at least those of ER-positive patients, if not better.

In the absence of cure, the overall goal of treatment of metastatic disease is palliation, or, put simply, to "keep the patient feeling as well as she can for as long as she can." A secondary goal is improved survival. It is important to point out that survival has not been improved by advocating more aggressive, or toxic, therapies, such as high-dose or combination chemotherapy, but rather by more selective and biologically based therapy, such as use of endocrine or anti-HER2 therapies in patients with ER- or HER2-positive breast cancers, respectively. Generally, a new treatment is continued until either progression or unacceptable toxicities are evident. These are both evaluated by serial history and physical examinations and periodic serologic evaluation for hematologic or hepatic abnormalities, as well as circulating tumor biomarker tests (assays for MUC1, such as CA15-3 or CA27.29, and for carcinoembryonic antigen or occasionally CA125). If all these evaluations fail to suggest progression, it is unlikely that imaging will contribute. However, if one or more of these suggest progression, whole-body imaging with either a PET/CT or a scintigraphic bone scan and dedicated CT are indicated. Brain imaging is not recommended unless the patient has some sort of central nervous system (CNS) symptom or finding.

The choice of therapy requires consideration of local therapy needs, specifically surgical approaches to particularly worrisome long-bone lytic lesions or isolated CNS metastases. New back pain in patients with breast cancer should be explored aggressively on an emergent basis; to wait for neurologic symptoms is a potentially catastrophic error. Metastatic involvement of endocrine organs can occasionally cause profound dysfunction, including adrenal insufficiency and hypopituitarism. Similarly, obstruction of the biliary tree or other impaired organ function may be better managed with a local therapy than with a systemic approach. Radiation as an adjunct to or instead of surgery is an important consideration for particularly symptomatic disease in long or vertebral bones, local-regional recurrences, and CNS metastases. In many cases, systemic therapy can be withheld while the patient is managed with appropriate local therapy.

There is no evidence that aggressive local treatment, such as excision; radiation; radiofrequency ablation; or cryotherapy of metastases to the lung, liver, or other distant sites, improves survival. Although appealing, these strategies are associated with increased toxicity and cost and should be reserved for palliation.

Selection of the systemic therapy strategy depends on the overall medical condition of the patient, the hormone receptor and HER2 status of the tumor, and clinical judgment. Because therapy of systemic disease is palliative, the potential toxicities of therapies should be balanced against expected response rates. Several variables influence the response to systemic therapy. For example, the presence of ER and PgR is a strong indication for endocrine therapy, even for patients with limited visceral (lung/liver) disease. On the other hand, patients with short disease-free intervals or rapidly progressive visceral disease (liver and lung) with end-organ dysfunction, such as lymphangitic pulmonary disease, are unlikely to respond to endocrine therapy.

Many patients with bone-only or bone-dominant disease have a relatively indolent course. Because the goal of therapy is to maintain well-being for as long as possible, emphasis should be placed on avoiding the most hazardous complications of metastatic disease, including pathologic fracture of the axial skeleton and spinal cord compression. Under such circumstances, systemic chemotherapy has a modest effect, whereas radiation therapy may be effective for long periods. Other systemic treatments, such as strontium-89, may provide a palliative benefit without inducing objective responses. Patients with bone involvement should receive concurrent bone strengthening agents, such as bisphosphonates or the humanized monoclonal anti-RANK ligand antibody, denosumab.

Many patients are inappropriately treated with toxic regimens into their last days of life. Often, oncologists are unwilling to have the difficult conversations that are required with patients nearing the end of life, and not uncommonly, patients and families can pressure physicians into treatments with very little survival value. Palliative care consultation and realistic assessment of treatment expectations need to be reviewed with patients and families. We urge consideration of palliative care consultations for patients who have received at least two lines of therapy for metastatic disease.

Endocrine Therapy ER-positive breast cancer will respond to endocrine therapy ~30–70% of the time. Potential endocrine therapies are summarized in Table 75-4. As in the adjuvant setting, one can choose among the SERM, tamoxifen, the AIs (anastrozole, letrozole, exemestane), or other strategies. Among the latter, the selective estrogen receptor downregulator (SERD), fulvestrant, has substantial activity. Early clinical studies with this drug were unexciting, but more recent studies have proven a very steep dose-response curve, and at higher levels (500 mg/month), it is as or more active than either tamoxifen or the AIs. Additive endocrine therapies, including treatment with progestins, and androgens, and enigmatically, pharmacologic doses of estrogens, are all active, but they may be associated with unacceptable side effects in many women. The mechanism of action of these latter therapies is unknown. Cases in which tumors shrink in response to tamoxifen withdrawal (as well as withdrawal of pharmacologic doses of estrogens) have been reported, but with the advent of so many other therapies for metastatic disease, this strategy is rarely used in modern oncology.

TABLE 75-4 Endocrine Therapies for Breast Cancer

THERAPY	COMMENTS
Castration Surgical LHRH agonists	For premenopausal women
Antiestrogens	
Tamoxifen	Useful in pre- and postmenopausal women[a]
Fulvestrant	Responses in tamoxifen-resistant and aromatase inhibitor–resistant patients[a]
Aromatase inhibitors	Low toxicity; now first choice for metastatic disease[a]
High-dose progestogens	Common fourth-line choice after aromatase inhibitors, tamoxifen, and fulvestrant
Additive androgens or estrogens	Plausible fourth-line therapies; potentially toxic

[a]Consider retreatment with everolimus in combination for disease progression.

Abbreviation: LHRH, luteinizing hormone–releasing hormone.

TABLE 75-5 Common Agents Added to Endocrine Therapies for Metastatic Breast Cancer

CLASS	HOW ADMINISTERED	AGENTS	COMMON TOXICITIES
Anti-mTOR	Oral	Everolimus	Mucositis, diarrhea, rash
CDK4/6 inhibitors	Oral	Palbociclib, ribociclib, abemaciclib (not FDA approved)	Neutropenia; uncommon leukopenia, fatigue, and nausea

Abbreviations: CDK4/6, cyclin D kinase 4/6; FDA, Food and Drug Administration; mTOR, mammalian target of rapamycin.

TABLE 75-6 Common Anti-HER2 Agents for Breast Cancer

CLASS	HOW ADMINISTERED	AGENTS	COMMON TOXICITIES
Humanized monoclonal antibodies	IV	Trastuzumab, pertuzumab	Cardiac dysfunction GI (diarrhea)
Tyrosine Kinase Inhibitors	Oral	Lapatinib neratinib (not FDA approved)	Diarrhea, mucositis, rash
Antibody-drug conjugate	IV	Ado-trastuzumab emtansine	Peripheral neuropathy, thrombocytopenia

The sequence of endocrine therapy is variable. Patients who respond to one endocrine therapy have at least a 50% chance of responding to a second endocrine therapy. It is not uncommon for patients to respond to two or three sequential endocrine therapies. In most postmenopausal patients, the initial endocrine therapy should be an AI rather than tamoxifen. As noted, AIs are not used in premenopausal women because their hypothalamus can respond to estrogen deprivation by producing gonadotropins that promote estrogen synthesis. Tamoxifen and fulvestrant are usually used in sequence after AI therapy. Combination endocrine therapies increase the chances of response initially, but they do not appear to increase the ultimate time to chemotherapy use or overall survival. Combinations of chemotherapy with endocrine therapy are not useful, as summarized in Table 75-4.

At least two different targeted agents have been shown to enhance outcomes of patients with ER-positive metastatic breast cancer when combined with endocrine therapy. Addition of an inhibitor of the mammalian target of rapamycin (mTOR), everolimus, to the hormonal treatment can lead to AIs, tamoxifen, or fulvestrant improves time to progression, and this agent is now being explored as front-line therapy and in the adjuvant setting. Likewise, inhibitors of cyclin D kinase 4/6 (CDK4/6) (palbociclib, ribociclib, abemaciclib) have also been shown to substantially improve progression-free survival when combined either with an AI or fulvestrant. These agents are also being tested in the adjuvant setting. Data regarding overall survival benefits from the mTOR or CDK4/6 inhibitors are still pending, but addition of one or the other in combination with ET for women with ER-positive metastatic breast cancer is becoming the standard of care. These should not be given simultaneously but rather in sequence as appropriate, as summarized in Table 75-5.

Chemotherapy Unlike many other epithelial malignancies, breast cancer responds to multiple chemotherapeutic agents, including anthracyclines, alkylating agents, taxanes, and antimetabolites. Multiple combinations of these agents have been found to improve response rates somewhat, but they have had little effect on duration of response or survival. Unless patients have rapidly progressive visceral (lung, liver) metastases with end-organ dysfunction, single-agent chemotherapy, used in sequence as one drug fails going on the next, is preferable. Given the significant toxicity of most drugs, the use of a single effective agent will minimize toxicity by sparing the patient exposure to drugs that would be of little value. No method to select the drugs most efficacious for a given patient has been demonstrated to be useful.

Most oncologists use either capecitabine or an anthracycline or a taxane for first-line chemotherapy, either in a patient with ER-positive disease that is refractory to endocrine therapy or for a patient with ER-negative breast cancer. Within these general classes, it is not clear that one particular agent (such as doxorubicin vs epirubicin or paclitaxel vs docetaxel) is preferable, and the choice has to be balanced with individual needs. Objective responses in previously treated patients may also be seen with gemcitabine, vinorelbine, and oral etoposide, as well as a new class of agents, epothilones. Platinum-based agents have become far more widely used in both the adjuvant and advanced disease settings for some breast cancers, particularly those of the "triple-negative" subtype.

Anti-HER2 therapy Treatment of patients with anti-HER2 metastatic breast cancer is one of the great success stories in the last 30 years of oncology. Initial use of a trastuzumab, either alone or with chemotherapy, was shown to improve response rate and survival for women with HER2-positive disease. Indeed, anecdotal reports of a few patients with remarkably sustained complete responses suggest that, on occasion, a few may be cured. Chronologically, the tyrosine kinase, lapatinib, was subsequently shown to be effective when added to chemotherapy after patients progressed on prior trastuzumab. Further, both continuation of trastuzumab after progression, in combination with the next chemotherapeutic regimen and combination of trastuzumab and lapatinib in patients who had progressed on trastuzumab are both superior to discontinuing the trastuzumab.

For patients who have become refractory to trastuzumab–based therapy, and more recently even in the upfront setting, other therapies have remarkably high activity. A novel antibody drug conjugate (ADC) that links trastuzumab to a cytotoxic agent, ado-trastuzumab emtansine, is active even in patients who have progressed on trastuzumab. More recently, the combination of chemotherapy and trastuzumab and pertuzumab has been shown to result in prolonged overall survival compared to trastuzumab alone. These recommendations are summarized in Table 75-6.

Other Therapies Bevacizumab is an agent that targets the vascular endothelial growth factor (VEGF). Bevacizumab with paclitaxel or other chemotherapeutic agents modestly increases the response rate and response duration to paclitaxel, but without improvement in overall survival and with occasional major toxicities. After initial excitement and FDA approval, its use has been mostly abandoned in breast cancer. As in the metastatic setting, trials are ongoing testing the value of PARP (poly-ADP ribose polymerase) inhibitors in patients with known germline *BRCA1/2* mutations or cancers that have BRCA-like biologies. The excitement over immune check-point inhibitors has spread to metastatic breast cancer, especially of the triple-negative subtype, but at present there are no agents approved for it.

MALE BREAST CANCER

Breast cancer is ~1/150th as frequent in men as in women; ~2000 men developed breast cancer annually in the United States. Risk factors include inherited, deleterious SNPs in *BRCA2*, as well as Klinefelter's syndrome. Men with Klinefelter's syndrome have two or more copies of the X chromosome and have lower levels of and higher levels of estrogen. Other conditions of hyperestrogenism, such as in hepatic failure, are also associated with higher risk of male breast cancers. However, the vast majority of men who present with breast cancer have none of these conditions.

Breast cancer usually presents in men as a unilateral lump in the breast and is frequently not diagnosed promptly. Given the small amount of soft tissue and the unexpected nature of the problem, locally advanced presentations are somewhat more common. Although gynecomastia may initially be unilateral or asymmetric, any unilateral mass in a man aged >40 years should receive a careful workup including biopsy. On the other hand, bilateral symmetric breast development rarely represents breast cancer and is almost invariably due to endocrine disease or a drug effect. It should be kept in mind, nevertheless, that the risk of cancer is much greater in men with gynecomastia; in such men, gross asymmetry of the breasts should arouse suspicion of cancer.

Approximately 90% of male breast cancers contain ERs, and it behaves similarly to that in a postmenopausal woman. When matched to female breast cancer by age and stage, its overall prognosis is identical. Male breast cancer is best managed by mastectomy and axillary lymph node dissection or SLNB, although some men prefer breast-conserving therapy. Patients with locally advanced disease or positive nodes should also be treated with irradiation, and ~60% of cases with metastatic disease respond to endocrine therapy. Tamoxifen is usually the agent of choice, and it is unknown if the AIs are effective in men. No randomized studies have evaluated adjuvant therapy for male breast cancer. Two historic experiences suggest that the disease responds well to adjuvant systemic therapy, and, if not medically contraindicated, the same criteria for the use of adjuvant therapy in women should be applied to men.

The sites of relapse and spectrum of response to chemotherapeutic drugs are virtually identical for breast cancers in either sex.

76 Upper Gastrointestinal Tract Cancers

Robert J. Mayer

Upper gastrointestinal cancers include malignancies arising in the esophagus, stomach, and small intestine.

ESOPHAGEAL CANCER

INCIDENCE AND ETIOLOGY

Cancer of the esophagus is an increasingly common and extremely lethal malignancy. The diagnosis was made in 16,940 Americans in 2017 and led to 15,690 deaths. Almost all esophageal cancers are either squamous cell carcinomas or adenocarcinomas; the two histologic subtypes have a similar clinical presentation but different causative factors.

Worldwide, squamous cell carcinoma is the more common cell type, having an incidence that rises strikingly in association with geographic location. It occurs frequently within a region extending from the southern shore of the Caspian Sea on the west to northern China on the east, encompassing parts of Iran, central Asia, Afghanistan, Siberia, and Mongolia. Familial increased risk has been observed in regions with high incidence, although gene associations are not yet defined. High-incidence "pockets" of the disease are also present in such disparate locations as Finland, Iceland, Curaçao, southeastern Africa, and northwestern France. In North America and western Europe, the disease is more common in blacks than whites and in males than females; it appears most often after age 50 and seems to be associated with a lower socioeconomic status. Such cancers generally arise in the cervical and thoracic portions of the esophagus.

A variety of causative factors have been implicated in the development of squamous cell cancers of the esophagus **(Table 76-1)**. In the United States, the etiology of such cancers is primarily related to excess alcohol consumption and/or cigarette smoking. The relative risk increases with the amount of tobacco smoked or alcohol consumed, with these factors acting synergistically. The consumption of whiskey is linked to a higher incidence than the consumption of wine or beer. Squamous cell esophageal carcinoma has also been associated with the ingestion of nitrates, smoked opiates, and fungal toxins in pickled vegetables, as well as mucosal damage caused by such physical insults as long-term exposure to extremely hot tea, the ingestion of lye, radiation-induced strictures, and chronic achalasia. The presence of an esophageal web in association with glossitis and iron deficiency (i.e., Plummer-Vinson or Paterson-Kelly syndrome) and congenital hyperkeratosis and pitting of the palms and soles (i.e., tylosis palmaris et plantaris) have each been linked with squamous cell esophageal cancer, as have dietary deficiencies of molybdenum, zinc, selenium, and vitamin A. Patients with head and neck cancer are at increased risk of squamous cell cancer of the esophagus.

For unclear reasons, the incidence of squamous cell esophageal cancer has decreased somewhat in both the black and white populations in the United States over the past 40 years, whereas the rate of adenocarcinoma has risen sevenfold, particularly in white males (male-to-female ratio of 6:1). Whereas squamous cell cancers comprised the vast majority of esophageal cancers in the United States as recently as 40–50 years ago, >75% of esophageal tumors are now adenocarcinomas, with the incidence of this histologic subtype continuing to increase rapidly. Understanding the cause for this increase is the focus of current investigation.

Several strong etiologic associations have been observed to account for the development of adenocarcinoma of the esophagus **(Table 76-2)**.

TABLE 76-1 Some Etiologic Factors Associated with Squamous Cell Cancer of the Esophagus

Excess alcohol consumption
Cigarette smoking
Other ingested carcinogens
Nitrates (converted to nitrites)
Smoked opiates
Fungal toxins in pickled vegetables
Mucosal damage from physical agents
Hot tea
Lye ingestion
Radiation-induced strictures
Chronic achalasia
Host susceptibility
Esophageal web with glossitis and iron deficiency (i.e., Plummer-Vinson or Paterson-Kelly syndrome)
Congenital hyperkeratosis and pitting of the palms and soles (i.e., tylosis palmaris et plantaris)
? Dietary deficiencies of selenium, molybdenum, zinc, and vitamin A

TABLE 76-2 Some Etiologic Factors Associated with Adenocarcinoma of the Esophagus
Chronic gastroesophageal reflux
Obesity
Barrett's esophagus
Male sex
Cigarette smoking

Such tumors arise in the distal esophagus in association with chronic gastric reflux, often in the presence of Barrett's esophagus (replacement of the normal squamous epithelium of the distal esophagus by columnar mucosa), which occurs more commonly in obese individuals. Adenocarcinomas arise within dysplastic columnar epithelium in the distal esophagus. Even before frank neoplasia is detectable, aneuploidy and *p53* mutations are found in the dysplastic epithelium. The value of proton-pump inhibitors in reducing the risk of cancer in individuals with chronic gastric reflux or Barrett's esophagus is uncertain. These adenocarcinomas behave clinically like gastric adenocarcinomas, although they are not associated with *Helicobacter pylori* infections. Approximately 15% of esophageal adenocarcinomas overexpress the *HER2/neu* gene.

CLINICAL FEATURES

About 5% of esophageal cancers occur in the upper third of the esophagus (cervical esophagus), 20% in the middle third, and 75% in the lower third. Squamous cell carcinomas and adenocarcinomas cannot be distinguished radiographically or endoscopically.

Progressive dysphagia and weight loss of short duration are the initial symptoms in the vast majority of patients. Dysphagia initially occurs with solid foods and gradually progresses to include semisolids and liquids. By the time these symptoms develop, the disease is already very advanced, because difficulty in swallowing does not occur until >60% of the esophageal circumference is infiltrated with cancer. Dysphagia may be associated with pain on swallowing (odynophagia), pain radiating to the chest and/or back, regurgitation or vomiting, and aspiration pneumonia. The disease most commonly spreads to adjacent and supraclavicular lymph nodes, liver, lungs, pleura, and bone. Tracheoesophageal fistulas may develop, primarily in patients with upper and mid-esophageal tumors. As with other squamous cell carcinomas, hypercalcemia may occur in the absence of osseous metastases, probably from parathormone-related peptide secreted by tumor cells **(Chap. 89)**.

DIAGNOSIS

Attempts at endoscopic and cytologic screening for carcinoma in patients with Barrett's esophagus, while effective as a means of detecting high-grade dysplasia, have not yet been shown to reduce the likelihood of death from esophageal adenocarcinoma. Esophagoscopy should be performed in all patients suspected of having an esophageal abnormality, to both visualize and identify a tumor and also to obtain histopathologic confirmation of the diagnosis. Because the population of persons at risk for squamous cell carcinoma of the esophagus (i.e., smokers and drinkers) also has a high rate of cancers of the lung and the head and neck region, endoscopic inspection of the larynx, trachea, and bronchi should also be carried out. A thorough examination of the fundus of the stomach (by retroflexing the endoscope) is imperative as well. The extent of tumor spread to the mediastinum and para-aortic lymph nodes should be assessed by computed tomography (CT) scans of the chest and abdomen and by endoscopic ultrasound. Positron emission tomography scanning provides a useful assessment of the presence of distant metastatic disease, offering accurate information regarding spread to mediastinal lymph nodes, which can be helpful in defining radiation therapy fields. Such scans, when performed sequentially, appear to provide a means of making an early assessment of responsiveness to preoperative chemotherapy and have increasingly been used in guiding a change in clinical management.

TREATMENT

Esophageal Cancer

The prognosis for patients with esophageal carcinoma is poor. Approximately 10% of patients survive 5 years after the diagnosis; thus, management focuses on symptom control. Surgical resection of all gross tumor (i.e., total resection) is feasible in only 45% of cases, with residual tumor cells frequently present at the resection margins. Such esophagectomies have been associated with a postoperative mortality rate of ~5% due to anastomotic fistulas, subphrenic abscesses, and cardiopulmonary complications. Although debate regarding the comparative benefits of transthoracic versus transhiatal resections has continued, experienced thoracic surgeons are now favoring minimally invasive transthoracic esophagectomies. Endoscopic resections of superficial squamous cell cancers or adenocarcinomas are being examined but have not yet been shown to result in a similar likelihood of survival as observed with conventional surgical procedures. Similarly, the value of endoscopic ablation of dysplastic lesions in an area of Barrett's esophagus on reducing subsequent mortality from esophageal carcinoma is uncertain. Some experts have advocated fundoplication surgery (i.e., the removal of the gastroesophageal junction) as a means of cancer prevention in patients with Barrett's esophagus; again, objective data are not yet available to fully assess the risks versus benefits of this invasive procedure. About 20% of patients who survive a total surgical resection live for 5 years. The evaluation of chemotherapeutic agents in patients with esophageal carcinoma has been hampered by ambiguity in the definition of "response" and the debilitated physical condition of many treated individuals, particularly those with squamous cell cancers. Nonetheless, significant reductions in the size of measurable tumor masses have been reported in 15–25% of patients given single-agent treatment and in 30–60% of patients treated with drug combinations that include a platinum form of chemotherapy. In the small subset of patients whose tumors overexpress the *HER2/neu* gene, the addition of the monoclonal antibody trastuzumab (Herceptin) appears to further enhance the likelihood of benefit, particularly in patients with gastroesophageal lesions. The use of the antiangiogenic agent bevacizumab (Avastin) seems to be of limited value in the setting of esophageal cancer. Combination chemotherapy and radiation therapy as the initial therapeutic approach, either alone or followed by an attempt at operative resection, seems to be beneficial. When administered along with radiation therapy, chemotherapy produces a better survival outcome than radiation therapy alone. The use of preoperative chemotherapy and radiation therapy followed by esophageal resection appears to prolong survival compared with surgery alone according to several randomized trials and a meta-analysis; some reports suggest that no additional benefit accrues when surgery is added if significant shrinkage of tumor has been achieved by the chemoradiation combination.

For the incurable, surgically unresectable patient with esophageal cancer, dysphagia, malnutrition, and the management of tracheoesophageal fistulas are major issues. Approaches to palliation include repeated endoscopic dilatation, the surgical placement of a gastrostomy or jejunostomy for hydration and feeding, endoscopic placement of an expansive metal stent to bypass the tumor, and radiation therapy.

TUMORS OF THE STOMACH

GASTRIC ADENOCARCINOMA

Incidence and Epidemiology For unclear reasons, the incidence and mortality rates for gastric cancer have decreased in the United States during the past 80 years, although the disease remains the third most frequent cause of worldwide cancer-related death. The mortality rate from gastric cancer in the United States has dropped in men from 28 to 7.4 per 100,000 persons, whereas in women, the rate has decreased from 27 to 2.4 per 100,000. Nonetheless,

in 2017, 28,000 new cases of stomach cancer were diagnosed in the United States, and 10,960 Americans died of the disease. Although the incidence of gastric cancer has decreased worldwide, it remains high in such disparate geographic regions as Japan, China, Chile, and Ireland.

The risk of gastric cancer is greater among lower socioeconomic classes. Migrants from high- to low-incidence nations maintain their susceptibility to gastric cancer, whereas the risk for their offspring approximates that of the new homeland. These findings suggest that an environmental exposure, probably beginning early in life, is related to the development of gastric cancer, with dietary carcinogens considered the most likely factor(s).

Pathology About 85% of stomach cancers are adenocarcinomas, with 15% due to lymphomas, gastrointestinal stromal tumors (GISTs), and leiomyosarcomas. Gastric adenocarcinomas may be subdivided into two pathologically defined categories: a *diffuse type*, in which cell cohesion is absent, so that individual cells infiltrate and thicken the stomach wall without forming a discrete mass; and an *intestinal type*, characterized by cohesive neoplastic cells that form glandlike tubular structures. The diffuse carcinomas occur more often in younger patients, develop throughout the stomach (including the cardia), result in a loss of distensibility of the gastric wall (so-called *linitis plastica*, or "leather bottle" appearance), and carry a poorer prognosis. Diffuse cancers have defective intercellular adhesion, mainly as a consequence of loss of expression of E-cadherin. Intestinal-type lesions are frequently ulcerative, more commonly appear in the antrum and lesser curvature of the stomach, and are often preceded by a prolonged precancerous process, often initiated by *H. pylori* infection. Although the incidence of diffuse carcinomas is similar in most populations, the intestinal type tends to predominate in the high-risk geographic regions and is less likely to be found in areas where the frequency of gastric cancer is declining. Thus, different etiologic factor(s) are likely involved in these two subtypes. In the United States, ~30% of gastric cancers originate in the distal stomach, ~20% arise in the midportion of the stomach, and ~40% originate in the proximal third of the stomach. The remaining 10% involve the entire stomach.

Genomic profiling of gastric adenocarcinomas has led to subdividing the disease into four molecularly defined subgroups: chromosomally unstable tumors (50% of cases correlating with intestinal type histology), genomically stable tumors (20% of cases correlating with diffuse type histology), microsatellite unstable tumors (22% of cases), and Epstein-Barr virus (EBV) positive tumors (9% of cases) **(Fig. 76-1)**. Efforts to incorporate these molecular subtypes into clinical management are underway.

Etiology The long-term ingestion of high concentrations of nitrates found in dried, smoked, and salted foods appears to be associated with a higher risk. The nitrates are thought to be converted to carcinogenic nitrites by bacteria **(Table 76-3)**. Such bacteria may be introduced exogenously through the ingestion of partially decayed foods, which are consumed in abundance worldwide by the lower socioeconomic classes. Bacteria such as *H. pylori* may also contribute to this effect by causing chronic inflammatory atrophic gastritis, loss of gastric acidity, and bacterial growth in the stomach. Although the risk for developing gastric cancer is thought to be sixfold higher in people infected with *H. pylori*, it remains uncertain whether eradicating the bacteria after infection has already occurred actually reduces this risk. Loss of acidity may occur when acid-producing cells of the gastric antrum have been removed surgically to control benign peptic ulcer disease or when achlorhydria, atrophic gastritis, and even pernicious anemia develop in the elderly. Serial endoscopic examinations of the stomach in patients with atrophic gastritis have documented replacement of the usual gastric mucosa by intestinal-type cells. This process of intestinal metaplasia may lead to cellular atypia and eventual neoplasia. Because the declining incidence of gastric cancer in the United States primarily reflects a decline in distal, ulcerating, intestinal-type lesions, it is conceivable that better food preservation and the availability of refrigeration for all socioeconomic classes have decreased the dietary ingestion of exogenous bacteria. *H. pylori* has not been associated with the diffuse, more proximal form of gastric carcinoma or with cancers arising at the gastroesophageal junction or in the distal esophagus. Approximately 10–15% of adenocarcinomas appearing in the proximal stomach, the gastroesophageal junction, and the distal esophagus overexpress the *HER2/neu* gene; individuals whose tumors demonstrate this overexpression benefit from treatment directed against this target (i.e., trastuzumab [Herceptin]).

Several additional etiologic factors have been associated with gastric carcinoma. Gastric ulcers and adenomatous polyps have occasionally been linked, but data on a cause-and-effect relationship are unconvincing. The inadequate clinical distinction between benign gastric ulcers and small ulcerating carcinomas may, in part, account for this presumed association. The presence of extreme hypertrophy of gastric rugal folds (i.e., Ménétrier's disease), giving the impression of polypoid

TABLE 76-3 Nitrate-Converting Bacteria as a Factor in the Causation of Gastric Carcinomaa

Exogenous sources of nitrate-converting bacteria:
Bacterially contaminated food (common in lower socioeconomic classes, who have a higher incidence of the disease; diminished by improved food preservation and refrigeration)
Helicobacter pylori infection
Endogenous factors favoring growth of nitrate-converting bacteria in the stomach:
Decreased gastric acidity
Prior gastric surgery (antrectomy) (15- to 20-year latency period)
Atrophic gastritis and/or pernicious anemia
? Prolonged exposure to histamine H_2-receptor antagonists

[a]Hypothesis: Dietary nitrates are converted to carcinogenic nitrites by bacteria.

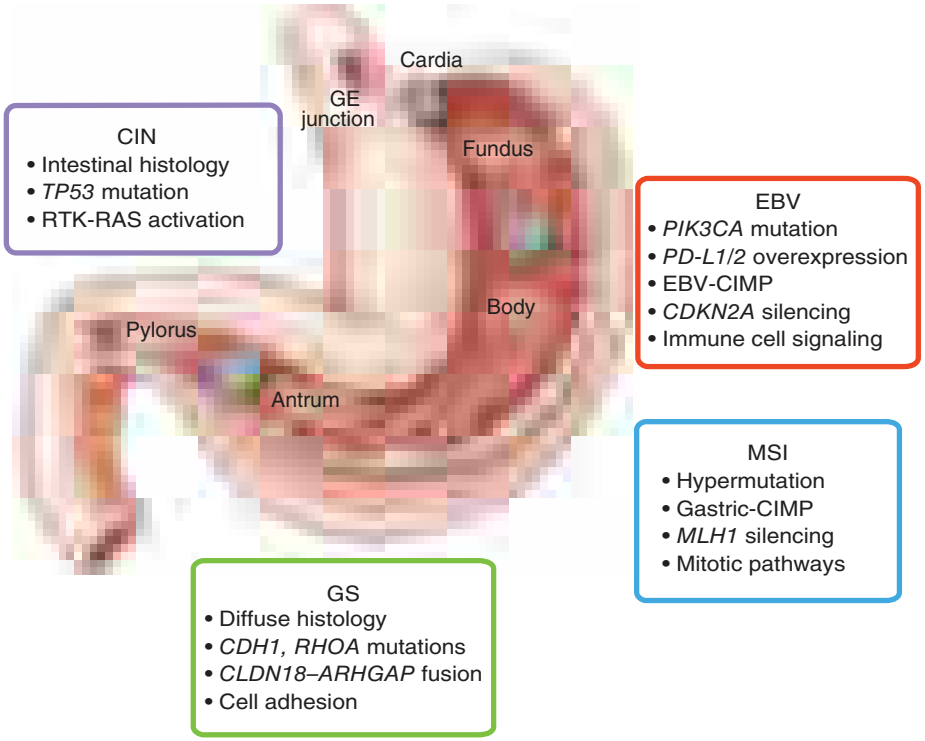

FIGURE 76-1 Molecular/genomic characterization of subtypes of gastric carcinomas. CIMP, CpG-island methylator phenotype; CIN, chromosomally unstable; EBV, Epstein-Barr virus-associated; GS, genomically stable; MSI, microsatellite instability-associated.

lesions, has been associated with a striking frequency of malignant transformation; such hypertrophy, however, does not represent the presence of true adenomatous polyps. Individuals with blood group A have a higher incidence of gastric cancer than persons with blood group O; this observation may be related to differences in the mucous secretion, leading to altered mucosal protection from carcinogens. A germline mutation in the E-cadherin gene (*CDH1*), inherited in an autosomal dominant pattern and coding for a cell adhesion protein, has been linked to a high incidence of occult diffuse-type gastric cancers in young asymptomatic carriers in whom the endoscopic appearance of the gastric mucosa appears normal but foci of tumor are frequently present deeper in the stomach wall; this observation has led to a recommendation that they undergo a prophylactic gastrectomy. Carriers of this mutation are also at greater risk for the development of lobular breast cancer. Duodenal ulcers are not associated with gastric cancer.

Clinical Features Gastric cancers, when superficial and surgically curable, usually produce no symptoms. As the tumor becomes more extensive, patients may complain of an insidious upper abdominal discomfort varying in intensity from a vague, postprandial fullness to a severe, steady pain. Anorexia, often with slight nausea, is very common but is not the usual presenting complaint. Weight loss may eventually be observed, and nausea and vomiting are particularly prominent in patients whose tumors involve the pylorus; dysphagia and early satiety may be the major symptoms caused by diffuse lesions originating in the cardia. There may be no early physical signs. A palpable abdominal mass indicates long-standing growth and predicts regional extension. Gastric carcinomas spread by direct extension through the gastric wall to the perigastric tissues, occasionally adhering to adjacent organs such as the pancreas, colon, or liver. The disease also spreads via lymphatics or by seeding of peritoneal surfaces. Metastases to intraabdominal and supraclavicular lymph nodes occur frequently, as do metastatic nodules to the ovary (Krukenberg's tumor), periumbilical region ("Sister Mary Joseph node"), or peritoneal cul-de-sac (Blumer's shelf palpable on rectal or vaginal examination); malignant ascites may also develop. The liver is the most common site for hematogenous spread of tumor.

The presence of iron-deficiency anemia in men and of occult blood in the stool in both sexes mandates a search for an occult gastrointestinal tract lesion. A careful assessment is of particular importance in patients with atrophic gastritis or pernicious anemia. Unusual clinical features associated with gastric adenocarcinomas include migratory thrombophlebitis, microangiopathic hemolytic anemia, diffuse seborrheic keratoses (so-called Leser-Trélat sign), and acanthosis nigricans.

Diagnosis The use of double-contrast radiographic examinations has been supplanted by esophagogastroscopy and CT scanning for the evaluation of patients with epigastric complaints.

Gastric ulcers identified at the time of such endoscopic procedure may appear benign but merit biopsy in order to exclude a malignancy. Malignant gastric ulcers must be recognized before they penetrate into surrounding tissues, because the rate of cure of early lesions limited to the mucosa or submucosa is >80%. Because gastric carcinomas are difficult to distinguish clinically or endoscopically from gastric lymphomas, endoscopic biopsies should be made as deeply as possible, due to the submucosal location of lymphoid tumors.

The clinical staging system for gastric carcinoma is shown in Table 76-4.

TABLE 76-4 Staging System for Gastric Carcinoma

STAGE	TNM	FEATURES	DATA FROM ACS IN THE UNITED STATES	
			NO. OF CASES, %	5-YEAR SURVIVAL, %
0	T_{is}N0M0	Node negative; limited to mucosa	1	90
IA	T1N0M0	Node negative; invasion of lamina propria or submucosa	7	59
IB	T2N0M0 T1N1M0	Node negative; invasion of muscularis propria	10	44
II	T1N2M0 T2N1M0 T3N0M0	Node positive; invasion beyond mucosa but within wall *or* Node negative; extension through wall	17	29
IIIA	T2N2M0 T3N1-2M0	Node positive; invasion of muscularis propria or through wall	21	15
IIIB	T4N0-1M0	Node negative; adherence to surrounding tissue	14	9
IIIC	T4N2-3M0 T3N3M0	>3 nodes positive; invasion of serosa or adjacent structures 7 or more positive nodes; penetrates wall without invading serosa or adjacent structures		
IV	T4N2M0 T1-4N0-2-M1	Node positive; adherence to surrounding tissue *or* Distant metastases	30	3

Abbreviations: ACS, American Cancer Society; TNM, tumor, node, metastasis.

TREATMENT

Gastric Adenocarcinoma

Complete surgical removal of the tumor with resection of adjacent lymph nodes offers the only chance for cure. However, this is possible in less than a third of patients. A subtotal gastrectomy is the treatment of choice for patients with distal carcinomas, whereas total or near-total gastrectomies are required for more proximal tumors. The inclusion of extended lymph node dissection in these procedures appears to confer an added risk for complications without providing a meaningful enhancement in survival. The prognosis following complete surgical resection depends on the degree of tumor penetration into the stomach wall and is adversely influenced by regional lymph node involvement and vascular invasion, characteristics found in the vast majority of American patients. As a result, the probability of survival after 5 years for the 25–30% of patients able to undergo complete resection is ~20% for distal tumors and <10% for proximal tumors, with recurrences continuing for at least 8 years after surgery. In the absence of ascites or extensive hepatic or peritoneal metastases, even patients whose disease is believed to be incurable by surgery should be offered resection of the primary lesion. Reduction of tumor bulk is the best form of palliation and may enhance the probability of benefit from subsequent therapy. In high-incidence regions such as Japan and Korea, where the use of endoscopic screening programs has identified patients with superficial tumors, the use of laparoscopic gastrectomy has gained popularity. In the United States and western Europe, the use of this less invasive surgical approach remains investigational.

Gastric adenocarcinoma is a relatively radioresistant tumor, and the adequate control of the primary tumor requires doses of external-beam irradiation that exceed the tolerance of surrounding structures, such as bowel mucosa and spinal cord. As a result, the major role of radiation therapy in patients has been palliation of pain. Radiation therapy alone after a complete resection does not prolong survival. In the setting of surgically unresectable disease limited to the epigastrium, patients treated with 3500–4000 cGy did not live longer than similar patients not receiving radiotherapy; however, survival was prolonged slightly when 5-fluorouracil (5-FU) plus leucovorin was given in combination with radiation therapy (3-year survival 50% vs 41% for radiation therapy alone). In this clinical setting, the 5-FU likely functions as a radiosensitizer.

The administration of combinations of cytotoxic drugs to patients with advanced gastric carcinoma has been associated with partial

responses in 30–50% of cases; responders appear to benefit from treatment. Such drug combinations have generally included cisplatin combined with epirubicin or docetaxel and infusional 5-FU or capecitabine, or with either irinotecan or oxaliplatin. Despite the encouraging response rates, complete remissions are uncommon, the partial responses are transient, and the overall impact of multidrug therapy on survival has been limited; the median survival time for patients treated in this manner remains less than 12 months. As with adenocarcinomas arising in the esophagus, the addition of bevacizumab (Avastin) to chemotherapy regimens in treating gastric cancer appears to provide limited benefit. However, preliminary results utilizing another antiangiogenic compound—ramucirumab (Cyranza)—in the treatment of gastric cancer are encouraging, particularly when combined with paclitaxel. Additionally, initial experiences with checkpoint inhibitors (PD-1 and PD-2) have shown such immunotherapy to provide benefit to some patients. The administration of adjuvant chemotherapy alone following the complete resection of a gastric cancer has only minimally improved survival. However, combination chemotherapy administered before and after surgery (*perioperative treatment*) as well as postoperative chemotherapy combined with radiation therapy reduces the recurrence rate and prolongs survival.

PRIMARY GASTRIC LYMPHOMA

Primary lymphoma of the stomach is relatively uncommon, accounting for <15% of gastric malignancies and ~2% of all lymphomas. The stomach is, however, the most frequent extranodal site for lymphoma, and gastric lymphoma has increased in frequency during the past 35 years. The disease is difficult to distinguish clinically from gastric adenocarcinoma; both tumors are most often detected during the sixth decade of life; present with epigastric pain, early satiety, and generalized fatigue; and are usually characterized by ulcerations with a ragged, thickened mucosal pattern demonstrated by contrast radiographs or endoscopic appearance. The diagnosis of lymphoma of the stomach may occasionally be made through cytologic brushings of the gastric mucosa but usually requires a biopsy at gastroscopy or laparotomy. Failure of gastroscopic biopsies to detect lymphoma in a given case should not be interpreted as being conclusive, because superficial biopsies may miss the deeper lymphoid infiltrate. The macroscopic pathology of gastric lymphoma may also mimic adenocarcinoma, consisting of either a bulky ulcerated lesion localized in the corpus or antrum or a diffuse process spreading throughout the entire gastric submucosa and even extending into the duodenum. Microscopically, the vast majority of gastric lymphoid tumors are lymphomas of B-cell origin. Histologically, these tumors may range from well-differentiated, superficial processes (mucosa-associated lymphoid tissue [MALT]) to high-grade, large-cell lymphomas. Like gastric adenocarcinoma, infection with *H. pylori* increases the risk for gastric lymphoma in general and MALT lymphomas in particular. Large-cell lymphomas of the stomach spread initially to regional lymph nodes (often to Waldeyer's ring) and may then disseminate.

TREATMENT

Primary Gastric Lymphoma

Primary gastric lymphoma is a far more treatable disease than adenocarcinoma of the stomach, a fact that underscores the need for making the correct diagnosis. Antibiotic treatment to eradicate *H. pylori* infection has led to regression of about 75% of gastric MALT lymphomas and should be considered before surgery, radiation therapy, or chemotherapy is undertaken in patients having such tumors. A lack of response to such antimicrobial treatment has been linked to a specific chromosomal abnormality, i.e., t(11;18). Responding patients should undergo periodic endoscopic surveillance because it remains unclear whether the neoplastic clone is eliminated or merely suppressed, although the response to antimicrobial treatment is quite durable. Subtotal gastrectomy, usually followed by combination chemotherapy, has led to 5-year survival rates of 40–60% in patients with localized high-grade lymphomas. The need for a major surgical procedure has been questioned, particularly in patients with preoperative radiographic evidence of nodal involvement, for whom chemotherapy (CHOP [cyclophosphamide, doxorubicin, vincristine, and prednisone]) plus rituximab is highly effective therapy. A role for radiation therapy is not defined because most recurrences develop at distant sites.

GASTRIC (NONLYMPHOID) SARCOMA

Leiomyosarcomas and GISTs make up 1–3% of gastric neoplasms. They most frequently involve the anterior and posterior walls of the gastric fundus and often ulcerate and bleed. Even those lesions that appear benign on histologic examination may behave in a malignant fashion. These tumors rarely invade adjacent viscera and characteristically do not metastasize to lymph nodes, but they may spread to the liver and lungs. The treatment of choice is surgical resection with 3 years of postoperative therapy to be considered following the removal of a GIST if the primary tumor demonstrates high-risk features. All such tumors should be analyzed for a mutation in the c-*kit* receptor. GISTs are unresponsive to conventional chemotherapy; yet ~50% of patients experience objective response and prolonged survival when treated with imatinib mesylate (Gleevec) (400–800 mg PO daily), a selective inhibitor of the c-*kit* tyrosine kinase. Many patients with GIST whose tumors have become refractory to imatinib subsequently benefit from sunitinib (Sutent) or regorafenib (Stivarga), other inhibitors of the c-*kit* tyrosine kinase.

TUMORS OF THE SMALL INTESTINE

Small-bowel tumors comprise <3% of gastrointestinal neoplasms. Because of their rarity and inaccessibility, a correct diagnosis is often delayed. Abdominal symptoms are usually vague and poorly defined, and conventional radiographic studies of the upper and lower intestinal tract often appear normal. Small-bowel tumors should be considered in the differential diagnosis in the following situations: (1) recurrent, unexplained episodes of crampy abdominal pain; (2) intermittent bouts of intestinal obstruction, especially in the absence of inflammatory bowel disease (IBD) or prior abdominal surgery; (3) intussusception in the adult; and (4) evidence of chronic intestinal bleeding in the presence of negative conventional and endoscopic examination. A careful small-bowel barium study should be considered in such a circumstance; the diagnostic accuracy may be improved by infusing barium through a nasogastric tube placed into the duodenum (enteroclysis). Alternatively, capsule endoscopic procedures have been used.

BENIGN TUMORS

The histology of benign small-bowel tumors is difficult to predict on clinical and radiologic grounds alone. The symptomatology of benign tumors is not distinctive, with pain, obstruction, and hemorrhage being the most frequent symptoms. These tumors are usually discovered during the fifth and sixth decades of life, more often in the distal rather than the proximal small intestine. The most common benign tumors are adenomas, leiomyomas, lipomas, and angiomas.

Adenomas These tumors include those of the islet cells and Brunner's glands as well as polypoid adenomas. *Islet cell adenomas* are occasionally located outside the pancreas; the associated syndromes are discussed in **Chap. 80**. *Brunner's gland adenomas* are not truly neoplastic but represent a hypertrophy or hyperplasia of submucosal duodenal glands. These appear as small nodules in the duodenal mucosa that secrete a highly viscous alkaline mucus. Most often, this is an incidental radiographic finding not associated with any specific clinical disorder.

Polypoid Adenomas About 25% of benign small-bowel tumors are polypoid adenomas **(see Table 77-2)**. They may present as single polypoid lesions or, less commonly, as papillary villous adenomas. As in the colon, the sessile or papillary form of the tumor is sometimes associated with a coexisting carcinoma. Occasionally, patients with Gardner's syndrome develop premalignant adenomas in the small bowel; such lesions are generally in the duodenum. Multiple polypoid tumors may occur throughout the small bowel (and occasionally the

stomach and colorectum) in the Peutz-Jeghers syndrome. The polyps are usually hamartomas (juvenile polyps) having a low potential for malignant degeneration. Mucocutaneous melanin deposits as well as tumors of the ovary, breast, pancreas, and endometrium are also associated with this autosomal dominant condition.

Leiomyomas These neoplasms arise from smooth-muscle components of the intestine and are usually intramural, affecting the overlying mucosa. Ulceration of the mucosa may cause gastrointestinal hemorrhage of varying severity. Cramping or intermittent abdominal pain is frequently encountered.

Lipomas These tumors occur with greatest frequency in the distal ileum and at the ileocecal valve. They have a characteristic radiolucent appearance and are usually intramural and asymptomatic, but on occasion cause bleeding.

Angiomas While not true neoplasms, these lesions are important because they frequently cause intestinal bleeding. They may take the form of telangiectasia or hemangiomas. Multiple intestinal telangiectasias occur in a nonhereditary form confined to the gastrointestinal tract or as part of the hereditary Osler-Rendu-Weber syndrome. Vascular tumors may also take the form of isolated hemangiomas, most commonly in the jejunum. Angiography, especially during bleeding, is the best procedure for evaluating these lesions.

MALIGNANT TUMORS

While rare, small-bowel malignancies occur in patients with long-standing regional enteritis and celiac sprue as well as in individuals with AIDS. Malignant tumors of the small bowel are frequently associated with fever, weight loss, anorexia, bleeding, and a palpable abdominal mass. After ampullary carcinomas (many of which arise from biliary or pancreatic ducts), the most frequently occurring small-bowel malignancies are adenocarcinomas, lymphomas, carcinoid tumors, and leiomyosarcomas.

ADENOCARCINOMAS

The most common primary cancers of the small bowel are adenocarcinomas, accounting for ~50% of malignant tumors. These cancers occur most often in the distal duodenum and proximal jejunum, where they tend to ulcerate and cause hemorrhage or obstruction. Radiologically, they may be confused with chronic duodenal ulcer disease or with Crohn's disease if the patient has long-standing regional enteritis. The diagnosis is best made by endoscopy and biopsy under direct vision. Surgical resection is the treatment of choice with suggested postoperative adjuvant chemotherapy options generally following treatment patterns used in the management of colon cancer.

LYMPHOMAS

Lymphoma in the small bowel may be primary or secondary. A diagnosis of a primary intestinal lymphoma requires histologic confirmation in a clinical setting in which palpable adenopathy and hepatosplenomegaly are absent and no evidence of lymphoma is seen on chest radiograph, CT scan, or peripheral blood smear or on bone marrow aspiration and biopsy. Symptoms referable to the small bowel are present, usually accompanied by an anatomically discernible lesion. Secondary lymphoma of the small bowel consists of involvement of the intestine by a lymphoid malignancy extending from involved retroperitoneal or mesenteric lymph nodes (Chap. 104).

Primary intestinal lymphoma accounts for ~20% of malignancies of the small bowel. These neoplasms are non-Hodgkin's lymphomas; they usually have a diffuse, large-cell histology and are of T cell origin. Intestinal lymphoma involves the ileum, jejunum, and duodenum, in decreasing frequency—a pattern that mirrors the relative amount of normal lymphoid cells in these anatomic areas. The risk of small-bowel lymphoma is increased in patients with a prior history of malabsorptive conditions (e.g., celiac sprue), regional enteritis, and depressed immune function due to congenital immunodeficiency syndromes, prior organ transplantation, autoimmune disorders, or AIDS.

The development of localized or nodular masses that narrow the lumen results in periumbilical pain (made worse by eating) as well as weight loss, vomiting, and occasional intestinal obstruction. The diagnosis of small-bowel lymphoma may be suspected from the appearance on contrast radiographs of patterns such as infiltration and thickening of mucosal folds, mucosal nodules, areas of irregular ulceration, or stasis of contrast material. The diagnosis can be confirmed by surgical exploration and resection of involved segments. Intestinal lymphoma can occasionally be diagnosed by peroral intestinal mucosal biopsy, but because the disease mainly involves the lamina propria, full-thickness surgical biopsies are usually required.

Resection of the tumor constitutes the initial treatment modality. While postoperative radiation therapy has been given to some patients following a total resection, most authorities favor short-term (three cycles) systemic treatment with combination chemotherapy. The frequent presence of widespread intraabdominal disease at the time of diagnosis and the occasional multicentricity of the tumor often make a total resection impossible. The probability of sustained remission or cure is ~75% in patients with localized disease but is ~25% in individuals with unresectable lymphoma. In patients whose tumors are not resected, chemotherapy may lead to bowel perforation.

A unique form of small-bowel lymphoma, diffusely involving the entire intestine, was first described in oriental Jews and Arabs and is referred to as *immunoproliferative small intestinal disease* (IPSID), *Mediterranean lymphoma*, or *α heavy chain disease*. This is a B-cell tumor. The typical presentation includes chronic diarrhea and steatorrhea associated with vomiting and abdominal cramps; clubbing of the digits may be observed. A curious feature in many patients with IPSID is the presence in the blood and intestinal secretions of an abnormal IgA that contains a shortened α heavy chain and is devoid of light chains. It is suspected that the abnormal α chains are produced by plasma cells infiltrating the small bowel. The clinical course of patients with IPSID is generally one of exacerbations and remissions, with death frequently resulting from either progressive malnutrition and wasting or the development of an aggressive lymphoma. The use of oral antibiotics such as tetracycline appears to be beneficial in the early phases of the disorder, suggesting a possible infectious etiology. Combination chemotherapy has been administered during later stages of the disease, with variable results. Results are better when antibiotics and chemotherapy are combined.

CARCINOID TUMORS

Carcinoid tumors arise from argentaffin cells of the crypts of Lieberkühn and are found from the distal duodenum to the ascending colon, areas embryologically derived from the midgut. More than 50% of intestinal carcinoids are found in the distal ileum, with most congregating close to the ileocecal valve. Most intestinal carcinoids are asymptomatic and of low malignant potential, but invasion and metastases may occur, leading to the carcinoid syndrome (Chap. 80).

LEIOMYOSARCOMAS

Leiomyosarcomas often are >5 cm in diameter and may be palpable on abdominal examination. Bleeding, obstruction, and perforation are common. Such tumors should be analyzed for the expression of mutant c-*kit* receptor (defining GIST), and in the presence of metastatic disease, justifying treatment with imatinib mesylate (Gleevec) or, in imatinib-refractory patients, sunitinib (Sutent) or regorafenib (Stivarga).

77 Lower Gastrointestinal Cancers

Robert J. Mayer

Lower gastrointestinal cancers include malignant tumors of the colon, rectum, and anus.

COLORECTAL CANCER

INCIDENCE

Cancer of the large bowel is second only to lung cancer as a cause of cancer death in the United States: 135,430 new cases occurred in 2017, and 50,260 deaths were due to colorectal cancer. The incidence rate has decreased significantly during the past 25 years, likely due in large part to enhanced and more compliantly followed screening practices. Similarly, mortality rates in the United States have decreased by ~25%, resulting largely from earlier detection and improved treatment.

POLYPS AND MOLECULAR PATHOGENESIS

Most colorectal cancers, regardless of etiology, arise from adenomatous polyps. A polyp is a grossly visible protrusion from the mucosal surface and may be classified pathologically as a nonneoplastic hamartoma (e.g., *juvenile polyp*), a hyperplastic mucosal proliferation (*hyperplastic polyp*), or an adenomatous polyp. Only adenomas are clearly premalignant, and only a minority of adenomatous polyps evolve into cancer. Adenomatous polyps may be found in the colons of ~30% of middle-aged and ~50% of elderly people; however, <1% of polyps ever become malignant. Most polyps produce no symptoms and remain clinically undetected. Occult blood in the stool is found in <5% of patients with polyps.

A number of molecular changes are noted in adenomatous polyps and colorectal cancers that are thought to reflect a multistep process in the evolution of normal colonic mucosa to life-threatening invasive carcinoma. These developmental steps toward carcinogenesis include, but are not restricted to, point mutations in the K-*ras* protooncogene; hypomethylation of DNA, leading to gene activation; loss of DNA (*allelic loss*) at the site of a tumor-suppressor gene (the adenomatous polyposis coli [*APC*] gene) on the long arm of chromosome 5 (5q21); allelic loss at the site of a tumor-suppressor gene located on chromosome 18q (the deleted in colorectal cancer [*DCC*] gene); and allelic loss at chromosome 17p, associated with mutations in the *p53* tumor-suppressor gene **(see Fig. 67-2)**. Thus, the altered proliferative pattern of the colonic mucosa, which results in progression to a polyp and then to carcinoma, may involve the mutational activation of an oncogene followed by and coupled with the loss of genes that normally suppress tumorigenesis. It remains uncertain whether the genetic aberrations always occur in a defined order. Based on this model, however, cancer is believed to develop only in those polyps in which most (if not all) of these mutational events take place.

Clinically, the probability of an adenomatous polyp becoming a cancer depends on the gross appearance of the lesion, its histologic features, and its size. Polyps may be pedunculated (stalked) or sessile (flat-based), adenomatous or serrated. Invasive cancers develop more frequently in sessile, serrated (i.e. "flat") polyps. Histologically, adenomatous polyps may be tubular, villous (i.e., papillary), or tubulovillous. Villous adenomas, most of which are sessile, become malignant more than three times as often as tubular adenomas. The likelihood that any polypoid lesion in the large bowel contains invasive cancer is related to the size of the polyp, being negligible (<2%) in lesions <1.5 cm, intermediate (2–10%) in lesions 1.5–2.5 cm, and substantial (10%) in lesions >2.5 cm in size.

Following the detection of an adenomatous polyp, the entire large bowel should be visualized endoscopically because synchronous lesions are noted in about one-third of cases. Colonoscopy should then be repeated periodically, even in the absence of a previously documented malignancy, because such patients have a 30–50% probability of developing another adenoma and are at a higher-than-average risk for developing a colorectal carcinoma. Adenomatous polyps are thought to require >5 years of growth before becoming clinically significant; colonoscopy need not be carried out more frequently than every 3 years for the vast majority of patients.

ETIOLOGY AND RISK FACTORS

Risk factors for the development of colorectal cancer are listed in **Table 77-1**.

Diet The etiology for most cases of large-bowel cancer appears to be related to environmental factors. The disease occurs more often in upper socioeconomic populations who live in urban areas. Mortality from colorectal cancer is directly correlated with per capita consumption of calories, meat protein, and dietary fat and oil as well as elevations in the serum cholesterol concentration and mortality from coronary artery disease. Geographic variations in incidence largely are unrelated to genetic differences, since migrant groups tend to assume the large-bowel cancer incidence rates of their adopted countries. Furthermore, population groups such as Mormons and Seventh Day Adventists, whose lifestyle and dietary habits differ somewhat from those of their neighbors, have significantly lower-than-expected incidence and mortality rates for colorectal cancer. The incidence of colorectal cancer has increased in Japan since that nation has adopted a more "Western" diet. At least three hypotheses have been proposed to explain the relationship to diet, none of which is fully satisfactory.

ANIMAL FATS One hypothesis is that the ingestion of animal fats found in red meats and processed meat leads to an increased proportion of anaerobes in the gut microflora, resulting in the conversion of normal bile acids into carcinogens. This provocative hypothesis is supported by several reports of increased amounts of fecal anaerobes in the stools of patients with colorectal cancer. Diets high in animal (but not vegetable) fats are also associated with high serum cholesterol, which is also associated with enhanced risk for the development of colorectal adenomas and carcinomas.

INSULIN RESISTANCE The large number of calories in Western diets coupled with physical inactivity has been associated with a higher prevalence of obesity. Obese persons develop insulin resistance with increased circulating levels of insulin, leading to higher circulating concentrations of insulin-like growth factor type I (IGF-I). This growth factor appears to stimulate proliferation of the intestinal mucosa.

FIBER Contrary to prior beliefs, the results of randomized trials and case-controlled studies have *failed* to show any value for dietary fiber or diets high in fruits and vegetables in preventing the recurrence of colorectal adenomas or the development of colorectal cancer.

The weight of epidemiologic evidence, however, implicates diet as being the major etiologic factor for colorectal cancer, particularly diets high in animal fat and in calories.

HEREDITARY FACTORS AND SYNDROMES

Up to 25% of patients with colorectal cancer have a family history of the disease, suggesting a hereditary predisposition. Inherited large-bowel cancers can be divided into two main groups: the well-studied but uncommon polyposis syndromes and the more common nonpolyposis syndromes **(Table 77-2)**.

TABLE 77-1 Risk Factors for the Development of Colorectal Cancer

Diet: Animal fat
Hereditary syndromes
Polyposis coli
MYH-associated polyposis
Nonpolyposis syndrome (Lynch's syndrome)
Inflammatory bowel disease
Streptococcus bovis bacteremia
? Tobacco use

TABLE 77-2 Hereditable (Autosomal Dominant) Gastrointestinal Polyposis Syndromes

SYNDROME	DISTRIBUTION OF POLYPS	HISTOLOGIC TYPE	MALIGNANT POTENTIAL	ASSOCIATED LESIONS
Familial adenomatous polyposis	Large intestine	Adenoma	Common	None
Gardner's syndrome	Large and small intestines	Adenoma	Common	Osteomas, fibromas, lipomas, epidermoid cysts, ampullary cancers, congenital hypertrophy of retinal pigment epithelium
Turcot's syndrome	Large intestine	Adenoma	Common	Brain tumors
MYH-associated polyposis	Large intestine	Adenoma	Common	None
Nonpolyposis syndrome (Lynch's syndrome)	Large intestine (often proximal)	Adenoma	Common	Endometrial and ovarian tumors (most frequently) gastric, genitourinary, pancreatic, biliary cancers (less frequently)
Peutz-Jeghers syndrome	Small and large intestines, stomach	Hamartoma	Rare	Mucocutaneous pigmentation; tumors of the ovary, breast, pancreas, endometrium
Juvenile polyposis	Large and small intestines, stomach	Hamartoma, rarely progressing to adenoma	Rare	Various congenital abnormalities

Polyposis Coli Polyposis coli (familial polyposis of the colon) is a rare condition characterized by the appearance of thousands of adenomatous polyps throughout the large bowel. It is transmitted as an autosomal dominant trait; the occasional patient with no family history probably developed the condition due to a spontaneous mutation. Polyposis coli is associated with a deletion in the long arm of chromosome 5 (including the *APC* gene) in both neoplastic (somatic mutation) and normal (germline mutation) cells. The loss of this genetic material (i.e., allelic loss) results in the absence of tumor-suppressor genes whose protein products would normally inhibit neoplastic growth. The presence of soft tissue and bony tumors, congenital hypertrophy of the retinal pigment epithelium, mesenteric desmoid tumors, and ampullary cancers in addition to the colonic polyps characterizes a subset of polyposis coli known as *Gardner's syndrome*. The appearance of malignant tumors of the central nervous system accompanying polyposis coli defines *Turcot's syndrome*. The colonic polyps in all these conditions are rarely present before puberty but are generally evident in affected individuals by age 25. If the polyposis is not treated surgically, colorectal cancer will develop in almost all patients aged <40. Polyposis coli results from a defect in the colonic mucosa, leading to an abnormal proliferative pattern and impaired DNA repair mechanisms. Once the multiple polyps are detected, patients should undergo a total colectomy. Medical therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) such as sulindac and selective cyclooxygenase-2 inhibitors such as celecoxib can decrease the number and size of polyps in patients with polyposis coli; however, this effect on polyps is only temporary, and the use of NSAIDs has not been shown to reduce the risk of cancer. Colectomy remains the primary therapy/prevention. The offspring of patients with polyposis coli, who often are prepubertal when the diagnosis is made in the parent, have a 50% risk for developing this premalignant disorder and should be carefully screened by annual flexible sigmoidoscopy until age 35. Proctosigmoidoscopy is a sufficient screening procedure because polyps tend to be evenly distributed from cecum to anus, making more invasive and expensive techniques such as colonoscopy or barium enema unnecessary. Testing for occult blood in the stool is an inadequate screening maneuver. If a causative germline *APC* mutation has been identified in an affected family member, an alternative method for identifying carriers is testing DNA from peripheral blood mononuclear cells for the presence of the specific *APC* mutation. The detection of such a germline mutation can lead to a definitive diagnosis before the development of polyps.

MYH-Associated Polyposis MYH-associated polyposis (MAP) is a rare autosomal recessive syndrome caused by a biallelic mutation in the *MUT4H* gene. This hereditary condition may have a variable clinical presentation, resembling polyposis coli or colorectal cancer occurring in younger individuals without polyposis. Screening and colectomy guidelines for this syndrome are less clear than for polyposis coli, but annual to biennial colonoscopic surveillance is generally recommended starting at age 25–30.

Hereditary Nonpolyposis Colon Cancer Hereditary nonpolyposis colon cancer (HNPCC), also known as *Lynch's syndrome*, is another autosomal dominant trait. It is characterized by the presence of three or more relatives with histologically documented colorectal cancer, one of whom is a first-degree relative of the other two; one or more cases of colorectal cancer diagnosed before age 50 in the family; and colorectal cancer involving at least two generations. In contrast to polyposis coli, HNPCC is associated with an unusually high frequency of cancer arising in the proximal large bowel. The median age for the appearance of an adenocarcinoma is <50 years, 10–15 years younger than the median age for the general population. Despite having a poorly differentiated, mucinous histologic appearance, the proximal colon tumors that characterize HNPCC have a better prognosis than sporadic tumors from patients of similar age. Families with HNPCC often include individuals with multiple primary cancers; the association of colorectal cancer with either ovarian or endometrial carcinomas is especially strong in women, and an increased appearance of gastric, small-bowel, genitourinary, pancreaticobiliary, and sebaceous skin tumors has been reported as well. It has been recommended that members of such families undergo annual or biennial colonoscopy beginning at age 25 years, with intermittent pelvic ultrasonography and endometrial biopsy for afflicted women; such a screening strategy has not yet been validated. HNPCC is associated with germline mutations of several genes, particularly *hMSH2* on chromosome 2 and *hMLH1* on chromosome 3. These mutations lead to errors in DNA replication and are thought to result in DNA instability because of defective repair of DNA mismatches resulting in abnormal cell growth and tumor development. Testing tumor cells through molecular analysis of DNA for "microsatellite instability" or immunohistochemical staining for deficiency in mismatch repair proteins in patients with colorectal cancer and a positive family history for colorectal or endometrial cancer may identify probands with HNPCC.

INFLAMMATORY BOWEL DISEASE

(Chap. 319) Large-bowel cancer is increased in incidence in patients with long-standing inflammatory bowel disease (IBD). Cancers develop more commonly in patients with ulcerative colitis than in those with granulomatous (i.e., Crohn's) colitis, but this impression may result in part from the occasional difficulty of differentiating these two conditions. The risk of colorectal cancer in a patient with IBD is relatively small during the initial 10 years of the disease, but then appears to increase at a rate of ~0.5–1% per year. Cancer may develop in 8–30% of patients after 25 years. The risk is higher in younger patients with pancolitis.

Cancer surveillance strategies in patients with IBD are unsatisfactory. Symptoms such as bloody diarrhea, abdominal cramping, and obstruction, which may signal the appearance of a tumor, are similar to the complaints caused by a flare-up of the underlying disease. In patients with a history of IBD lasting ≥15 years who continue to experience exacerbations, the surgical removal of the colon can significantly

reduce the risk for cancer and also eliminate the target organ for the underlying chronic gastrointestinal disorder. The value of such surveillance techniques as colonoscopy with mucosal biopsies and brushings for less symptomatic individuals with chronic IBD is uncertain. The lack of uniformity regarding the pathologic criteria that characterize dysplasia and the absence of data that such surveillance reduces the development of lethal cancers have made this costly practice an area of controversy.

OTHER HIGH-RISK CONDITIONS

***Streptococcus bovis* Bacteremia** For unknown reasons, individuals who develop endocarditis or septicemia from this fecal bacterium have a high incidence of occult colorectal tumors and, possibly, upper gastrointestinal cancers as well. Endoscopic or radiographic screening appears advisable.

Tobacco Use Cigarette smoking is linked to the development of colorectal adenomas, particularly after >35 years of tobacco use. No biologic explanation for this association has yet been proposed.

PRIMARY PREVENTION

Several orally administered compounds have been assessed as possible inhibitors of colon cancer. The most effective class of chemopreventive agents is aspirin and other NSAIDs, which are thought to suppress cell proliferation by inhibiting prostaglandin synthesis. Regular aspirin use reduces the risk of colon adenomas and carcinomas as well as death from large-bowel cancer; such use also appears to diminish the likelihood for developing additional premalignant adenomas following successful treatment for a prior colon carcinoma. This effect of aspirin on colon carcinogenesis increases with the duration and dosage of drug use. Emerging data linking adequate plasma levels of vitamin D with reduced risk of adenomatous polyps and colorectal cancer appear promising. The value of vitamin D as a form of chemoprevention is under study. Antioxidant vitamins such as ascorbic acid, tocopherols, and β-carotene are ineffective at reducing the incidence of subsequent adenomas in patients who have undergone the removal of a colon adenoma. Estrogen replacement therapy has been associated with a reduction in the risk of colorectal cancer in women, conceivably by an effect on bile acid synthesis and composition or by decreasing synthesis of IGF-I.

SCREENING

The rationale for colorectal cancer screening programs is that the removal of adenomatous polyps will prevent colorectal cancer, and that earlier detection of localized, superficial cancers in asymptomatic individuals will increase the surgical cure rate. Such screening programs are particularly important for individuals with a family history of the disease in first-degree relatives. The relative risk for developing colorectal cancer increases to 1.75 in such individuals and may be even higher if the relative was afflicted before age 60. The prior use of rigid proctosigmoidoscopy as a screening tool was based on the observation that 60% of early lesions are located in the rectosigmoid. For unexplained reasons, however, the proportion of large-bowel cancers arising in the rectum has been decreasing during the past several decades, with a corresponding increase in the proportion of cancers in the more proximal descending colon. As such, the potential for rigid proctosigmoidoscopy to detect a sufficient number of occult neoplasms to make the procedure cost-effective has been questioned.

Screening strategies for colorectal cancer that have been examined during the past several decades are listed in Table 77-3.

Many programs directed at the early detection of colorectal cancers have focused on digital rectal examinations and fecal occult blood (i.e., stool guaiac) testing. The digital examination should be part of any routine physical evaluation in adults aged >40 years, serving as a screening test for prostate cancer in men, a component of the pelvic examination in women, and an inexpensive maneuver for the detection of masses in the rectum. However, because of the proximal migration of colorectal tumors, its value as an overall screening modality for colorectal cancer has become limited. The development of the fecal occult blood test has greatly facilitated the detection of occult fecal blood. Unfortunately, even when performed optimally, the fecal occult blood test has major limitations as a screening technique. About 50% of patients with documented colorectal cancers have a negative fecal occult blood test, consistent with the intermittent bleeding pattern of these tumors. When random cohorts of asymptomatic persons have been tested, 2–4% have fecal occult blood-positive stools. Colorectal cancers have been found in <10% of these "test-positive" cases, with benign polyps being detected in an additional 20–30%. Thus, a colorectal neoplasm will not be found in most asymptomatic individuals with occult blood in their stool. Nonetheless, persons found to have fecal occult blood-positive stool routinely undergo further medical evaluation, including sigmoidoscopy and/or colonoscopy—procedures that are not only uncomfortable and expensive but also associated with a small risk for significant complications. The added cost of these studies would appear justifiable if the small number of patients found to have occult neoplasms because of fecal occult blood screening could be shown to have an improved prognosis and prolonged survival. Prospectively controlled trials have shown a statistically significant reduction in mortality rate from colorectal cancer for individuals undergoing annual stool guaiac screening. However, this benefit only emerged after >13 years of follow-up and was extremely expensive to achieve because all positive tests (most of which were falsely positive) were followed by colonoscopy. Moreover, these colonoscopic examinations quite likely provided the opportunity for cancer prevention through the removal of potentially premalignant adenomatous polyps because the eventual development of cancer was reduced by 20% in the cohort undergoing annual screening.

With the appreciation that the carcinogenic process leading to the progression of the normal bowel mucosa to an adenomatous polyp and then to a cancer is the result of a series of molecular changes, investigators have examined fecal DNA for evidence of mutations associated with such molecular changes as evidence of the occult presence of precancerous lesions or actual malignancies. Such a strategy has been tested in >4000 asymptomatic individuals whose stool was assessed for occult blood and for 21 possible mutations in fecal DNA; these study subjects also underwent colonoscopy. Although the fecal DNA strategy suggested the presence of more advanced adenomas and cancers than did the fecal occult blood testing approach, the overall sensitivity, using colonoscopic findings as the standard, was <50%, diminishing enthusiasm for further pursuit of the fecal DNA screening strategy.

The use of imaging studies to screen for colorectal cancers has also been explored. Air contrast barium enemas had been used to identify sources of occult blood in the stool prior to the advent of fiberoptic endoscopy; the cumbersome nature of the procedure and inconvenience to patients limited its widespread adoption. The introduction of computed tomography (CT) scanning led to the development of virtual (i.e., CT) colonography as an alternative to the growing use of endoscopic screening techniques. Virtual colonography was proposed as being equivalent in sensitivity to colonoscopy and being available in a more widespread manner because it did not require the same degree of operator expertise as fiberoptic endoscopy. However, virtual colonography requires the same cathartic preparation that has limited widespread acceptance in association with endoscopic colonoscopy, is diagnostic but not therapeutic (i.e., patients with suspicious findings

TABLE 77-3 Screening Strategies for Colorectal Cancer

must undergo a subsequent endoscopic procedure for polypectomy or biopsy), and, in the setting of general radiology practices, appears to be less sensitive as a screening technique when compared with endoscopic procedures.

With the appreciation of the inadequacy of fecal occult blood testing alone, concerns about the practicality of imaging approaches, and the wider adoption of endoscopic examinations by the primary care community, screening strategies in asymptomatic persons have changed. At present, both the American Cancer Society and the National Comprehensive Cancer Network recommend either fecal occult blood testing annually coupled with flexible sigmoidoscopy every 5 years or colonoscopy every 10 years beginning at age 50 in asymptomatic individuals with no personal or family history of polyps or colorectal cancer. The recommendation for the inclusion of flexible sigmoidoscopy is strongly supported by the recently published results of three randomized trials performed in the United States, the United Kingdom, and Italy, involving >350,000 individuals, which consistently showed that periodic (even single) sigmoidoscopic examinations, after more than a decade of median follow-up, lead to an ~21% reduction in the development of colorectal cancer and a >25% reduction in mortality from the malignant disease. Less than 20% of participants in these studies underwent a subsequent colonoscopy. In contrast to the cathartic preparation required before colonoscopic procedures, which is only performed by highly trained specialists, flexible sigmoidoscopy requires only an enema as preparation and can be accurately performed by nonspecialty physicians or physician-extenders. The randomized screening studies using flexible sigmoidoscopy led to the estimate that ~650 individuals needed to be screened to prevent one colorectal cancer death; this contrasts with the data for mammography where the number of women needing to be screened to prevent one breast cancer death is 2500, reinforcing the efficacy of endoscopic surveillance for colorectal cancer screening. Presumably the benefit from the sigmoidoscopic screening is the result of the identification and removal of adenomatous polyps; it is intriguing that this benefit has been achieved using a technique that leaves the proximal half of the large bowel unvisualized.

It remains to be seen whether surveillance colonoscopy, which has gained increasing popularity in the United States for colorectal cancer screening, will prove to be more effective than flexible sigmoidoscopy. Ongoing randomized trials being conducted in Europe are addressing this issue. Although flexible sigmoidoscopy only visualizes the distal half of the large bowel, leading to the assumption that colonoscopy represents a more informative approach, colonoscopy has been reported as being less accurate for screening the proximal rather than the distal colon, perhaps due to technical considerations but also possibly because of a greater frequency of serrated (i.e., "flat") polyps in the right colon, which are more difficult to identify. At present, colonoscopy performed every 10 years has been offered as an alternative to annual fecal occult blood testing with periodic (every 5 years) flexible sigmoidoscopy. Colonoscopy has been shown to be superior to double-contract barium enema and also to have a higher sensitivity for detecting villous or dysplastic adenomas or cancers than the strategy using occult fecal blood testing and flexible sigmoidoscopy. Whether colonoscopy performed every 10 years beginning at age 50 is medically superior and economically equivalent to flexible sigmoidoscopy remains to be determined.

CLINICAL FEATURES

Presenting Symptoms Symptoms vary with the anatomic location of the tumor. Because stool is relatively liquid as it passes through the ileocecal valve into the right colon, cancers arising in the cecum and ascending colon may become quite large without resulting in any obstructive symptoms or noticeable alterations in bowel habits. Lesions of the right colon commonly ulcerate, leading to chronic, insidious blood loss without a change in the appearance of the stool. Consequently, patients with tumors of the ascending colon often present with symptoms such as fatigue, palpitations, and even angina pectoris and are found to have a hypochromic, microcytic anemia indicative of iron deficiency. Because the cancers may bleed intermittently, a random fecal occult blood test may be negative. As a result, the unexplained presence of iron-deficiency anemia in any adult (with the possible exception of a premenopausal, multiparous woman) mandates a thorough endoscopic and/or radiographic visualization of the entire large bowel (Fig. 77-1).

FIGURE 77-1 Double-contrast air-barium enema revealing a sessile tumor of the cecum in a patient with iron-deficiency anemia and guaiac-positive stool. The lesion at surgery was a stage II adenocarcinoma.

Because stool becomes more formed as it passes into the transverse and descending colon, tumors arising there tend to impede the passage of stool, resulting in the development of abdominal cramping, occasional obstruction, and even perforation. Radiographs of the abdomen often reveal characteristic annular, constricting lesions ("apple-core" or "napkin-ring") (Fig. 77-2).

Cancers arising in the rectosigmoid are often associated with hematochezia, tenesmus, and narrowing of the caliber of stool; anemia is an infrequent finding. While these symptoms may lead patients and their

FIGURE 77-2 Annular, constricting adenocarcinoma of the descending colon. This radiographic appearance is referred to as an "apple-core" lesion and is always highly suggestive of malignancy.

physicians to suspect the presence of hemorrhoids, the development of rectal bleeding and/or altered bowel habits demands a prompt digital rectal examination and proctosigmoidoscopy.

Staging, Prognostic Factors, and Patterns of Spread The prognosis for individuals having colorectal cancer is related to the depth of tumor penetration into the bowel wall and the presence of both regional lymph node involvement and distant metastases. These variables are incorporated into a TNM classification method, in which T represents the depth of tumor penetration, N the presence of lymph node involvement, and M the presence or absence of distant metastases **(Fig. 77-3)**. Superficial lesions that do not involve regional lymph nodes and do not penetrate through the submucosa (T1) or the muscularis (T2) are designated as *stage I* (T1–2N0M0) disease; tumors that penetrate through the muscularis but have not spread to lymph nodes are *stage II* disease (T3-4N0M0); regional lymph node involvement defines *stage III* (TXN1-2M0) disease; and metastatic spread to sites such as liver, lung, or bone indicates *stage IV* (TXNXM1) disease. Unless gross evidence of metastatic disease is present, disease stage cannot be determined accurately before surgical resection and pathologic analysis of the operative specimens.

Most recurrences after a surgical resection of a large-bowel cancer occur within the first 4 years, making 5-year survival a fairly reliable indicator of cure. The likelihood for 5-year survival in patients with colorectal cancer is stage-related (Fig. 77-3). That likelihood has improved during the past several decades when similar surgical stages have been compared. The most plausible explanation for this improvement is more thorough intraoperative and pathologic staging. In particular, more exacting attention to pathologic detail has revealed that the prognosis following the resection of a colorectal cancer is not related merely to the presence or absence of regional lymph node involvement; rather, prognosis may be more precisely gauged by the number of involved lymph nodes (one to three lymph nodes ["N1"] vs four or more lymph nodes ["N2"]) and the number of nodes examined. A minimum of 12 sampled lymph nodes is thought necessary to accurately define tumor stage, and the more nodes examined, the better. Other predictors of a poor prognosis after a total surgical resection include tumor penetration through the bowel wall into pericolic fat, poorly differentiated histology, perforation and/or tumor adherence to adjacent organs (increasing the risk for an anatomically adjacent recurrence), and venous invasion by tumor **(Table 77-4)**. Regardless of the clinicopathologic stage, a preoperative elevation of the plasma carcinoembryonic antigen (CEA) level predicts eventual tumor recurrence. The presence of specific chromosomal aberrations, particularly a mutation in the *b-raf* gene in tumor cells, appears to predict for a higher risk for metastatic spread. Conversely, the detection of microsatellite instability in tumor tissue indicates a more favorable outcome. Tumors arising in the left colon are associated with a better prognosis than those appearing in the right colon, likely due to differences in molecular patterns. In contrast to most other cancers, the prognosis in colorectal cancer is not influenced by the size of the primary lesion when adjusted for nodal involvement and histologic differentiation.

TABLE 77-4 Predictors of Poorer Outcomes Following Total Surgical Resection of Colorectal Cancer

Tumor spread to regional lymph nodes
Number of regional lymph nodes involved
Tumor penetration through the bowel wall
Poorly differentiated histology
Perforation
Tumor adherence to adjacent organs
Venous invasion
Preoperative elevation of CEA titer (>5 ng/mL)
Specific chromosomal deletion (e.g., mutation in the *b-raf* gene)
Right-sided location of primary tumor

Abbreviation: CEA, carcinoembryonic antigen.

Cancers of the large bowel generally spread to regional lymph nodes or to the liver via the portal venous circulation. The liver represents the most frequent visceral site of metastasis; it is the initial site of distant spread in one-third of recurring colorectal cancers and is involved in more than two-thirds of such patients at the time of death. In general, colorectal cancer rarely spreads to the lungs, supraclavicular lymph nodes, bone, or brain without prior spread to the liver. A major exception to this rule occurs in patients having primary tumors in the distal rectum, from which tumor cells may spread through the paravertebral venous plexus, escaping the portal venous system and thereby reaching the lungs or supraclavicular lymph nodes without hepatic involvement. The median survival after the detection of distant metastases has increased during the last 30 years from 6–9 months (hepatomegaly, abnormal liver chemistries) to 27–30 months (small

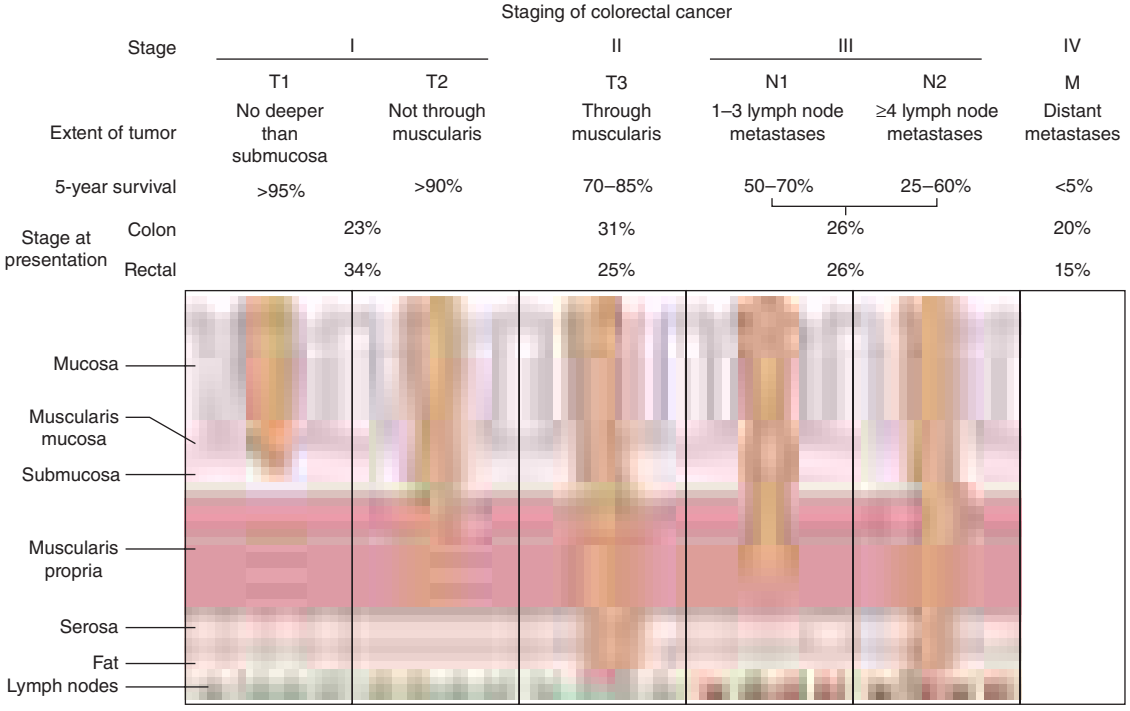

FIGURE 77-3 Staging and prognosis for patients with colorectal cancer.

liver nodule initially identified by elevated CEA level and subsequent CT scan) with increasingly effective systemic therapy improving this prognosis further.

Efforts to use gene expression profiles to identify patients at risk of recurrence or those particularly likely to benefit from adjuvant therapy have not yet yielded practice-changing results. Despite a burgeoning literature examining a host of prognostic factors, pathologic stage at diagnosis remains the best predictor of long-term prognosis. Patients with lymphovascular invasion and high preoperative CEA levels are likely to have a more aggressive clinical course.

TREATMENT

Colorectal Cancer

Total resection of tumor is the optimal treatment when a malignant lesion is detected in the large bowel. An evaluation for the presence of metastatic disease, including a thorough physical examination, biochemical assessment of liver function, measurement of the plasma CEA level, and a CT scan of the chest, abdomen, and pelvis, should be performed before surgery. When possible, a colonoscopy of the entire large bowel should be performed to identify synchronous neoplasms and/or polyps. The detection of metastases should not preclude surgery in patients with tumor-related symptoms such as gastrointestinal bleeding or obstruction, but it often prompts the use of a less radical operative procedure. The necessity for a primary tumor resection in asymptomatic individuals with metastatic disease is an area of controversy. At the time of laparotomy, the entire peritoneal cavity should be examined, with thorough inspection of the liver, pelvis, and hemidiaphragm and careful palpation of the full length of the large bowel. Following recovery from a complete resection, patients should be observed carefully for 5 years by semiannual physical examinations and blood chemistry measurements. If a complete colonoscopy was not performed preoperatively, it should be carried out within the first several postoperative months. Some authorities favor measuring plasma CEA levels at 3-month intervals because of the sensitivity of this test as a marker for otherwise undetectable tumor recurrence. Subsequent endoscopic surveillance of the large bowel, probably at triennial intervals, is indicated, because patients who have been cured of one colorectal cancer have a 3–5% probability of developing an additional bowel cancer during their lifetime and a >15% risk for the development of adenomatous polyps. Anastomotic ("suture-line") recurrences are infrequent in colorectal cancer patients, provided the surgical resection margins were adequate and free of tumor. The value of periodic CT scans of the abdomen, assessing for an early, asymptomatic indication of tumor recurrence, while uncertain, has been recommended annually for the first 3 postoperative years.

Radiation therapy to the pelvis is recommended for patients with rectal cancer because it reduces the 20–25% probability of regional recurrences following complete surgical resection of stage II or III tumors, especially if they have penetrated through the serosa. This alarmingly high rate of local disease recurrence is believed to be due to the fact that the contained anatomic space within the pelvis limits the extent of the resection and because the rich lymphatic network of the pelvic side wall immediately adjacent to the rectum facilitates the early spread of malignant cells into surgically inaccessible tissue. The use of sharp rather than blunt dissection of rectal cancers (*total mesorectal excision*) appears to reduce the likelihood of local disease recurrence to ~10%. Radiation therapy, either pre- or postoperatively, further reduces the likelihood of pelvic recurrences but does not appear to prolong survival. Combining radiation therapy with 5-fluorouracil (5-FU)-based chemotherapy, preferably prior to surgical resection, lowers local recurrence rates and improves overall survival. Preoperative radiotherapy is indicated for patients with large, potentially unresectable rectal cancers; such lesions may shrink enough to permit subsequent surgical removal. Radiation therapy alone is not effective as the primary treatment of colon cancer.

Systemic therapy for patients with colorectal cancer has become more effective. 5-FU remains the backbone of treatment for this disease. Partial responses are obtained in 15–20% of patients. The probability of tumor response appears to be somewhat greater for patients with liver metastases when chemotherapy is infused directly into the hepatic artery, but intraarterial treatment is costly and toxic and does not appear to appreciably prolong survival. The concomitant administration of folinic acid (leucovorin [LV]) improves the efficacy of 5-FU in patients with advanced colorectal cancer, presumably by enhancing the binding of 5-FU to its target enzyme, thymidylate synthase. 5-FU is generally administered intravenously but may also be given orally in the form of capecitabine (Xeloda) with seemingly similar efficacy.

Irinotecan (CPT-11), a topoisomerase 1 inhibitor, has been added to 5-FU and LV (e.g., FOLFIRI) with resultant improvement in response rates and survival of patients with metastatic disease. The *FOLFIRI regimen* is as follows: irinotecan, 180 mg/m^2 as a 90-min infusion on day 1; LV, 400 mg/m^2 as a 2-h infusion during irinotecan administration; immediately followed by 5-FU bolus, 400 mg/m^2, and 46-h continuous infusion of 2.4–3 g/m^2 every 2 weeks. Diarrhea is the major side effect from irinotecan. Oxaliplatin, a platinum analogue, also improves the response rate when added to 5-FU and LV (FOLFOX) as initial treatment of patients with metastatic disease. The *FOLFOX regimen* is as follows: 2-h infusion of LV (400 mg/m^2 per day) followed by a 5-FU bolus (400 mg/m^2 per day) and 22-h infusion (1200 mg/m^2) every 2 weeks, together with oxaliplatin, 85 mg/m^2 as a 2-h infusion on day 1. Oxaliplatin frequently causes a dose-dependent sensory neuropathy that often but not always resolves following the cessation of therapy. FOLFIRI and FOLFOX are equal in efficacy. In metastatic disease, these regimens may produce median survivals of 2 years.

Monoclonal antibodies are also effective in patients with advanced colorectal cancer. Cetuximab (Erbitux) and panitumumab (Vectibix) are directed against the epidermal growth factor receptor (EGFR), a transmembrane glycoprotein involved in signaling pathways affecting growth and proliferation of tumor cells. Both cetuximab and panitumumab, when given alone, have been shown to benefit a small proportion of previously treated patients, and cetuximab appears to have therapeutic synergy with such chemotherapeutic agents as irinotecan, even in patients previously resistant to this drug; this suggests that cetuximab can reverse cellular resistance to cytotoxic chemotherapy. The antibodies are not effective in the ~65% subset of colon tumors that contain mutations in *ras* or *b-raf* genes. The use of both cetuximab and panitumumab can lead to an acne-like rash, with the development and severity of the rash being correlated with the likelihood of antitumor efficacy. Inhibitors of the EGFR tyrosine kinase such as erlotinib (Tarceva) or sunitinib (Sutent) do not appear to be effective in colorectal cancer.

Bevacizumab (Avastin) is a monoclonal antibody directed against the vascular endothelial growth factor (VEGF) and is thought to act as an antiangiogenesis agent. The addition of bevacizumab to irinotecan-containing combinations and to FOLFOX initially appeared to significantly improve the outcome observed with chemotherapy alone, but subsequent studies have suggested a more modest degree of benefit. The use of bevacizumab can lead to hypertension, proteinuria, and an increased likelihood of thromboembolic events.

Preliminary data suggest that the use of checkpoint inhibitors (i.e., PD-1 and PD-2) as immunotherapy is effective in the small subset of patients with metastatic colorectal cancer whose tumors are mismatch repair protein deficient (i.e., microsatellite unstable). Patients with solitary hepatic metastases without clinical or radiographic evidence of additional tumor involvement should be considered for partial liver resection, because such procedures are associated with 5-year survival rates of 25–30% when performed on selected individuals by experienced surgeons.

The administration of 5-FU and LV for 6 months after resection of tumor in patients with stage III disease leads to a 40% decrease in recurrence rates and 30% improvement in survival. The likelihood of recurrence has been further reduced when oxaliplatin has been

combined with 5-FU and LV (e.g., FOLFOX), particularly in patients whose tumor has spread to 4 or more regional lymph nodes (N2). Unexpectedly, the addition of irinotecan to 5-FU and LV as well as the addition of either bevacizumab or cetuximab to FOLFOX did not significantly enhance outcome. Patients with stage II tumors do not appear to benefit appreciably from adjuvant therapy, with the use of such treatment generally restricted to those patients having biologic characteristics (e.g., perforated tumors, T4 lesions, lymphovascular invasion) that place them at higher likelihood for recurrence. The addition of oxaliplatin to adjuvant treatment for patients aged >70 and those with stage II disease does not appear to provide any therapeutic benefit.

In rectal cancer, the delivery of preoperative or postoperative combined-modality therapy (5-FU or capecitabine plus radiation therapy) reduces the risk of recurrence and increases the chance of cure for patients with stage II and III tumors, with the preoperative approach being better tolerated.

CANCERS OF THE ANUS

Cancers of the anus account for 1–2% of the malignant tumors of the large bowel. Most such lesions arise in the anal canal, the anatomic area extending from the anorectal ring to a zone approximately halfway between the pectinate (or dentate) line and the anal verge. Carcinomas arising proximal to the pectinate line (i.e., in the transitional zone between the glandular mucosa of the rectum and the squamous epithelium of the distal anus) are known as *basaloid*, *cuboidal*, or *cloacogenic* tumors; about one-third of anal cancers have this histologic pattern. Malignancies arising distal to the pectinate line have squamous histology, ulcerate more frequently, and constitute ~55% of anal cancers. The prognosis for patients with basaloid and squamous cell cancers of the anus is identical when corrected for tumor size and the presence or absence of nodal spread.

The development of anal cancer is associated with infection by human papillomavirus, the same organism etiologically linked to cervical cancer. The virus is sexually transmitted. The infection may lead to anal warts (condyloma acuminata), which may progress to anal intraepithelial neoplasia and on to squamous cell carcinoma. The risk for anal cancer is increased among homosexual males, presumably related to anal intercourse. Anal cancer risk is increased in both men and women with AIDS, possibly because their immunosuppressed state permits more severe papillomavirus infection. Vaccination against human papilloma viruses appears to reduce the eventual risk for anal cancer. Anal cancers occur most commonly in middle-aged persons and are more frequent in women than men. At diagnosis, patients may experience bleeding, pain, sensation of a perianal mass, and pruritus.

Radical surgery (abdominal-perineal resection with lymph node sampling and a permanent colostomy) was once the treatment of choice for this tumor type. The 5-year survival rate after such a procedure was 55–70% in the absence of spread to regional lymph nodes and <20% if nodal involvement was present. An alternative therapeutic approach combining external beam radiation therapy with concomitant chemotherapy (5-FU and mitomycin C) has resulted in biopsy-proven disappearance of all tumor in >80% of patients whose initial lesion was <3 cm in size. Tumor recurrences develop in <10% of these patients, meaning that ~70% of patients with anal cancers can be cured with nonoperative treatment and without the need for a colostomy. Surgery should be reserved for the minority of individuals who are found to have residual tumor after being managed initially with radiation therapy combined with chemotherapy.

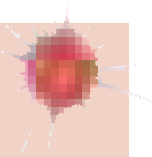
78 Tumors of the Liver and Biliary Tree



Josep M. Llovet

The burden of cancer is increasing worldwide. Lung, breast, and colorectal cancers are the most commonly diagnosed while lung and liver cancers are the most common causes of cancer death. Liver cancer is the sixth most common cancer worldwide, the second leading cause of cancer-related deaths and one of the few neoplasms whose incidence and mortality rates have been steadily increasing. Liver cancer comprises a heterogeneous group of malignant tumors with different histologic features and unfavorable prognosis that range from hepatocellular carcinoma (HCC; 85–90% cases), intrahepatic cholangiocarcinoma (iCCA; 10%), and other malignancies accounting for <1% of tumors, such as fibrolamellar HCC, mixed HCC-iCCA, epithelioid hemangiothelioma, and the pediatric cancer hepatoblastoma. The burden of liver cancer is increasing globally in almost all countries, and it is estimated to reach one million cases by 2030.

HEPATOCELLULAR CARCINOMA

EPIDEMIOLOGY AND RISK FACTORS

Overall, liver cancer accounts for 7% of all cancers (~850,000 new cases each year), and HCC represents 90% of primary liver cancers. The highest incidence rates of HCC occur in Asia and sub-Saharan Africa due to the high prevalence of hepatitis B virus (HBV) infection, with 20–35 cases per 100,000 inhabitants. Southern Europe, and now North America have intermediate incidence rates (10 cases per 100,000), whereas Northern and Western Europe have low incidence rates of less than 5 cases per 100,000 inhabitants. In the United States, liver cancer is ranked number one in terms of increased mortality during the past two decades **(Fig. 78-1)**, with an incidence of 35,000 cases per year. HCC has a strong male preponderance with a male to female ratio estimated to be 2.5. The incidence increases with age, reaching a peak at 65–70 years old. In Chinese and in black African populations (where vertical transmission of HBV occurs), the mean age is 40–50 years. By contrast, in Japan mean age in men is now around 75 years.

The risk factors for HCC are well established **(Fig. 78-2)**. The main risk factor is cirrhosis—and associated chronic liver damage caused by inflammation and fibrosis—of any etiology, which underlies 80% of HCC cases worldwide and results from chronic infection by HBV or hepatitis C virus (HCV) infection, alcohol abuse, metabolic syndrome, and hemochromatosis (associated to *HFE1* gene germ-line mutations). Cirrhotic patients represent 1% of the human population and one-third of them will develop HCC during their lifetime. Long-term follow-up studies have established an annual risk of HCC development of 2% in HBV-infected cirrhotic patients and 3–7% in HCV-infected cirrhotic patients. HCC is less common in cirrhosis associated with alpha-1 antitrypsin deficiency, autoimmune hepatitis, Wilson's disease, and cholestatic liver disorders. Predictors of liver cancer development

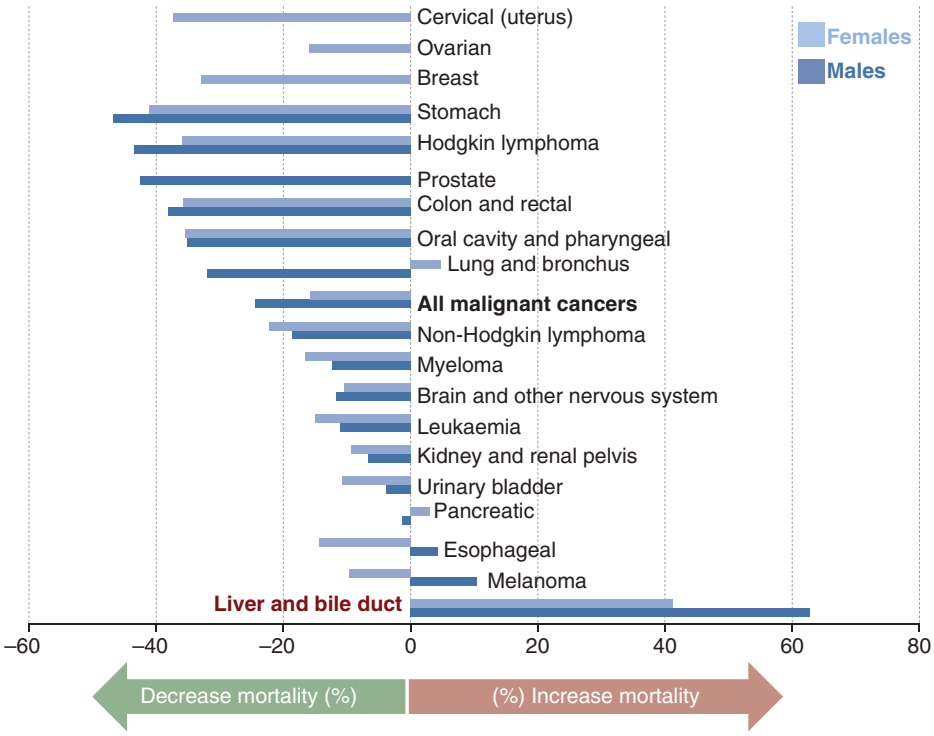


FIGURE 78-1 Mortality trends of patients with different malignancies in the United States between 1990 and 2009. Changes in cancer mortality across tumor types in the United States. Liver and bile duct cancer rank first in terms of increase mortality for both men and women. *(Reprinted with permission from JM Llovet et al: Nat Rev Clin Oncol 12:408, 2015.)*

among cirrhotic patients have been associated with liver disease severity (platelet count of <100,000/mm^3, presence of portal hypertension), the degree of liver stiffness as measured by transient elastography, and liver gene signatures capturing the *cancer field effect*.

In terms of attributable risk fraction, HBV infection—a DNA virus that can cause insertional mutagenesis and affects 400 million people globally—accounts for 50% of HCC cases, and is the predominant cause in Asia and Africa. Among patients with HBV infection, a family history of HCC, HBeAg seropositivity, high viral load and genotype C are independent predictors of HCC development. Chronic treatments with effective antiviral HBV therapies are able to significantly decrease the risk of cancer. HCV infection—an RNA virus that affects 170 million people—is responsible for 30% of cases, and is the main cause of HCC in Europe and North America. Among patients with HCV infection, HCC occurs almost exclusively when relevant liver damage is present (either advanced fibrosis—Metavir F3 [Metavir is a scoring system for hepatic histology that grades fibrosis from 0 to 4 with higher numbers indicating more fibrosis]—or cirrhosis), particularly if associated with HCV genotype 1b. In addition, a polymorphism that activates *EGFR*, the EGF receptor, has been established as associated with HCV-HCC in several studies. Antiviral therapies with interferon regimes are able to prevent cirrhosis development and HCC occurrence. The impact of new direct-acting antiviral (DAA) regimes on HCC incidence has not yet been established.

Alcohol consumption and metabolic syndrome due to diabetes and obesity are responsible for ~20% of cases. Non-alcoholic steatohepatitis (NASH), related to metabolic syndrome, is now an emerging cause of

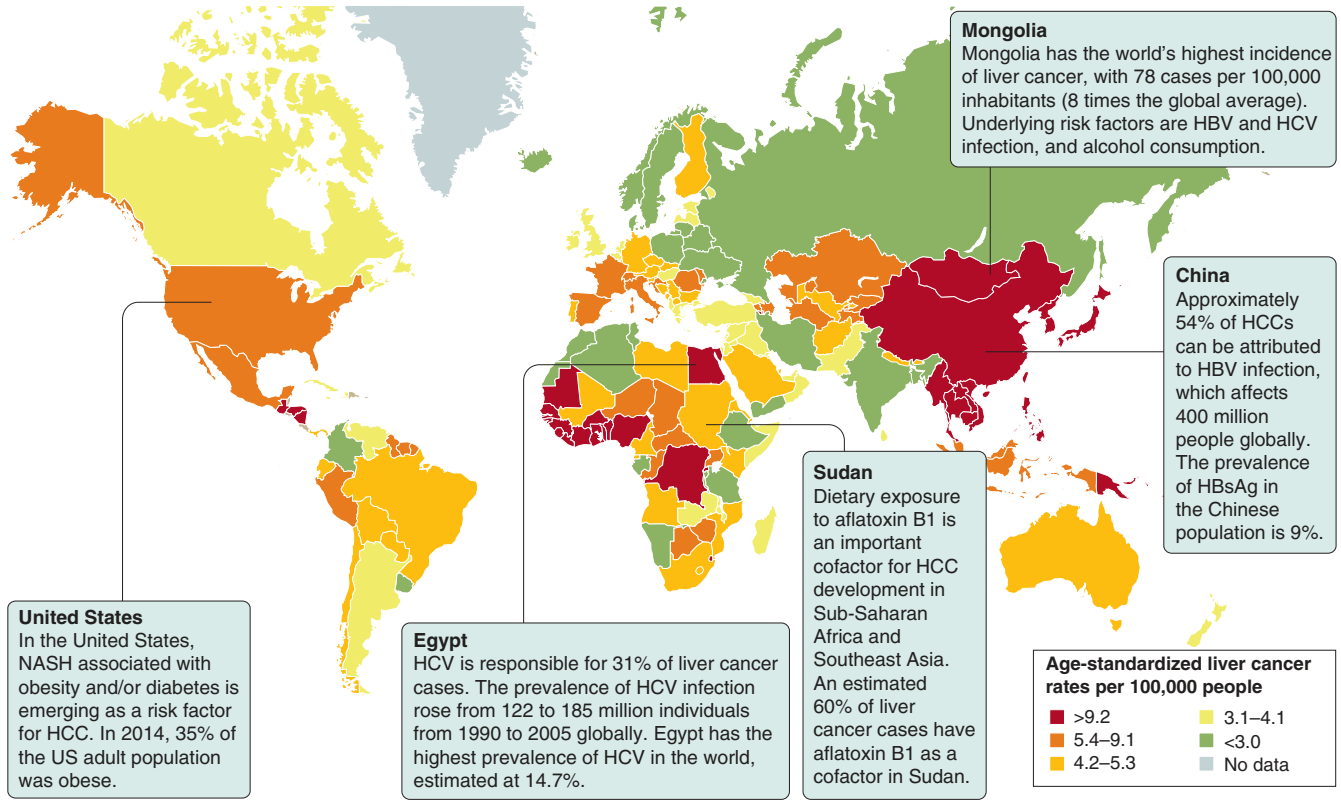

FIGURE 78-2 The global burden of hepatocellular carcinoma. Incidence of hepatocellular carcinoma (HCC) and risk factors. ASR, Age-standardized rate per 100,000 inhabitants. The main risk factors for HCC development are HBV infection (China), HCV infection (example: Egypt), alcohol intake, non-alcoholic steatohepatitis (United States), and aflatoxin B1 (Sudan). Mongolia has the highest incidence of HCC globally, with 78 cases per 100,000 inhabitants. *(Reprinted with permission from JM Llovet et al: Nat Rev Dis Primers 2:16018, 2016.)*

HCC in developed countries. A *PNPLA3* polymorphism is strongly associated with fatty and alcoholic chronic liver diseases and HCC occurrence. Other co-factors contributing to HCC development are tobacco and aflatoxin B1, a fungal carcinogen present in food supplies that induces *TP53* mutations. Finally, infection with adeno-associated virus 2 is associated with HCC in individuals without cirrhosis. Aside from the associations described above, genome-wide association studies have not yet confirmed polymorphisms predisposing to HCC development.

There is a growing incidence of HCC world-wide. The growth in U.S. incidence results from the emergence of end-stage liver disease due to hepatitis C, the increase in HBV-related HCC among immigrants from endemic countries, and the accelerating prevalence of obesity and fatty liver disease. In Europe and Asia, the growth has been less prominent. In some countries the incidence is declining, like Italy and Japan, a country where the impact of HCV-related HCC was first noticed after World War II. Finally, the impact of universal infant vaccination against HBV has decreased the rate of HBV-related HCC in endemic countries, such as Taiwan.

MOLECULAR PATHOGENESIS

HCC development is a complex multistep process that starts with precancerous cirrhotic nodules, so-called low-grade dysplastic nodules (LGDN) that evolve to high-grade dysplastic nodules (HGDN) that can transform into early-stage HCC. Molecular studies support the pivotal role of adult hepatocytes as the cell of origin, either by directly transforming to HCC or by de-differentiating into hepatocyte precursor cells. Alternatively, progenitor cells also give rise to HCC with progenitor markers.

Genomic analysis has provided a clear picture of the main drivers responsible for HCC initiation and progression. This tumor results from the accumulation of around 35–40 somatic genomic alterations per tumor, among which 4–8 are considered driver cancer genes. HCC is a prototypical inflammation-associated cancer, where immune microenvironment and oxidative stress present in chronically damaged livers play pivotal roles in inducing mutations. In pre-neoplastic HGDN, mutations in telomere reverse transcriptase (*TERT*) gene (20% cases) and gains in 8q have been described. Oncogenic transformation occurs upon additional genomic hits including Wnt/β-catenin pathway activation, re-expression of fetal genes, deregulation of protein folding machinery and the response to oxidative stress. Genomic studies and next-generation sequencing conducted during the past decade enables a description of the landscape of mutations, signaling pathways and a molecular classification of the disease. Nonetheless, none of these data have yet translated into actual clinical benefits for molecularly defined tumor subgroups.

Molecular Drivers The landscape of mutational drivers in HCC identified by deep-genome sequencing of ~1,000 samples is detailed in Table 78-1. The most common mutations are in the telomerase reverse transcriptase (*TERT*) promoter (56%), *TP53* (27%), *CTNNB1* (26%), *ARID2* (7%), *ARID1A* (6%), and *AXIN1* (5%) genes. These mutated genes participate in cell-cycle control and senescence -*TERT* or *TP53*-, in cell differentiation—*CTNNB1* and *AXIN-1*, and chromatin remodeling -*ARID2* and *ARID1A*-. Genes commonly mutated in other solid tumors such as *EGFR*, HER2, *PIK3CA, BRAF*, or *KRAS* are rarely mutated in HCC (<5%). Thus, the most prominent drivers are not currently targetable. Some risk factors have been associated with specific molecular aberrations. HBV integrates into the genome of driver genes, such as the *TERT* promoter, *MLL4*, and cyclin E1 (*CCNE1*). HCV infection and alcohol abuse have been significantly associated with *CTNNB1* mutations. *TP53* mutations are the most frequent alterations with a specific hotspot of mutation (R249S) in patients with aflatoxin B1 exposure.

Studies assessing copy-number alterations in HCCs have consistently identified: (i) high level amplifications at 5–10% prevalence containing oncogenes in 11q13 (CCND1 and *FGF19*) and 6p21 (*VEGFA*), *TERT* focal amplification and homozygous deletion of *CDKN2A*; and (ii) common amplifications containing *MYC* (8q gain) and *MET* genes (focal gains 7q31). High-level amplifications of 11q13 include *CCND1* and *FGF19*, which have been demonstrated as prominent oncogenes in HCC and are potential therapeutic targets. Similarly, high-level gains of 6p21 containing more than four copies of *VEGFA* were identified in 4–8% of HCCs. *VEGFA* amplification can induce tumor proliferation by unleashing macrophage-mediated hepatocyte growth factor secretion.

TABLE 78-1 Molecular Aberrations Common in HCC[a]

PATHWAY	TARGET	PREVALENCE (%)
Mutations		
Telomere stability	*TERT* promoter	56
p53/cell cycle control	*TP53*	27

[a]Recurrent mutations, focal amplifications or homozygous deletions in HCC based on next-generation sequencing analyses.

Signaling Pathways Several signaling pathways have been implicated in HCC progression and dissemination. Activation of these pathways can result from structural alterations (mutations and amplifications/losses), or epigenetic modifications. In brief, (a) TERT overexpression occurs in 90% of cases, particularly related to promoter *TERT* mutations or amplifications; (b) inactivation of p53 and alterations of cell cycle are major defects in HCC, particularly in cases related to HBV infection; (c) Wnt/β-Catenin pathway activation occurs in 50% of cases, either as a result of β-catenin or *AXIN1* mutation, or overexpression of Frizzled receptors or inactivation of E-cadherin; (d) PI3K/PTEN/Akt/mTOR pathway is activated in 40–50% of HCCs due to mutation and focal deletion of the tuberous sclerosis complex (*TSC*)*1*/*TSC2* genes, *PTEN* or ligand overexpression of EGF or IGF upstream signals; (e) Ras MAPK signaling is activated in half of early and almost all advanced HCCs, activation results from up-stream signaling by EGF, IGF, and MET activation, and from the epigenetic silencing of tumor suppressors such as *NORE1A* and *RASSF1A15*; (f) insulin-like growth factor receptor (IGFR) signaling is activated in 20% of cases through overexpression of the oncogenic ligand IGF2 or allelic loss affecting the tumor suppressor IGF2R; (g) dysregulation of the c-MET receptor and its ligand HGF, critical for hepatocyte regeneration after liver injury, are common events in advanced HCC (50%); (h) vascular endothelial growth factor (VEGF) signaling is the cornerstone of angiogenesis in HCC, along with activated angiogenic pathways such as Ang2 and FGF signaling; and (i) chromatin remodelling complexes and epigenetic regulators are frequently altered in HCC due to *ARID1A* and *ARID2* mutations. Several agents that target these different processes are currently being tested in Phase I-III trials.

Molecular Classes and Prognostic Gene Signatures Genomic studies have revealed two molecular subclasses of HCC, each representing ~50% of patients. The proliferative subclass is enriched by activation of Ras, mTOR, and insulin-like growth factor (IGF) signaling

and *FGF19* amplification, and is associated with HBV-related etiologies, overexpression of α-fetoprotein and poor outcomes (particularly those tumors enriched in progenitor cell markers). By contrast, the so called non-proliferative subclass contains a subtype characterized by *CTNNB1* mutations and better outcome. Another classification based upon immune status has been proposed. It defines an immune HCC class in ~25% of cases characterized by immune infiltrate with expression of PD1/PDL1, enrichment of T-cell activation, and better outcome. Direct translation of molecular subclasses into clinical decision-making is yet to be achieved.

PREVENTION AND EARLY DETECTION

Prevention Primary prevention of HCC can be achieved by vaccination against HBV and effective treatment of HBV and HCV infection. Studies assessing the impact of universal vaccination against HBV infection started in Taiwan in 1984 have reported a significant decrease of the incidence of HCC. Nowadays, HBV vaccination is recommended to all newborns and high risk groups, following World Health Organization guidelines. Vaccination is also recommended in people with risk factors for acquiring HBV infection, such as health workers, travelers to areas where HBV-infection is prevalent, injecting drug users, and people with multiple sex partners.

Effective antiviral treatments for patients with chronic HBV infection—achieving undetectable viral titres (circulating HBV-DNA)—reduce the risk of HCC development. Evidence of this effect is supported by one randomized trial and several cohort studies. Regarding HCV infection, eradication of hepatitis C results in decreased HCC incidence. Anti-viral therapies achieving a sustained virological response (SVR) in patients with chronic hepatitis prevent the development of advanced stage disease and cirrhosis, hence resulting in a decreased risk of HCC development. However, once cirrhosis is established no high-level evidence suggests that SVR leads to HCC prevention. A meta-analysis of observational studies concluded that interferon-based regimens achieving SVR in patients with cirrhosis were associated with a substantially reduced risk of HCC development. Treatment of HCV has dramatically advanced with the new DAAs (drug antiviral agents) that yield >90% SVR rates after 12 weeks of treatment. A few observational studies with a short follow-up reported an HCC annual incidence of 3–5% in patients with cirrhosis following successful DAA therapy, an incidence similar to that of untreated patients, and higher than those observed with interferon-based therapies. Similarly, there is controversy on the effect of DAA-based SVR on HCC recurrence after curative therapies. Some studies suggest a 6-month recurrence rate higher than historical controls, thus emphasizing the need for large prospective studies. It is too early to estimate the effect of DAA therapy on the burden of HCC. Due to all these circumstances, surveillance remains recommended in patients with cirrhosis achieving SVR.

Additional putative chemopreventive agents have been proposed to reduce HCC incidence in at-risk populations, including statins and metformin. Nonetheless, the evidence is not strong enough to recommend using these therapies in at-risk patients. Finally, coffee consumption is associated with a reduced risk of HCC in population studies.

Surveillance The aim of surveillance is to obtain a reduction in disease-related mortality. This is usually achieved through early detection that enhances the applicability and cost-effectiveness of curative therapies. United States and European guidelines recommend surveillance for patients at high risk for HCC on the basis of cost-effectiveness analyses. As a general rule, high-risk populations are considered those presenting an incidence cut-off > 1.5% for patients with cirrhosis and 0.2% for patients with chronic hepatitis B. However, the strength of evidence supporting surveillance is modest, and is based upon two randomized studies conducted in China and meta-analysis of observational studies. Overall, these studies conclude that surveillance identifies patients with smaller tumors who are more likely to undergo curative procedures. Because of lead time bias and length time bias it cannot be concluded that surveillance ultimately reduces HCC-related mortality.

Surveillance is recommended for cirrhotic patients owing to any cause, those with HCV-related advanced fibrosis (Metavir score of F3), and for patients with chronic HBV infection if Asian aged >40 years, African aged >20 years or family history of HCC. In terms of liver dysfunction, the presence of advanced cirrhosis (Child-Pugh class C) prevents potentially curative therapies from being employed, and thus surveillance is not recommended. As an exception, patients on the waiting list for liver transplantation, regardless of liver functional status, should be screened for HCC in order to detect tumors exceeding conventional criteria and to define priority policies for transplantation. Complex scoring systems to identify at-risk populations are not yet recommended by guidelines.

Ultrasonography every 6 months is the recommended method of surveillance. It has a sensitivity of 65–80% and a specificity of >90% for early detection. A 3-month interval does not enhance outcomes, and survival is lower with 12 month compared with 6 month intervals. A shorter follow-up interval (every 3–4 months) is recommended when a nodule of <1 cm has been detected. Computed tomography (CT) and magnetic resonance imaging (MRI) are not recommended as screening tools due to lack of data on accuracy, high cost and possible harm (i.e., radiation with CT). Exceptionally, these techniques can be considered in patients with obesity and fatty liver, where visualization with ultrasound is difficult. Accurate tumor biomarkers for early detection need to be developed. Use of alpha-fetoprotein (AFP) levels identifies patients with HCC with 60% sensitivity, but high false-positive results. One main limitation of AFP is that only a small proportion of early tumors (~20%) present with abnormal AFP serum levels. Combining AFP with ultrasound performed by experienced personnel only increase 6–8% the HCC detection rate. Nonetheless, testing AFP is still widely used and this remains an area of controversy. Particularly, testing AFP might be considered in special populations or health care environments when ultrasound is not available. The accuracy of other serum biomarkers proposed, such as des-γ carboxyprothrombin (DCP) and the L3 fraction of AFP (AFP-L3), in early detection is not known.

Despite the fact that surveillance is cost-effective in HCC, the global implementation of such programs is estimated to engage ~50% of the target population in Europe and ~30% in the United States. Public health policies encouraging the implementation of such programs should lead to an increase in early tumor detection.

Diagnosis HCC is generally diagnosed at early or intermediate stages in Western countries, but at advanced stages in most Asian (except Japan) and African countries. A surveillance program yields early diagnosis in 70–80% of cases. At these stages the tumor is asymptomatic, and diagnosis can be made by non-invasive (radiological) or invasive (biopsy) approaches. Without surveillance, HCC is discovered either as a radiological finding or due to cancer-related symptoms. If symptoms are present the disease is already at an advanced stage with a median life expectancy <1 year. Symptoms include malaise, weight loss, anorexia, abdominal discomfort, or signs related to advanced liver dysfunction.

NON-INVASIVE (RADIOLOGICAL) DIAGNOSIS Patients enrolled in a surveillance program are diagnosed by identification of a new liver nodule on abdominal ultrasound. Non-invasive criteria can only be applied to cirrhotic patients and are based on imaging techniques obtained by 4-phase multidetector CT scan (four phases are unenhanced, arterial, venous, and delayed) or dynamic contrast-enhanced MRI. A flow-chart of diagnosis and recall policy recommended by U.S. and European guidelines is summarized in Fig. 78-3. Radiological diagnosis is achieved with a high degree of confidence if the lesion is ≥2 cm in diameter and shows the *radiological hallmarks of HCC* by one imaging technique. Using contrast-enhanced imaging techniques, the typical hallmark of HCC consists of vascular uptake of the nodule in the arterial phase with washout in the portal venous or delayed phases. This radiological pattern captures the hypervascular nature characteristic of HCC. In these scenarios the diagnostic specificity is ~95–100% and a biopsy is not necessary. For lesions 1–2 cm in diameter, the radiological hallmarks of HCC define diagnosis, but need to be confirmed by two imaging techniques in non-specialized centers. Nodules <1 cm in size are unlikely to be HCC and would be very difficult to diagnose, and thus ultrasound follow-up at 3–4 months is recommended. MRI with liver specific contrast agents might help in the diagnosis of HCC, but

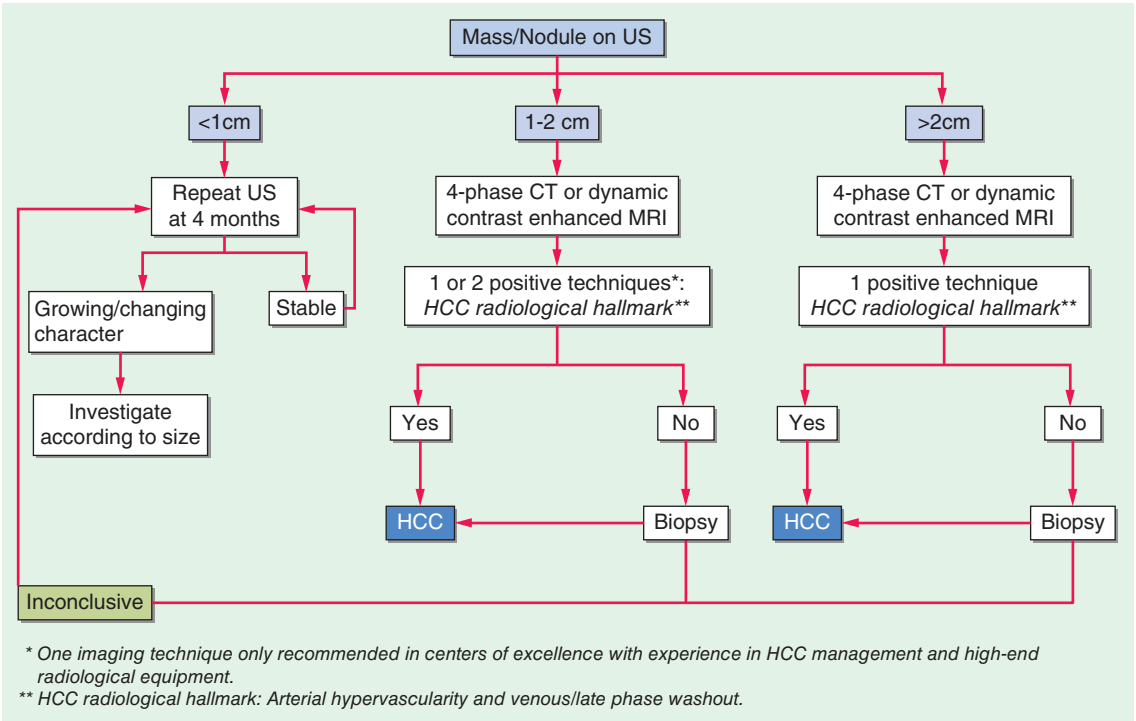

FIGURE 78-3 Recall diagnosis schedule for HCC (EASL). EASL, European Association for the Study of Liver Disease; HCC, hepatocellular carcinoma. *(Reprinted with permission from EASL-EORTC guidelines. J Hepatology 56: 908, 2012.)*

the specificity of these agents is still suboptimal. Contrast-enhanced ultrasound (CEUS) and angiography are less accurate for HCC diagnosis. Positron emission tomography (PET)-scan performs poorly for early diagnosis. AFP levels ≥ 400 ng/dL are highly suspicious, but not diagnostic of HCC according to guidelines.

PATHOLOGICAL DIAGNOSIS Pathological diagnosis is required in two scenarios: (a) in patients without cirrhosis, and (b) if radiology is not typical in at least one of two imaging techniques (CT and MRI). This occurs mainly with early-stage HCC lesions. Biopsy is not an ideal gold standard, because of variation introduced by sampling and complications. Sensitivity of liver biopsies ranges between 70 and 90% for all tumor sizes, but decrease to <50% in tumors 1–2 cm in size. The risk of complications such as tumor seeding and bleeding after liver biopsy is ~3%. Biopsies should be assessed by an expert hepatopathologist. The use of special stains may help to resolve diagnostic uncertainties. Positive staining in two of four markers [glypican 3 (GPC3), glutamine synthetase, heat shock protein 70 (HSP70), and clathrin heavy chain] is highly specific for HCC. Gene expression blueprints (glypican 3, LYVE1, and survivin) are also able to differentiate high grade dysplastic nodules from early HCC. Additional staining can be considered to detect progenitor cell features (K19 and EpCAM) or assess neovascularization (CD34). A negative biopsy does not eliminate the diagnosis of HCC. A second biopsy is recommended in case of inconclusive findings, or growth or change in enhancement pattern identified during follow up. European guidelines advocate obtaining tissue samples in the setting of all research studies in HCC, even if radiological criteria are met.

TREATMENT

Staging Systems and Treatment Allocation Staging systems are aimed at stratifying patients according to prognostic factors and outcome, and to allocate the best available therapies according to evidence. The most accepted staging system is the Barcelona-Clinic-Liver Cancer (BCLC) Classification, which is endorsed by U.S. and European clinical practice guidelines (Fig. 78-4). This staging system defines five prognostic subclasses and allocates specific treatments for each stage. The BCLC staging system has been externally validated by numerous studies. It is an evolving system that allows incorporation of new therapies and treatment-dependent variables as new evidence emerges. Six treatments have been demonstrated to improve survival in HCC, five are adopted by guidelines and BCLC classification: surgical resection, liver transplantation, radiofrequency (RF) ablation, chemoembolization, and systemic therapies (sorafenib, regorafenib, lenvatinib, cabozantinib, ramucirumab). The BCLC system will also incorporate lenvatinib in first line and regorafenib as standard of care in patients with advanced HCC progressing on sorafenib as a consequence of a positive randomized controlled trial (RCT). The BCLC assigns each patient with a given treatment allocation. Treatment stage migration is also applied by this scheme, meaning that if patients are not candidates for the selected therapy, the next effective therapy at more advanced stages can be given.

In HCC, three parameters are relevant for defining treatment strategy: tumor status, cancer-related symptoms, and liver dysfunction. The BCLC staging captures all three variables and allocates patients to treatments according to evidence. Since >80% of patients have two diseases, HCC and cirrhosis, a clear measurement of liver dysfunction should be in place. The prognosis of chronic liver disease is commonly assessed using the Child-Pugh score, which uses five clinical measures—total bilirubin, serum albumin, prothrombin time, ascites severity, and hepatic encephalopathy grade—to classify patients into one of three groups (A–C) of predicted survival rates. In brief, Child-Pugh's A reflects well-preserved liver function, Child's B moderate liver dysfunction with a median life expectancy of ~3 years and Child C severe liver dysfunction with life expectancy of ~1 year. At early BCLC stages more granular criteria to define patients with very-well preserved liver function (Child-Pugh's hyper-A class without portal hypertension) needs to be in place to select candidates for resection. Modifications of Child-Pugh scoring or model for end-stage liver disease (MELD) score have not been adopted for treatment allocation, except for prioritization on the waiting list for liver transplantation (MELD score). More sophisticated measures of liver dysfunction (i.e., assessment of portal hypertension) are recommended for preoperative assessment of candidates for resection. Performance status is assessed by Eastern Cooperative Oncology Group (ECOG) and presence of cancer-related symptoms (ECOG 1-2) is considered a sign of advanced stage. Patients with severe liver dysfunction (Child-Pugh's C class) or performance status impairment (ECOG 3-4) are offered supportive care management.

Considering all these prognostic/predictive variables and evidence-based treatment efficacy, five BCLC stages have been defined

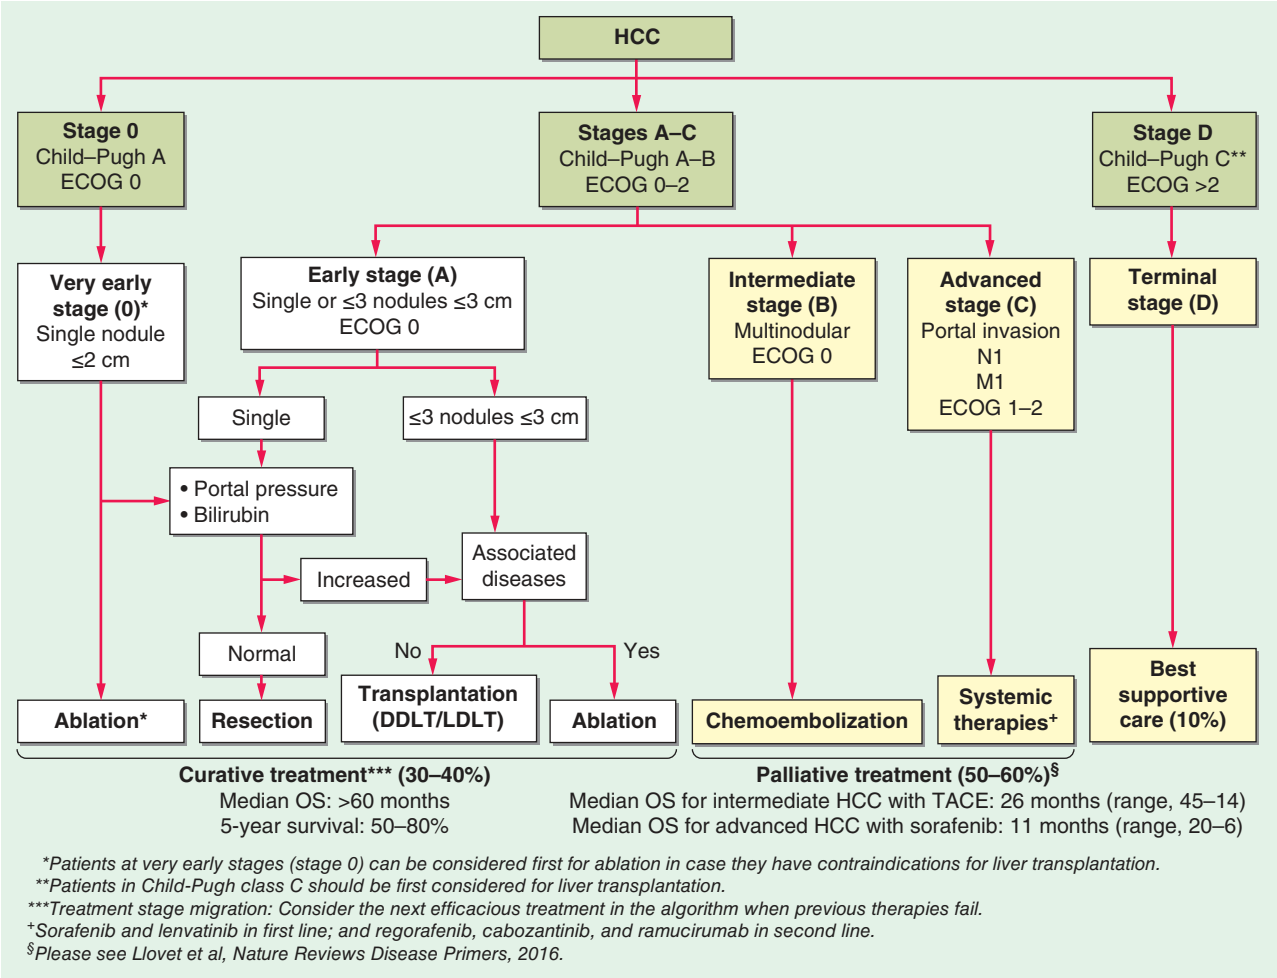

FIGURE 78-4 BCLC staging system and therapeutic strategy. BCLC classification comprises five stages that select the best candidates for therapies according to evidence-based data. Patients with asymptomatic early tumors (stages 0–A) are candidates for radical therapies (resection, transplantation, or local ablation). Asymptomatic patients with multinodular HCC (stage B) are suitable for transcatheter arterial chemoembolization (TACE), whereas patients with advanced symptomatic tumors and/or an invasive tumoral pattern (stage C) are candidates to receive sorafenib. End-stage disease (stage D) includes patients with poor prognosis that should be treated by best supportive care. BCLC, Barcelona Clinic Liver Cancer; DDLT, deceased donor liver transplantation; EASL, European Association for the Study of Liver Disease; ECOG, Eastern Cooperative Oncology Group Performance Status; EORTC, European Organisation for Research and Treatment of Cancer; GRADE, grading of recommendations assessment, development, and evaluation; HCC, hepatocellular carcinoma; LDLT, living donor liver transplantation; OS, overall survival; PEI, percutaneous ethanol injection; RF, radiofrequency ablation; TACE, transcatheter arterial chemoembolization. *(Reprinted with permission from JM Llovet et al: Nat Rev Dis Primers 2:16018, 2016; A Forner, JM Llovet, J Bruix: Hepatocellular carcinoma. Lancet 379:1245, 2012.)*

(Fig. 78-4). Patients with liver only neoplastic disease, no symptoms (ECOG 0) and with mild to moderate liver dysfunction (Child-Pugh A-B) can be classified as very early (Stage 0) or early (Stage A) or intermediate (stage B) stages depending upon tumor size and number. Very early HCC (BCLC 0) is defined by single tumors ≤2 cm (if pathology is available they should be well-differentiated with absence of microvascular invasion or satellites). Early HCC (BCLC A) includes either single tumors or a maximum of three nodules of ≤3 cm in diameter. Intermediate stage (BCLC B) is defined by all other liver-only tumors. Conversely, HCC is considered at advanced stages (BCLC C) when patients present cancer-related symptoms (ECOG 1-2) or tumors with macrovascular invasion (of any type, including branch, hepatic, or portal vein), lymph node involvement, or extrahepatic spread. Finally, end-stage disease (BCLC D) is considered in cases of several impairment of quality of life/cancer-related symptoms (ECOG 3-4) or severe liver dysfunction (Child-Pugh C).

Around 40% of patients are diagnosed at Stages 0 and A, and hence are eligible for potentially curative therapies, resection, transplantation, or local ablation. These treatments provide median survival rates of 60 months and beyond, which are in sharp contrast with outcomes of 36 months reported in historical controls **(Fig. 78-5)**. No adjuvant therapy is recommended. Patients at intermediate stage (Stage B) with preserved liver function have a documented natural history of around 16 months. These patients benefit from transarterial chemoembolization (TACE) as reported in two randomized studies and one meta-analysis, and achieve an estimated survival of 25–30 months. None of the combination therapies with TACE have shown outcome advantages. Patients progressing on TACE or at advanced stage (Stage C) benefit from systemic sorafenib, which extends survival by ~3 months (from 7.9 to 10.7 months). Lenvatinib showed non inferiority results compared to sorafenib (13.6 months vs. 12.3 month, respectively). Regorafenib improves survival from 7.8 to 10.6 months in patients progressing on sorafenib (second-line advanced HCC). Therefore, these treatments have been adopted by guidelines and incorporated to the BCLC classification. Patients with end-stage disease (BCLC D) should be considered for nutritional and psychological support and proper management of pain.

Although the BCLC establishes validated stages and treatment assignment according to evidence, clinical practice is not always aligned with this classification. In large cohort studies and surveys, only half of patients, or even less in Asia, are treated accordingly. Alternative staging or scoring systems have been proposed, but none of them has acquired global consensus. In contrast to BCLC, some proposed systems capture the standard of practice in Asia, such as the Hong Kong classification or the Japan Integrated Staging score. These systems capture extended indications for resection and TACE applied in clinical practice in Asia. Other systems define prognostic stratification, such as the Cancer of the Liver Italian Program (CLIP) score, although they do not incorporate treatment allocation to distinct stages.

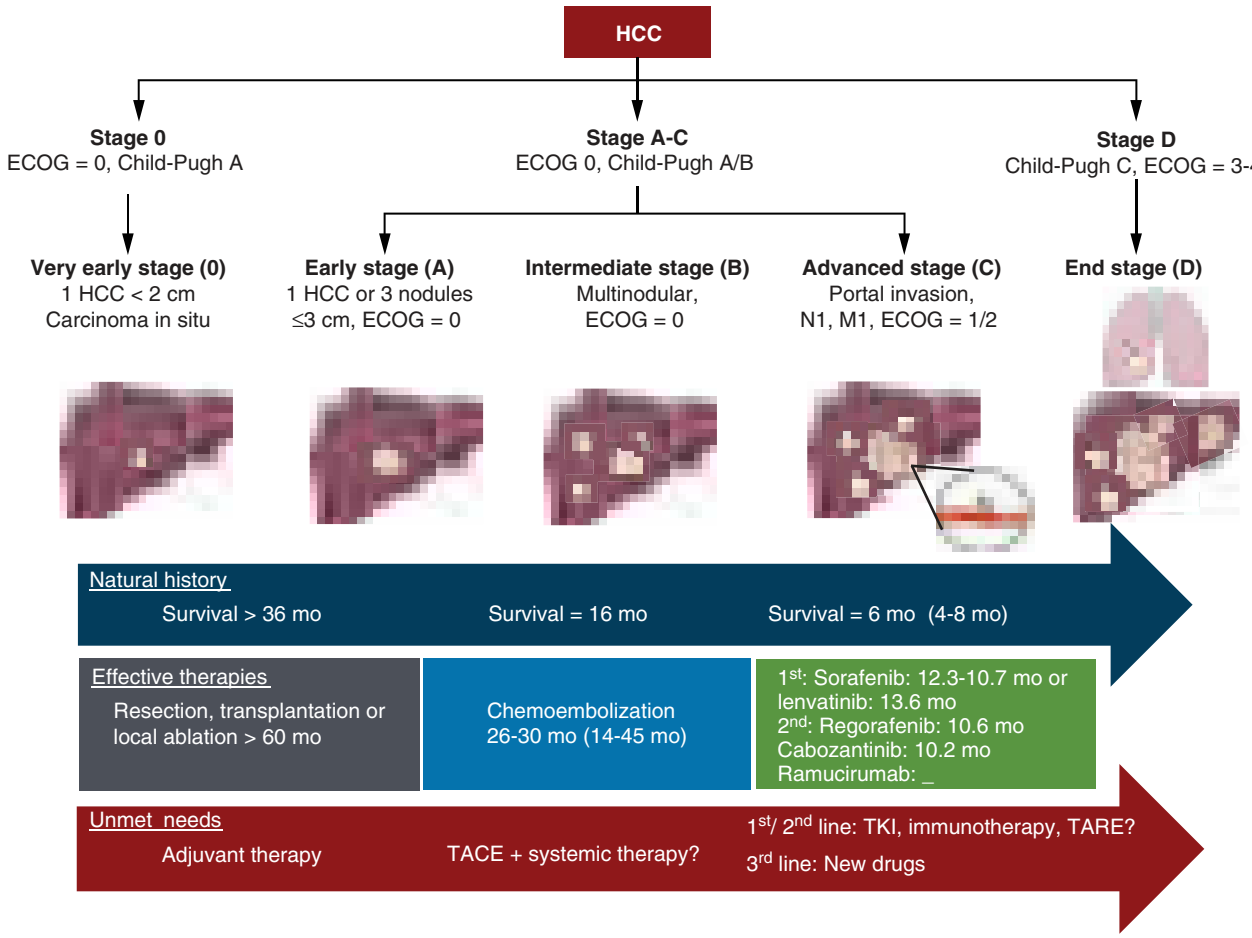

FIGURE 78-5 Natural history, impact of therapies, and unmet needs in HCC.

Finally, the tumor-node-metastasis (TNM) staging system is not used in HCC since it does not incorporate the main prognostic variables related to liver function and performance status.

The BCLC system does not incorporate molecular classes or biomarkers. Some biomarkers (i.e., AFP at a cut-off of >200 or 400 ng/mL) or molecular classes/signatures have prognostic or biological significance. However, they are not ready for clinical application due to the lack of data on biomarker-based response to therapies. A few Phase III studies are currently conducted based upon biomarker-enriched populations (i.e., ramucirumab in AFP >400 ng/mL) or as proof-of-concept studies (i.e., FGFR4 inhibitors in patients with FGF19 amplification/overexpression). Ramucirumab trial has been positive, and thus biomarkers will be incorporated in the treatment allocation system.

Due to the complexities of HCC diagnosis and management, it is recommended to send patients to a referral center where all the armamentarium of therapies can be offered. In principle, patient management and outcome benefit from liver cancer multidisciplinary programs that include hepatologist, oncologist, hepatobiliary and transplant surgeons, interventional and body imaging radiologist, hepatopathologist, and specialized nurses.

SURGICAL THERAPIES

Resection Surgical resection is the first-line option for non-cirrhotic patients at early-stage HCC (BCLC 0 or A) with solitary tumors (Fig. 78-4). In cirrhotic patients, ablation competes with resection for BCLC 0 tumors (<2 cm in diameter). Which is better is not defined. Cost-effectiveness approaches report a benefit for local ablation with RF. For single tumors >2 cm (BCLC A), resection remains the mainstay of treatment in patients with Child-Pugh's hyper-A class, those patients with normal bilirubin and absence of portal hypertension (portal hypertension is defined by hepatic venous pressure gradient ≥10 mmHg). Surrogate measures of portal hypertension are presence of esophageal varices or platelet count <100,000/mm^3 associated with splenomegaly. Anatomic resections following the functional segments of the liver are recommended to spare uninvolved liver parenchyma and to remove satellite tumors. Predictors of recurrence are tumor size, number, presence of microsatellites, or microvascular invasion at the specimen analysis. Macrovascular invasion, extrahepatic involvement, and liver dysfunction (Child-Pugh B-C) are major contraindications for resection.

ADJUVANT TREATMENTS Tumor recurrence represents the major complication of resection (and local ablation) and occurs in 70% of cases at 5 years. Most of recurrences are intrahepatic metastases, but at least one third are considered *de novo* tumor, new clones developing in the cirrhotic carcinogenic field. The type of recurrence can only be defined by molecular studies. So far, no adjuvant therapies have proven to improve outcome or prevent recurrence after resection/ablation. Randomized trials testing adjuvant sorafenib, retinoids, chemotherapies or chemoembolization have been negative. Some trials testing adoptive immunotherapy or interferon showed positive results, but these treatments have not been adopted by guidelines of management due to weakness of the evidence or small magnitude of benefit. Therefore, the current recommendations are that in case of recurrence patients will be re-assessed by BCLC staging, and re-treated accordingly.

Liver Transplantation Liver transplantation is the first treatment choice for cirrhotic patients with single tumors ≤5 cm and portal hypertension (including Child-Pugh's B and C) or with small multinodular tumors (≤3 nodules, each ≤3 cm) (Fig. 78-4). These so-called Milan criteria have been validated over the years and a meta-analysis reported 5-year and 10-year survival rates of ~70 and ~50%, respectively, similar to outcomes achieved in non-HCC transplantation indications. Perioperative mortality rates have been reduced to <3%. Transplantation simultaneously cures the tumor and the underlying cirrhosis, and it is associated with a low risk of recurrence, around 10–15% at 5 years. No immunosuppressive regimens or anti-tumor therapies

after transplantation have demonstrated any preventive effect on recurrence. Milan criteria are integrated in the BCLC treatment strategy (BCLC 0 and A) and have also been adopted by the United Network for Organ Sharing (UNOS) pre-transplant staging for organ allocation in the United States (Stage T2). Aside from size and number, conventional contraindications for organ transplantation procedures (ABO incompatibility, co-morbidities, etc.) are applied in this setting.

Liver transplantation has a couple of important limitations, such as cost and donor availability, which limit this procedure to <5% of HCC cases. The scarcity of donors represents a major drawback of liver transplantation. Donor scarcity varies geographically, and deceased liver donation is almost zero in some Asian countries. Due to the shortage of donors, median waiting times in Western programs is ~6–12 months leading to 20% of candidates dropping off the list due to tumor progression before receiving the procedure. Predictors of drop-out are treatment failure, baseline AFP >400 ng/mL or steady increase of AFP level >15 ng/mL per month. Several strategies have been proposed to overcome this limitation. First, apply neo-adjuvant therapies in patients on the waiting list. Neo-adjuvant treatments testing TACE or RF ablation have been assessed in the setting of cohort and cost-effectiveness studies. In principle, the use of these therapies is recommended when the waiting time exceeds 6 months, even though impact on long-term outcome is uncertain. Second, a priority policy has been established for patients enlisted. UNOS has implemented a scoring system based upon the dropout risk, giving priority to tumors 2–5 cm in size and multinodular tumors.

The Milan criteria are universally used as the basis for transplant eligibility, and adherence to them yields good post-transplant survival. Modest expansion of Milan criteria applying the "up-to-seven" criteria (i.e., those HCCs having the number 7 as the sum of the size of the largest tumor and the number of tumors) in patients without microvascular invasion achieves competitive outcomes. These pathologically-defined criteria are being used in clinical practice to predict the expected outcome after transplantation. Similarly, *down-staging to Milan criteria* is currently explored by several groups. Down-staging is defined as the reduction of HCC burden by loco-regional treatments to achieve Milan staging before transplantation. A few studies claim that down-staging lasting for >3 months achieves competitive outcomes, but robust long-term survival data is scarce, and thus it cannot yet be recommended. Down-staging policy is only endorsed by guidelines for patients outgrowing the Milan criteria while on the waiting list.

Since policies for enhancing organ donation have reached a ceiling during the past several years, alternatives to donation have emerged. Living donor liver transplantation represents a plausible alternative that accounts of ~5% of total transplantations performed globally. Outcomes reported are similar to those with deceased liver donors, and it is recommended as an alternative option in patients on a waiting list exceeding 6–7 months. The risks and benefits of this procedure should take into account both donor (death is estimated in 0.3%) and recipient, a concept known as *double equipoise*. Due to the complexity of this treatment, it must be restricted to centers of excellence in hepatobiliary surgery and transplantation.

LOCO-REGIONAL THERAPIES

Local Ablation RF ablation is recommended as the primary ablative technique (Fig. 78-4). The energy generated by RF ablation (heating of tissue at 80°–100°C) induces coagulative necrosis of the tumor producing a *safety ring* in the peritumoral tissue, which might eliminate small-undetected satellites. Treatment consists of 1 or 2 sessions performed using a percutaneous approach, although in some instances ablation with laparoscopy is needed. RF ablation is more effective in response rate and time-to-recurrence compared with the once-conventional percutaneous ethanol injection. Long-term outcome of HCC patients treated by RF ablation have 5-year survival rates of ~60%. In tumors <2 cm, BCLC 0, RF ablation achieves complete responses in >90% of cases with good long-term outcome and is competitive with resection in terms of cost-effectiveness. For BCLC A cases, RF ablation is the first-line treatment for single tumors 2–5 cm or multinodular up to three nodules, each ≤3 cm in diameter, unsuitable for surgery.

The main limitation of RF ablation is that its failure rate increases in tumors >3 cm because of the heat loss due to perfusion-mediated tissue cooling within the area ablated. In tumors 3–5 cm in diameter, complete pathological tumor necrosis of <50% has been reported. Particularly, ~10–15% of tumors with difficult-to-treat locations, such as a subcapsular location or adjacent to the gallbladder, have a higher risk of incomplete ablation or major complications and can be approached by ethanol injection. Several approaches have been proposed to enhance the anti-tumor activity of RF ablation. The combination of RF ablation with either chemoembolization or with a heat-activated formulation of liposomal doxorubicin yielded good results in cohort studies. Other treatments, such as microwave ablation, high-intensity focused ultrasound or stereotactic body radiotherapy for small tumors are under investigation.

Chemoembolization TACE is the most widely used primary treatment for unresectable HCC worldwide, and the first-line indication for patients with intermediate BCLC B stage (Fig. 78-4). Conventional chemoembolization (c-TACE) consists of the local hepatic artery administration of chemotherapy (either doxorubicin 50 mg/m^2 or cisplatin) mixed with an emulsion of lipiodol followed by obstruction of the feeding artery with sponge particles. c-TACE mainly benefits patients with liver-only disease, Child-Pugh A Class, or B without ascites, good performance status (ECOG 0), and absence of branch or trunk vascular invasion. Median survival is ~20 months (compared to 16 months for pooled control arms). The best randomized trial and subsequent Phase II studies have provided median survivals for TACE of 25–30 months in properly selected populations. Median objective response rates are of 50–70%. In randomized studies, the treatment is performed at a regular schedule of 0, 2, and 6 months (median number of sessions: 3), although no consensus has been established. TACE procedures should be stopped upon tumor progression or any other contraindication. Exceptionally, occurrence of a new small untreated nodule as the only progression feature can be considered for treatment. Around ~50% of patients present a limited postembolization syndrome of fever and abdominal pain related to ischemic injury and release of cytokines. Less than 5% of patients present major complications (liver abscess, ischemic cholecystitis, or liver failure) and in <2% of cases treatment-related death occurs.

Applicability of c-TACE in BCLC B patients is limited to half of cases, mostly as a result of the presence of liver failure (Child B, or ascites or encephalopathy), technical contraindications to the procedure (i.e., impaired portal-vein blood flow), or infiltrative/massive tumor burden (i.e., generally main tumor size >10 cm). Super-selective TACE minimize the ischemic insult to non-tumor tissue. According to guidelines, treatment-stage migration allows performing TACE on patients at early stages not suitable for surgical or ablative therapies. In selective studies, median survival rates of 5 year have been reported in patients with single HCC treated by supra-selective TACE. On the other hand, TACE performed beyond guidelines as a conventional practice to patients with formal contraindications (generally BCLC C) yields poor outcomes.

Drug-eluting beads chemoembolization (DEB-TACE) differs from c-TACE in the use of more standardized embolic spheres of regular size embedded with chemotherapy. This strategy ensures drug release over a 1-week period resulting in an enhancement of drug concentration within the tumor. DEB-TACE achieves similar anti-tumor activity (objective responses of ~60%) as c-TACE associated with significantly less systemic cytotoxic effects and better tolerance, but with no clear differences in clinical outcomes. Phase II and III studies have compared DEB-TACE with the combination of DEB-TACE with sorafenib or brivanib, a VEGF receptor inhibitor. Median survival in both arms of these international trials was 25–30 months.

Radioembolization and Other Intraarterial Therapies Radioembolization using beads coated with yttrium-90 (Y-90)—an isotope that emits short-range β radiation—is the most promising alternative to TACE. Several Phase II studies reported objective responses and overall outcome with a safe profile. Due to the lack of Phase III trials, this treatment is currently not recommended in guidelines. Whether radioembolization might be effective in patients at an intermediate-stage not eligible for TACE needs to be studied. Radioembolization

requires prevention of severe lung shunting and intestinal radiation before the procedure. Around 20% of patients present liver-related toxicity and 3% treatment-related death. Due to the minimally embolic effect of Y-90 microspheres, treatment can be safely used in patients with portal vein thrombosis, a setting where survival results in Phase II were encouraging and Phase III investigations in combination with sorafenib are ongoing. Head to head comparison of Y-90 vs sorafenib did not hit the primary end-point of overall survival.

TACE should be distinguished from other intraarterial therapies, such as chemo-lipiodolization, which involves the delivery of an emulsion of chemotherapy mixed with lipiodol, bland transcatheter embolization (TAE), where no chemotherapeutic agent is delivered, and intra-arterial chemotherapy, where no embolization is performed. None of these approaches is recommended due to the lack of survival benefit.

SYSTEMIC THERAPIES

Conventional systemic chemotherapy and radiotherapy have not produced survival advantages. Randomized studies also failed with anti-estrogen therapies and vitamin D derivatives. External beam liver-directed radiotherapy (stereotactic body radiotherapy) efficacy is currently being tested with and without sorafenib in Phase III trials. In 2007 a Phase III trial demonstrated survival benefits for patients with advanced stage disease treated with sorafenib, and more recently lenvatinib showed similar effects to sorafenib in first line treatment. A second multikinase inhibitor, regorafenib, has been shown to benefit patients progressing to sorafenib.

Molecular Targeted Therapies Sorafenib is the standard of care systemic therapy for HCC. It is indicated for patients with well-preserved liver function (Child-Pugh A class) and with advanced tumors (i.e., BCLC C) or those tumors at intermediate stage (i.e., BCLC B) progressing upon loco-regional therapies (Fig. 78-4). A Phase III study comparing sorafenib vs placebo showed increased survival from 7.9 months to 10.7 months (HR 0.69; 31% reduction of risk of death). In this trial, 80% of patients were BCLC C and 20% BCLC B progressed to TACE. Overall, 35% of patients presented with macrovascular invasion and 50% with extrahepatic spread. A similar magnitude of benefit was observed in another positive Phase III study conducted in parallel in Asian patients, mostly with HBV-related HCC. Interestingly, objective responses account for 2% of patients assessed by RECIST criteria and ~10% assessed by the more refined modified RECIST (mRECIST) criteria. Patients with HCV-related HCC achieve significantly better outcomes with sorafenib, with a median survival of 14 months. No predictive biomarkers of responsiveness to sorafenib have been identified.

The recommended daily dose of sorafenib is 800 mg. Median treatment duration is about six months. Treatment is associated with manageable adverse events, such as diarrhea, hand-foot skin reactions, fatigue, and hypertension. Treatment-related liver failure or life-threatening complications are unusual. These toxicities lead to treatment discontinuation in 20% of patients and dose-reduction in up to half. Not all patients at advanced stages can receive sorafenib. It has been estimated that this therapy cannot be administered to around one-third of the targeted patients due to primary intolerance, advanced age, or liver failure (ascites or encephalopathy). Active vascular disease, either coronary or peripheral, is considered a formal contraindication.

The efficacy of sorafenib probably results from a balance between targeting cancer cells and the microenvironment by blocking up to 40 kinases, including anti-angiogenic (vascular endothelial growth factor receptor [VEGFR], platelet-derived growth factor receptor [PDGFR]), and anti-proliferative drivers (serine/threonine-protein kinase B-raf [BRAF] and mast/stem cell growth factor receptor [c-Kit]). Median time to progression on sorafenib is of 4–5 months in Phase III trials. Activation of MAPK14 signaling, IGF signaling, and enrichment in tumor-initiating cells is the main mechanisms of acquired resistance.

Several other agents have been tested with negative results in most of the cases (Table 78-2). Recently, a phase III study comparing lenvatinib (an inhibitor of VEGFR, fibroblast growth factor receptor [FGFR],

PDGFR, RET, and c-Kit) with sorafenib has shown non-inferiority results in terms of overall survival (HR = 0.92). It is estimated that only half of the patients progressing on sorafenib can be considered for second-line therapies, and their median survival with no treatment is 7–8 months (obtained from patients allocated to the placebo arm).

Recently, lenvatinib showed similar efficacy compared to sorafenib in a phase III trial (median survival 13.6 months vs 12.3 months, respectively). A Phase III study comparing regorafenib (a more potent multikinase inhibitor than sorafenib, but targeting similar kinases) vs placebo in patients progressing to sorafenib has reported a benefit in survival from 7.8 to 10.6 months (HR: 0.62; 38% reduction of risk of death) (Fig. 78-5). Treatment improved survival in all patient subgroups. In this trial, 88% of patients were BCLC C and 12% BCLC B, and all had progressed on sorafenib. Around 30% of patients presented with macrovascular invasion, 70% with extrahepatic spread, and 45% with AFP >400 ng/dL. Response rate was 10% based upon mRECIST. Treatment was started at 160 mg/day (3 weeks on /1 week off). Median time on treatment was 3.5 months. Prevalence of toxicity (hand-foot reaction, fatigue, and hypertension) was higher compared with reported toxicity from sorafenib, but adverse events only led to treatment discontinuation in 10% of cases. Patients progressing after second-line therapy, along with those at a BCLC D stage should receive best supportive palliative care including management of pain, nutrition, and psychological support. Emerging therapies are shown in Fig. 78-6.

CHOLANGIOCARCINOMA

Cholangiocarcinoma (CCA) is classified according to its anatomic location as intrahepatic (iCCA; ~30%), perihilar (pCCA; ~50%), and distal (dCCA: ~20%). The latter two are also known as extrahepatic cholangiocarcinomas (eCCA), with the second-order bile ducts acting as the separation point (Fig. 78-7). This classification is endorsed by the 7th edition of the American Joint Committee on Cancer (AJCC) Staging Manual. In addition, iCCA has been recognized as a distinct entity with specific *ad hoc* clinical practice guidelines. Treatment options beyond surgery are limited, and unlike most solid tumors, no molecular targeted therapies have been approved for its treatment. The three subtypes of CCA differ in their anatomic location, epidemiology and risk factors, cell of origin, pathogenesis, and treatment. iCCA originates from adult cholangiocytes, trans-differentiation of adult hepatocytes and hepatic progenitor cells, whereas eCCA arises from the biliary epithelium and peribiliary glands. Moreover, their mutational profile also differs. FGFR2 fusions and IDH1/2 mutations only occur in iCCA, whereas ERBB2 amplifications, APOBEC-associated mutation signatures, and PKA fusions occur in eCCA. Thus, clinical management

FIGURE 78-7 Classification of cholangiocarcinoma subtypes. The 7th edition AJCC/UICC TNM staging classification includes intrahepatic (iCCA, ***A***), perhiliar (pCCA, ***B***) and distal (dCCA, ***C***) tumors. *(Reprinted with permission from S Rizvi, GJ Gores: Hepatology 63:1356, 2016.)*

and trials testing molecular therapies should be tailored according to each biological/anatomical subtype of CCA, as opposed to a common approach for all biliary tract cancers.

EPIDEMIOLOGY, RISK FACTORS, AND MOLECULAR TRAITS

CCA is the second most common liver cancer following HCC, with a 5-year survival of 10%. iCCA has globally increasing incidence and mortality rates. The incidence of iCCA varies according to exposure to risk factors, ranging from 1–2 cases per 100,000 inhabitants in Europe and North America to the highest incidence in some areas of Southeast Asia, particularly in Thailand (>80 cases/100,000 inhabitants). The male/female ratio is 1.2. Overall, most cases occur with unknown risk factors. The classical risk factors for CCA development include primary sclerosing cholangitis (PSC), biliary duct cysts, hepatolithiasis, Caroli's disease. Parasitic biliary infestation with flukes (i.e., most common is *Opisthorchis viverrini* and *Clonorchis sinensis*), is a prevalent etiology in Asia that can be prevented with an antihelminth therapy, praziquantel. PSC is a clear risk factor for iCCA and pCCA development, with a lifetime incidence ranging from 5 to 10%. Surveillance in PSC patients is recommended with annual imaging techniques and CA 19.9 serum determination. Common risk factors for HCC, such as HBV and HCV infection and cirrhosis, have been associated to iCCA development.

Molecular classification and drivers. There is no established molecular classification of CCA. Genomic studies have provided insight on two subclasses of iCCA, a proliferation subclass—characterized by activation of oncogenic signaling pathways (including RAS and MET)—and an inflammation subclass, characterized by activation of inflammatory pathways, overexpression of cytokines, and STAT3 activation. The landscape of mutations discovered by whole exome sequencing techniques defines a distinct mutational fingerprint depending on etiology and CCA subtype (Fig. 78-7). iCCA mutation portrait is characterized by ~50–60% of tumors having at least one targetable driver including *FGFR2* fusion events (~25%), mutations in *IDH1-2* (15%), *KRAS* (15%), *BRAF* (5%) and *EGFR* (3%), and amplifications in *FGF19/CCDN1* (4%). While mutations in P53 (~30%) and *KRAS* (~25%) are more common in eCCA than in iCCA, some molecular drivers are specific for subypes, such as fusion of *PRKACA* or *PRKACB* for eCCA or *ERBB2* amplifications (~20%) for gallbladder cancer. Liver flukes-associated CCA have higher incidence of *TP53* and *SMAD4* mutations. Host genetic polymorphisms predisposing to CCA have not been established.

INTRAHEPATIC CHOLANGIOCARCINOMA

Diagnosis and Staging Diagnosis of iCCA requires pathological confirmation. Guidelines are currently not recommending surveillance for early diagnosis, when patients are asymptomatic, since at-risk populations are ill-defined. Cirrhotic patients at risk of HCC development are enrolled in surveillance programs, and can benefit for early detection of iCCA. Otherwise, incidental diagnosis occurs due to cross-sectional imaging performed for other reasons. In most cases, iCCA is diagnosed at advanced stages where symptoms such as weight loss, malaise, abdominal discomfort, or jaundice are present. Pathological diagnosis of iCCA is based on the WHO criteria. Differential diagnosis should be established with metastatic adenocarcinoma and mixed iCCA-HCC tumors, which may require evaluation of markers such as Hep-Par-1, GPC3, HSP70, and glutamine synthetase markers. Imaging studies with CT/MRI are not accurate enough to establish iCCA non-invasive diagnosis. Dynamic CT scanning characterizes 80% of iCCA as liver mass-forming tumors with progressive contrast uptake from the arterial to the venous/delayed phase. MRI dynamic images also show peripheral enhancement in the arterial phase followed by progressive filling-in of the tumor. Atypical radiological behavior with arterial enhancement recapitulating HCC occurs in 10% of cases. MRI with cholangiopancreatography (MRI/MRCP) is useful to visualize the ductal system and vascular structures. Guidelines do not recommend PET scan for diagnosis. Tumor biomarker carbohydrate antigen (CA) 19-9 at a cut-off level of 100 U/mL has prognostic significance, but lacks accuracy (sensitivity and specificity of ~60%) for early diagnosis.

Radiological criteria are inadequate for iCCA diagnosis in cirrhotic patients. However, in non-cirrhotic patients, guidelines endorse a presumed diagnosis of iCCA (i.e., venous phase contrast enhancement on dynamic CT/MRI) if resection is considered. Assessment of disease extent (venous or arterial invasion and extrahepatic disease) and resectability is best accomplished with CT and/or MRI studies. Doppler ultrasound is accurate in defining vascular invasion. Before surgery, PET scanning may be considered to rule out an occult primary or metastatic site.

Staging system. The staging system for iCCA resected cases is based on the TNM staging as per the 7th edition of the AJCC/UICCA staging, which is a new system that has already been validated. T1 tumors are solitary without vascular invasion; T2 disease includes multiple tumors (e.g., multi-focal disease, satellitosis, intrahepatic metastasis), or with vascular invasion (microvascular or major vascular invasion); T3 tumors directly invade adjacent structures; and T4 disease includes tumors with any periductal-infiltrating component. Regional lymph node metastasis in the hilar, periduodenal, and peripancreatic nodes are considered N1 disease, while distant spread is considered M1 disease. TNM stages I, II, and III overlap with T status, whereas stage IV includes either periductal invasion or N1/M1 disease.

TREATMENT

After adopting the TNM staging system, the International Liver Cancer Association (ILCA) guidelines for management of iCCA proposed the treatment algorithm depicted in Fig. 78-8. Overall, most of the treatments endorsed have a modest level of evidence and, thus guidelines are providing physicians with recommendations as standards of practice rather than standards of care supported by robust evidence-based data. Surgical resection represents the sole curative treatment option in 30–40% of patients with a 5-year survival of 30%. The largest systematic review including ~4500 iCCA patients undergoing resection reported a median survival of 28 months. In non-cirrhotic individuals, the best candidates for resection are patients at TNM stage I-II, whereas in patients with cirrhosis liver function should be assessed as previously described for HCC. Preoperative disease assessment should discard vascular invasion, N1 and M1. Lymphadenectomy of regional nodes is recommended given its prognostic value. The main predictors of recurrence (~50–60% at 3 years) and survival are identified at the pathological examination, including presence of vascular invasion, lymph node metastases, and poor differentiation. There is no established adjuvant therapy. Liver transplantation remains controversial, and few studies have reported good outcomes for single tumors ≤2 cm.

Non-surgical candidates have a dismal life expectancy. Overall, patients at stage III might be considered for loco-regional therapies, such as chemoembolization or radioembolization, but the level of evidence is low, mostly based on cohort studies. A meta-analysis of 14 trials testing loco-regional therapies reported median survival times of 15 months. External beam radiation therapy is not recommended as standard therapy. At more advanced stages (stage IV) in patients ECOG 0-1, systemic chemotherapy with the combination of gemcitabine and cisplatin is considered the standard of practice yielding median survival rates of 11.7 months compared to 8 months for gemcitabine alone. This recommendation for first-line treatment of advanced tumors is based on a subgroup analysis of 80 iCCA patients included in a large randomized Phase III trial (n = 410, ABC trial-02) of patients with advanced biliary tract tumors.

No molecular targeted therapy has been proven effective for iCCA. Patient stratification based on molecular biomarkers is ongoing with FGFR2 aberrations and IDH1/2 mutations. Preliminary data of a Phase II trial testing BGJ398 in advanced iCCA harboring FGFR2 gene fusions reported ~20% objective response.

Mixed HCC-iCCA is a rare neoplasm accounting for <0.5% of all primary liver cancers. Diagnosis is based on pathology. The 2010 WHO classification defined two subtypes: the classical and the stem cell feature type. Molecular data has also characterized a third unique entity, cholangiolocellular carcinoma, with distinct molecular traits and better outcome. Due to its low incidence, the demographic features and clinical behavior of these tumors remain ill-defined. Survival rates are similar to iCCA, and until specific guidelines are available, they should be managed following the treatment algorithm of iCCA.

EXTRAHEPATIC CHOLANGIOCARCINOMA

Perihiliar (pCCA) and Distal Cholangiocarcinoma (dCCA). The 7th edition AJCC/UICC TNM staging classification has established pCCA as tumors that arise between the second-order bile ducts up to the insertion of the cystic duct, whereas dCCA arise from this point to the ampulla of Vater (Fig. 78-7). Thus, dCCA can be difficult to distinguish from early pancreatic cancer. Both entities have a similar diagnostic approach. Acute onset of painless jaundice occurs in 90% of patients with pCCA, and 10% present with cholangitis. Primary biliary cholangitis with a cut-off for CA19.9 >129 U/mL is suspicious for CCA. Imaging assessment starts with CT and MRI; they have a good sensitivity and specificity (>85%) for detecting the degree of bile duct involvement, and hepatic and portal vein invasion. MRI-cholangiography is optimal for defining the extent of the bile duct lesion. Ruling out IgG-4 cholangiopathy by assessing serum IgG4 is mandatory. As a second step, endoscopic retrograde cholangiography with brushing to explore cytology and fluorescence in situ hybridization (FISH)—for exploring polysomy—is recommended. FISH enhances the sensitivity of cytology from 20 to ~40%.

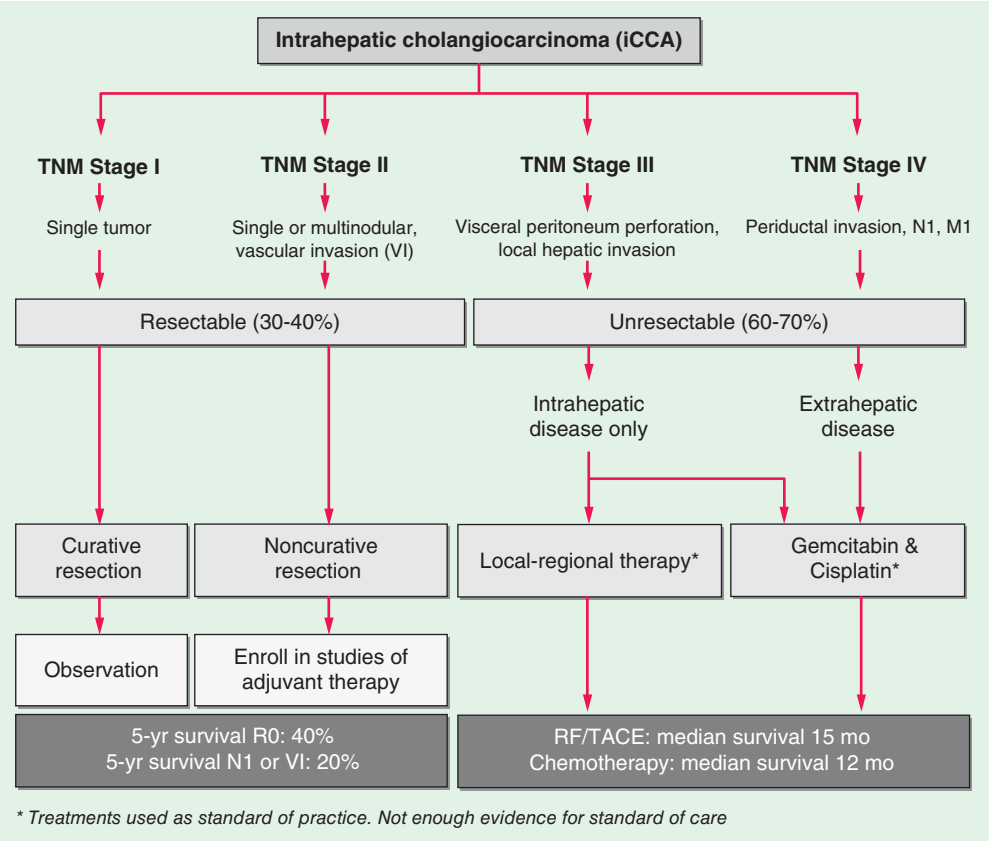

FIGURE 78-8 Staging and treatment schedule for iCCA proposed by the International Liver Cancer Association. *(Reprinted with permission from J Bridgewater: J Hepatology 60:1268–1289, 2014.)*

Diagnosis is based upon pathology. The treatment algorithm for pCCA indicates that in cases of a dominant stricture with positive cytology/biopsy or polysomy, a lymph node biopsy through endoscopic ultrasound should be obtained. pCCA with negative lymph node involvement is best treated by surgery, resection, or transplantation, the sole curative options. Resection entails hepatic and bile duct removal, Roux-en-Y-hepaticojejunostomy with regional lymphadenectomy. Bilobular involvement is considered a surgical contraindication. In few referral centers, unresectable single pCCA <3 cm without dissemination can be considered for liver transplantation with neoadjuvant chemoradiation. This procedure is associated with 5-year survival rates of ~70%. If lymph node involvement is present, systemic chemotherapy can be considered along with biliary tract stenting. Of note, the subgroup analysis of the Phase III ABC trial-02 did not identify differences between gemcitabine alone or in combination with cisplatin for pCCA. Surgical resection (Whipple procedure) is the primary option for management of dCCA, a procedure that achieves a median survival of 2 years and 5-year survival rates of ~25%. Main contraindications for resection are presence of distant lymph node involvement, metastases, or major vascular invasion. At the pathological examination, perineural invasion, lymph node metastasis, R0 resection (absence of residual tumor at pathological examination), and tumor differentiation are predictors of survival. Adjuvant therapy has not shown outcome benefits. There is no evidence of benefit of chemotherapy for unresectable cases. No molecular targeted therapies are available for these entities.

GALLBLADDER CANCER

Gallbladder cancer is the most common cancer of the biliary tract worldwide. The estimated cases of gallbladder cancer in the United States in 2016 are 11,400, more than CCA. The female:male ratio is 3:1. Cholelithiasis is the major risk factor, but <1% of patients with cholelithiasis develop this cancer. Gallbladder polyps at risk of transformation are those with ≥10 mm in diameter. Early cases are discovered incidentally at routine cholecystectomy. Clinical symptoms, such as jaundice, pain, and weight loss, are associated with advanced stages. Staging of gallbladder cancer follows the TNM classification. The most accurate technique to define staging and vascular and biliary tract invasion is the magnetic resonance cholangiopancreatography. CT and PET scan can be also useful for preoperative staging.

The mainstay of treatment is surgical, either simple or radical cholecystectomy (partial hepatectomy and regional lymph node dissection) for stage I or II disease, respectively. Only ~20% of patients are candidates for surgery with a curative intent. Survival rates are near 80–90% at 5 years for stage I, and range from 60 to 90% at 5 years for stage II. Regional nodal status and the depth of tumor invasion (T status) are the two most important prognostic factors. Adjuvant therapy has not proven effective. Gallbladder cancers at stage III and IV are considered unresectable. For patients with ECOG 0-1, chemotherapy with gemcitabine and cisplatin is the standard of practice based on data from the subgroup analysis including 181 patients with gallbladder cancer in the setting of two clinical trials. Overall, median survival is 10–12 months in advanced cases. Percutaneous transhepatic drainage is indicated in case of biliary obstruction. Radiotherapy is not effective.

OTHER MALIGNANT LIVER TUMORS

Fibrolamellar Hepatocellular Carcinoma (FLC) FLC is a rare form of primary liver cancer that typically affects children and young adults (10–30 years of age) without background liver disease. FLC accounts for 0.85% of all primary hepatic malignancies in the United States, and its incidence rate is 0.02 cases per 100,000 inhabitants. FLC is considered a unique entity with a specific fusion oncogene *PRKACA-DNAJB1* present in 80–100% of cases. A few mutations have been described, all at a level of <10%. FLC has a better prognosis than HCC, probably due to the absence of cirrhosis and the earlier age of presentation. Surgical resection is the mainstay of treatment and indications are less restrictive than for HCC. A retrospective series of 575 FLC cases reported a median survival of 70 months after resection. At advanced stages, the expected outcome is <20 months. Chemotherapy is not effective and there is no standard of care.

Hepatoblastoma (HB) HB is the most frequent primary liver tumor in children. The incidence of the disease is 1.5 cases per 1,000,000. Background liver disease is rare in these patients. WNT signaling plays a major role, with *CTNNB1* mutations (70%) as the most frequently reported molecular event. A gene signature is able to discriminate two molecular classes with distinct outcome. Resection followed by chemotherapy with doxorubicin is the mainstay treatment strategy. A study including 1605 patients randomized in eight clinical trials reported better outcome for patients with stage I-II of the PRETEXT classification (out of four stages), age <3 years, AFP >1,000 ng/mL, and absence of metastases. As opposed to HCC, low AFP indicates poor prognosis. Outcomes for best candidates after resection (stages I/II with small tumors, age <3 years and AFP >100 ng/mL) achieve 5-year disease-free survival of 90%, compared with worst candidates (metastatic disease and AFP <100 ng/mL) with 5-year disease-free survival of 20–30%.

BENIGN LIVER TUMORS

The most common benign liver tumors are hemangiomas, focal nodular hyperplasia (FNH), and hepatocellular adenomas (HCA). Most benign tumors are identified incidentally by abdominal ultrasound or other imaging techniques. *Hemangiomas* are present in ~5% of the general population, are diagnosed by ultrasound except in cirrhotic patients or oncology patients where contrast enhanced imaging (contrast enhanced ultrasound, CT, or MRI) is required. Conservative management is appropriate and follow-up is not recommended. Exceptionally, growing lesions causing symptoms by compression can be considered for resection. FNH is a benign tumor present in <2% of the population and occurring mostly in females aged 40–50 years. FNH is a polyclonal hepatocellular proliferation due to an arterial malformation. MRI has the highest diagnostic accuracy with a specificity of 100%, when typical imaging features are present (homogeneous enhancement in the arterial phase with a central scar). Atypical FNH requires biopsy for diagnosis. Treatment is not recommended since these tumors do not degenerate or cause complications. In exceptional cases of expanding symptomatic lesions, surgery is the treatment of choice.

Hepatic adenomas are clonal benign proliferations resulting from single gene driver mutations. HCA have a low prevalence of 0.001% of the population and are frequently diagnosed in women aged 35–40 years. The female:male ratio is 10:1, and the main risk factors are oral contraceptives in females and use of anabolic androgenic steroids in male body builders. HCA have the potential for hemorrhage and HCC development, particularly when sized >5 cm. Nowadays, there is a clear understanding of the molecular classification of HCA: (a) HCA with *CTNNB1* mutations (10–20%) are at-risk of HCC development and are present in men treated with androgens; (b) inflammatory adenomas (50–60%) are associated with single mutations (*Gp130*: 65%) and are more prevalent in females with obesity or diabetes; and (c) adenomas with inactivated *HNF-1A*. Diagnosis is based on MRI imaging, which is able to correlate with molecular subtypes in 80% of cases (Inflammatory and HNF-1A type). For defining HCA with *CTNNB1* mutations, biopsy is required. Upon diagnosis, discontinuation of oral contraceptives and weight loss is recommended. Resection is indicated in all cases of size >5 cm or men or *CTNNB1* mutation. For HCA <5 cm, 1-year follow-up is recommended. In case of active HCA bleeding, embolization followed by resection is the treatment of choice. The presence of multiple HCA is common, and guidelines endorse treating them based on the size of the main nodule.

79 Pancreatic Cancer

Daniel D. Von Hoff

Pancreatic cancer is the third leading cause of death from cancer in the United States with >53,000 Americans diagnosed and >43,000 dying from the disease each year. Unfortunately, pancreatic cancer is projected to be the second leading cause of death from cancer in the United States by 2030. Worldwide pancreatic cancer is the eleventh most common cancer with 338,000 new patients diagnosed and >334,000 deaths (seventh cause of cancer deaths). Pancreatic cancer currently has the worst survival rate of any cancer with an overall 5-year survival (regardless of stage) of ~8.2%. However, that situation is changing because some advances have been made against the disease with some improvements in survival (see below) that may affect the 5-year survival statistics. In particular, knowledge about specific molecular subsets of the disease has become crucial so that one can provide the best possible care for their patients with pancreatic cancer.

EPIDEMIOLOGY

Pancreatic cancer accounts for 3.2% of all new cancer cases in the United States and for 7.2% of all deaths from cancer in the United States. The lifetime risk of developing pancreatic cancer is ~1.6%. The incidence of pancreatic cancer has been increasing between 0.5 and 1% per year. Pancreatic cancer is more common with increasing age and more common in men than in women. The 5-year survival rate for all stages has increased from 3% in 1975 to 8.2% in 2013. The latest information from the U.S. Surveillance, Epidemiology, and End Results (SEER) database predicts that the 5-year survival for patients with localized pancreatic cancer is about 31.5%, 11.5% for those with regional disease, and 2–5% for patients with advanced metastatic disease. Pancreatic cancer is more common in developed countries (although generally it tracks with the prevalence of smoking). The incidence is highest in North America and Western Europe followed by other areas in Europe, Australia, New Zealand, and South-Central Asia. Of note is that the population at greatest risk are women living in Scandinavian countries, while the lowest risk is seen for women living in middle Africa.

RISK FACTORS

Age is one of the greatest risk factors for pancreatic cancer with median age at diagnosis of 70 years (the disease is most frequently diagnosed in the 65–74 age group). The number of new cases per 100,00 persons and the number of deaths per 100,000 persons are higher for males and blacks of both sexes. Both the number of cases and the number of deaths per 100,000 people are lower for American Indian/Alaskan natives and Asian Pacific Islanders. Both the number of cases and deaths are intermediate for the Hispanic population.

Environment The greatest risk factor for pancreatic cancer is cigarette smoking. The risk correlates with the increased number of cigarettes smoked. It has been estimated that 30% of pancreatic cancer is caused by smoking. Exposure to cadmium as part of cigarette smoking or via exposure to welding, soldering, or dietary exposure has been weakly associated with an increased risk of pancreatic cancer.

Although dietary factors are often difficult to interpret, evidence suggests that high intakes of fat or meat (particularly well-done barbequed meat) are risk factors. High intakes of fruits and vegetables are associated with a decreased risk. Coffee and low-to-moderate alcohol consumption have been determined not to be associated with an increased risk for pancreatic cancers, while consumption of sugary fizzy drinks has been associated with an increased risk.

Microbiome To date, there is no solid evidence of an association between *Helicobacter pylori* infection and pancreatic cancer. Some data link the oral microbiome associated with poor dentition to pancreatic cancer but the evidence is very thin.

Hereditary/Genetics Hereditary factors may account for 10–16% of all pancreatic cancers. It is very important to recognize these factors for determining risk for family members of the patient affected with pancreatic cancer. (These family members should seek participation in an early detection program with genetic counseling, definition of risk and perhaps, if appropriate, periodic MRI screening of the abdomen, though this recommendation is not based on research data.) In addition, the identification of any of these germ-line mutations can lead to specific and effective new therapeutics for patients with these abnormalities in their tumors. Table 79-1 identifies the various germ-line mutations along with their familial cancer syndromes where an increased risk for pancreatic cancer is known.

Knowing the patient has a BRCA2 or PALB2 germ-line mutation or any of the above mutations should lead one to not only refer the patient's relatives to an early detection or high-risk individual clinic but also realize that for the BRCA2/PALB2 germ-line mutation patients consideration for treatment with a poly (ADP-ribose) polymerase (PARP) inhibitor should be entertained. Other germ-line mutations are under study to determine their increased risk of pancreatic cancer including *CDK4, FANCC, PALLD, APC, ATM, BMPR1A, BRCA1, EPCAM, MEN1, MLH1, MSH2, MSH6, NF1, PMS2, SMAD4, TP53, TSC1, TSC2,* and *VHL*. Some of these mutations are associated with pancreatic neuroendocrine tumors (Chap. 80).

TABLE 79-1 Germ-line Mutations, Their Familial Cancer Syndrome, and Fold Risk of Pancreatic Cancer

GERM-LINE MUTATION	FAMILIAL CANCER SYNDROME	ESTIMATED INCREASED RISK (FOLD) OF PANCREATIC CANCER
BRCA2[a]	Familial breast/ovarian cancer	3.5–10
PALB2 (partner and localizer of BRCA2)	Familial breast cancer and others	~sixfold
p16/CDKN2A	Familial atypical multiple mole melanoma (FAMMM)	13–38
STKII (LKB1)	Peutz-Jeghers syndrome	132
PRSS1 or SPIN11[b]	Hereditary (familial) pancreatitis	53
ATM	Ataxia-telangiectasia	Not yet established
MLH1, MSH2, MSH6, PMS2	Heredity nonpolyposis colorectal syndrome or Lynch syndrome[c]	9–30

[a]Particularly common in individuals with Ashkenazi Jewish heritage. [b]Forty percent chance of pancreatic cancer by the age of 70. [c]Very important because this is associated with microsatellite instability, which is a marker for response to an anti-PD-1/PD-L1 agent.

In addition to the recognized genetic syndromes, other possible familial pancreatic cancer genes have not yet been discovered. For example, a family history of pancreatic cancer is associated with a 13-fold increase in the disease. If you have one first-degree relative, the risk is increased 4.6-fold, 2 first-degree relatives 6.4-fold, and ≥3 first degree relatives a 32-fold increase. The risk is also increased if a relative developed pancreatic cancer at <55 years old.

Other Considerations Most patients with pancreatic cancer relate that they have had developing symptoms over the last few years. However, Yachida and colleagues suggest that pancreatic cancer could be growing over a period of 21 years. Thus, there is a possibility for early detection of the disease.

Medical Conditions Chronic pancreatitis that is nonfamilial is also associated with an increased risk of pancreatic cancer (2.3–16.5-fold increase). It is also increased in people with chronic pancreatitis associated with cystic fibrosis or tropical pancreatitis.

A clear association exists between diabetes mellitus and pancreatic cancer. Whether this is a causal association or whether the diabetes is the result of the cancer is not exactly clear. What is clear is that when a person presents with new onset diabetes, they should be considered at risk for having pancreatic cancer. The excessive insulin or insulin-like growth factors associated with adult onset diabetes and metabolic syndrome may promote pancreatic carcinogenesis.

Obesity is considered a possible risk factor for pancreatic cancer. A high body mass index (BMI) ≥30 is associated with a doubling of the risk of pancreatic cancer. Since obesity is a risk factor for diabetes, the contribution of obesity alone is unclear. Interestingly, patients with severe obesity who undergo a gastric bypass experience a reduction in the incidence of gastrointestinal (GI) cancer including pancreatic cancer by >30% in the first 3 years (along with a dramatic decrease in their Hgb A1c and blood glucose). Physical inactivity also has been associated with an increased risk in pancreatic cancer.

PATHOLOGY AND MOLECULAR CONSIDERATION

Location The posterior location of the pancreas in the abdomen is likely one of the issues that leads to a late diagnosis **(Fig. 79-1*A*)**.

Pathology Cancers of the pancreas can be divided into neoplasms of the endocrine pancreas **(Chap. 80)** and tumors of the exocrine pancreas. The most common neoplasm of the exocrine pancreas and most deadly is pancreatic infiltrating ductal adenocarcinoma. These tumors arise in the head, body, or tail of the pancreas and are characterized by infiltrating desmoplastic stromal reactions **(Fig. 79-1*B*)**.

Other subtypes of nonneuroendocrine pancreatic cancers include acinar cell carcinoma (tumors of the exocrine enzyme producing cell); medullary carcinoma, adenosquamous, and other rare subtypes. Each of these are different in their behaviors and in their molecular characteristics and often require specific other types of treatment.

Molecular Characteristics The molecular characteristics of pancreatic ductal adenocarcinoma reveal four genes that are commonly mutated or inactivated (sometimes referred to as the "4 horsemen"). The most common is *KRAS* (usually in codon12), which is seen in virtually 100% of pancreatic adenocarcinomas. In fact, with the deep sequencing now available, if a *KRAS* mutation is not detected in the patient's tumor, one should consider the tumor being of a different origin (such as small bowel, gallbladder, or cholangiocarcinoma)—all of which could require different treatments. *p16/CDKn2A* is also noted in >90% of invasive pancreatic adenocarcinomas. *TP53* and *DPC4/MADH4* are mutated in about half of these tumors. As a reference point, the BRCA2 gene noted in Table 79-1 is mutated in 7–10% of pancreatic adenocarcinomas.

Precursor Lesions Many pancreatic adenocarcinomas seem to arise from noninvasive epithelial precursor lesions. Detection of these could allow for early diagnosis of pancreatic cancer. These pancreatic intraepithelial neoplasias (PanINs) have varying degrees of dysplasia designated as PanINs 1–3 (and constitute a progression model for pancreatic cancer). Genetic alterations become more frequent as the PanIN grade increases (e.g., grade 3). Not all PanIN lesions progress to invasive malignancy. PanINs that are ≥1 cm are called *intraductal papillary neoplasms* and are usually noninvasive. If the intraductal tumor is in a branch duct, it is usually noninvasive; however, if the intraductal tumor is in a main duct and is large and nodular, it is more likely to have malignant behavior.

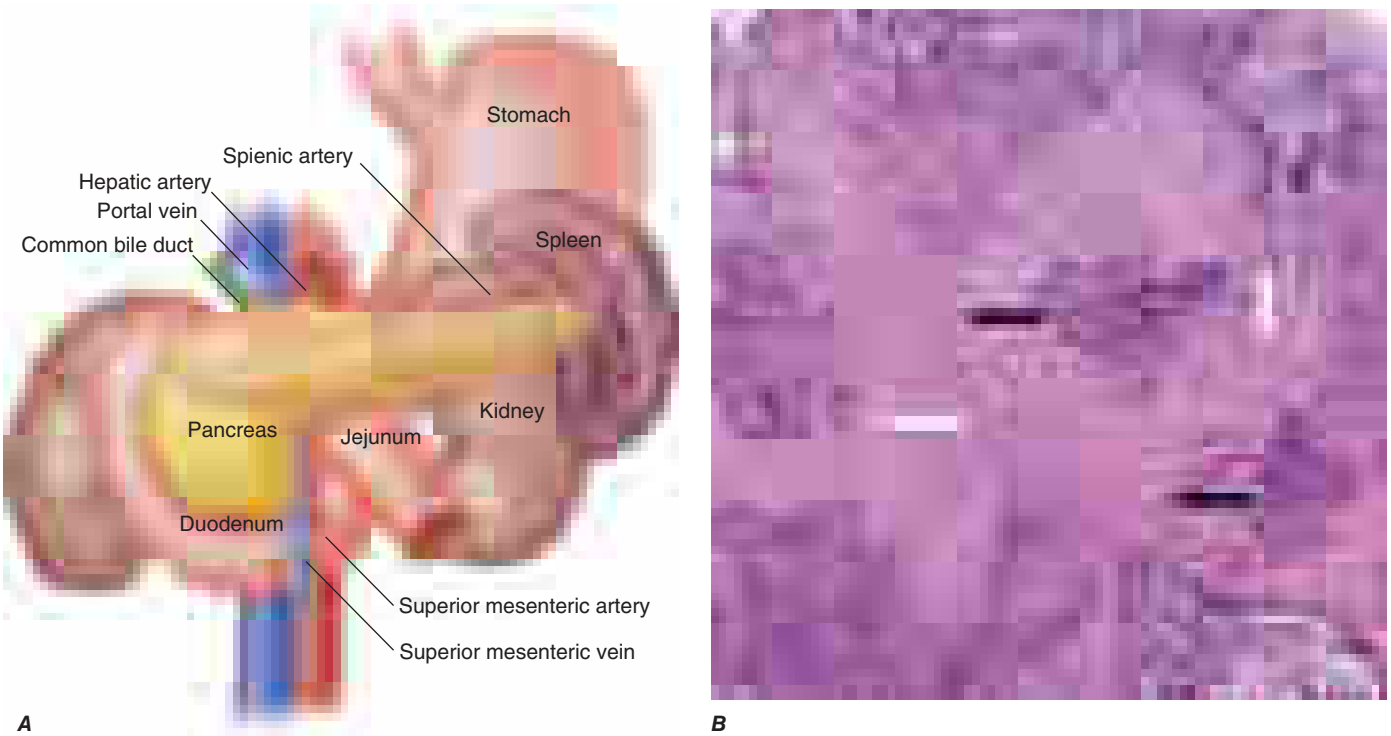

FIGURE 79-1 ***A.*** Note the relationship of the pancreas to the major vessels of the retroperitoneum. ***B.*** Ductal adenocarcinoma of the pancreas (*black arrows*), with intense stromal component (*white arrows*). *(Part A is courtesy of Mary Kay Washington, MD, PhD Vanderbilt University. Part B is courtesy of Haiyong Han, PhD Translational Genomics Research Institute [TGen].)*

One other pancreatic tumor is the mucinous cystic neoplasm; they may be seen as incidental findings on scans. These lesions are less likely invasive (20%) unless they are large and have nodules in them.

CLINICAL FEATURES

History and Physical The classic presentation for a patient with pancreatic cancer has been abdominal pain and weight loss with or without jaundice. The pain is midepigastric (sometimes described as a "boring-like" pain). Often the pain is in the back (due to retroperitoneal invasion of the splanchnic nerve plexus). The pain may be exacerbated by eating or lying flat. Other items of note in a history is lightening in stool color (steatorrhea also causes malodorous stools), or the onset of diabetes in the prior year. Jaundice, first detectable with a bilirubin of 2.5–3.0 mg/dL, is usually associated with tumor in the head of the pancreas. In some instances, depression is noted (with a higher subsequent number of suicides). Pruritis may be seen when the bilirubin reaches 6–8 mg/dL.

Physical signs include jaundice, signs of weight loss, a palpable gallbladder (Courvoisier's sign), hepatomegaly, an abdominal mass, and even an enlarged spleen (usually indicating a portal vein thrombosis). Migratory superficial thrombophlebitis can also be seen (Trousseau's syndrome). Signs of late disease include a lymph node palpable in the supraclavicular fossa (usually on the left where the thoracic duct enters the subclavian vein). This is clinically referred to as Virchow's node. Occasionally one can palpate subcutaneous metastases in the periumbilical area referred to as a Sister Mary Joseph's node—named after one of the scrub nurses on the Mayo Clinic Operative Team who noted that when she prepped that area and felt those nodules, the patient often had peritoneal metastases.

The history and symptoms noted above may lead a person to see a physician; often CT and MRI scanning detects the disease before advanced disease symptoms appear.

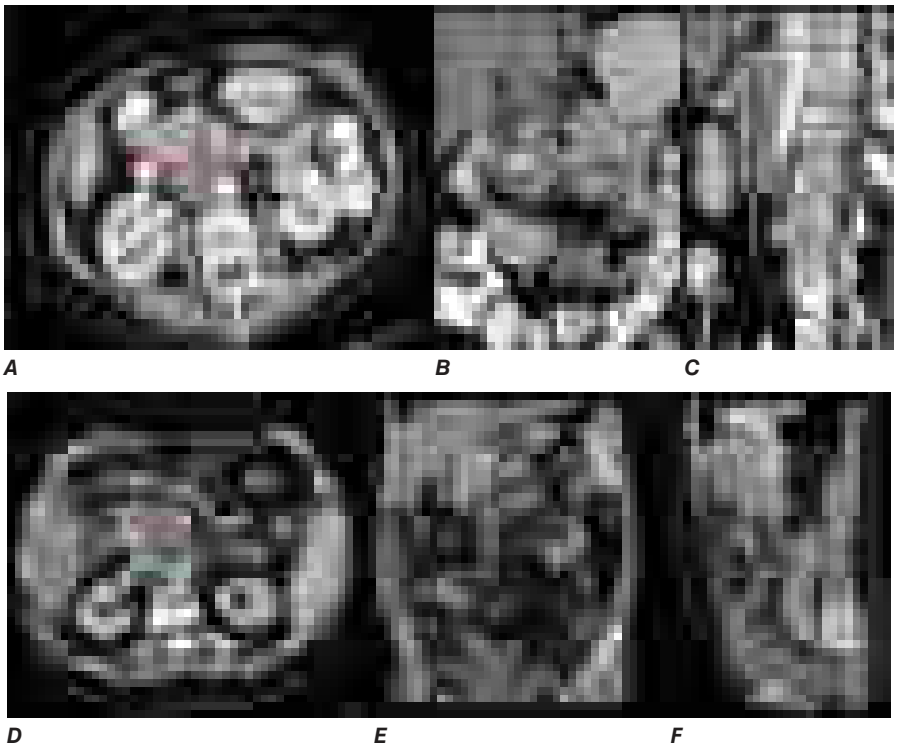

FIGURE 79-2 Selected images from contrast-enhanced CT in patients with locally advanced adenocarcinoma of the pancreas. A high-quality contrast-enhanced CT scan (arterial phase in Panels ***A–C*** and portal venous phase in Panels ***D–F***) is required for optimal staging of pancreas cancer. Panel ***A*** demonstrates the typical features of adenocarcinoma of the pancreas on arterial phase axial CT scans (*dotted outline*) with tumor encasement of the superior mesenteric artery (*white arrow*). Note the dilatation of the common bile duct (*red arrow*). Panels ***B*** (magnified coronal) and ***C*** (sagittal) show reconstruction of CT images into additional orthogonal planes with exquisite details to confirm the unresectable nature of the tumor due to vascular encasement. Panel ***D*** demonstrates the typical features of adenocarcinoma of the pancreas on portal venous phase axial CT scans in a different subject. The dotted line outlines a pancreas cancer lesion in the pancreatic head, which is encasing the portal splenic confluence (*dotted outline*). Panels ***E*** (*white arrow*) and ***F*** show the pinched appearance of the portal splenic confluence by tumor abutment and invasion of the superior mesenteric vein (*white arrow*) on coronal and sagittal views. Note the presence of a stent in the common bile duct (*red arrow*) to help relieve biliary obstruction caused by the tumor. CA, celiac axis; SMA, superior mesenteric artery.

DIAGNOSTIC WORKUP

Imaging Diagnostic imaging plays a major role in diagnosing pancreatic cancer and other intraabdominal diseases. The best technique is the use of a dual-phase contrast-enhanced spiral CT using the pancreatic cancer protocol which allows arterial phase enhancement and portal venous phase enhancement. This special protocol can provide helpful prospective staging and assessment of resectability. Figure 79-2 demonstrates such a CT scan (with vascular involvement). Figure 79-3 demonstrates the use of an 18F glucose positron emission tomography (PET) scan.

Histologic Diagnosis A histologic (tissue) diagnosis is essential and should be obtained with a cutting biopsy needle (not a skinny needle with cytology). Misdiagnosis is more common based on only fine-needle aspirates. Obtaining a tissue diagnosis allows not only for accuracy but also for molecular testing for *KRAS* mutations, microsatellite instability, and other important molecular abnormalities. Those molecular abnormalities and others will be increasingly important as more targeted therapies are developed for patients with pancreatic cancer.

The core needle (16–18 gauge) biopsy can be obtained via endoscopic ultrasound-guided techniques for a tumor localized to the pancreas or, if there are liver lesions or Virchow's node, via percutaneous biopsy by interventional radiologists.

FIGURE 79-3. PET scan demonstrating metastatic disease—baseline and after 6 weeks of chemotherapy with some resolution of liver metastases.

Serum Markers Before treatment, a serum sample should be obtained for levels of CA19-9, carcinoembryonic antigen (CEA), or if both are negative, for CA125 (can be positive when the CA19-9 is negative due to the patient not being a Lewis antigen secretor). These markers are not useful for staging but can be useful in following the course of pancreatic cancer.

IMPORTANT IMMEDIATE CONSIDERATIONS IN PATIENT CARE

While the patient is being evaluated and staged, one must be alert for biliary tract obstruction (and the attendant risk for sepsis from the biliary tree). A stent can be placed (plastic if temporary or metal if needed longer) to relieve the jaundice and pruritus. If surgery is being contemplated, an early surgical consultation is in order as there are surgeons who will want to proceed to surgery without placement of a stent.

Patients with pancreatic cancer are often hypercoagulable and frequently have migratory thrombophlebitis (Trousseau's sign) as well as deep vein thrombosis with pulmonary emboli (a frequent cause of death). Appropriate examinations plus being alert to thromboses on the routine workup are mandatory so appropriate management can be put in place.

Control of pain or of any of the symptoms should be obtained if at all possible to help patients be as comfortable as possible for their decision-making. Sometimes simple approaches like the use of a replacement pancreatic enzyme (at good therapeutic doses) can relieve the bloating, cramping, and diarrhea these patients suffer from. Early involvement of a palliative care team can improve a patient's quality of life and sometimes even its length.

CLINICAL STAGING

The clinical staging of pancreatic cancer according to the American Joint Commission on cancer staging is presented in Table 79-2.

Table 79-3 presents another clinical way to express extent of disease as well as therapeutic approaches (to be discussed later).

For proper staging, some physicians believe that a laparoscopy either before or at the time of contemplated surgery is important. If metastatic disease is found at laparoscopy, one can avoid surgery that would not be helpful because disease is already advanced.

TREATMENT

Resectable Disease

For patients with resectable disease (as defined in Table 79-3), the best option is surgery. Only a small percentage of patients are in this category (10–20%). The surgery for patients with tumors in the head or uncinate body of the pancreas is usually a pylorus-sparing pancreaticoduodenectomy (a modified Whipple procedure). For tumors in the body or tail, a distal pancreatomy is usually performed. Clinical and pathologic findings of the resection are defined as either, an Ro

TABLE 79-2 Definition of Primary Tumor (T)

T CATEGORY	T CRITERIA
TX	Primary tumor cannot be assesed
T0	No evidence of primary tumor
Tis	Carcinoma in situ This includes high-grade pancreatic intraepithelial neoplasia (PanIn-3), intraductal papillary mucinous neoplasm with high-grade dysplasia, intraductal tubulopapillary neoplasm with high-grade dysplasia, and mucinous cystic neoplasm with high-grade dysplasia
T1	Tumor ≤2 cm in greatest dimension
T1a	Tumor is ≤0.5 cm in greatest dimension
T1b	Tumor >0.5 cm and <1 cm in greatest dimension
T1c	Tumor 1–2 cm in greatest dimension
T2	Tumor >2 cm and ≤4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension
T4	Tumor involves celiac axis, superior mesenteric artery, and/or common hepatic artery, regardless of size
M CATEGORY	**M CRITERIA**
M0	No distant metastasis
M1	Distant metastasis
N CATEGORY	**N CRITERIA**
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in one to three regional lymph nodes
N2	Metastasis in four or more regional lymph nodes

TABLE 79-3 Extent of Disease and Therapeutic Approach

DESIGNATION (MEDIAN SURVIVAL)	THERAPEUTIC APPROACHES
1. Resectable (localized): (18–23 mo) • No encasement of celiac axis or superior mesenteric artery (SMA) • Patent superior mesenteric—portal veins • No extrapancreatic disease	Surgical option (or preoperative-neoadjuvant therapy first). Surgery is followed by postsurgery adjuvant therapy • Currently gemcitabine + capecitabine
2. Locally advanced: (6–10 mo) • Encasement of arteries • Venous occlusion (superior mesenteric vein [SMV] or portal) • No extrapancreatic disease	Either chemotherapy or chemotherapy + radiation therapy
3. Metastatic: (8.3–12.8 mo)	Systemic chemotherapy

TABLE 79-4 Combination Chemotherapy Regimens that Have an Impact on Survival

STUDY DESIGN (AUTHOR/REF)	NO. OF PATIENTS	MEDIAN SURVIVAL (MONTHS)
Gemcitabine + erlotinib vs Gemcitabine, (Moore et al: J. Clin Oncol. 26:1960, 2007.)	569	6.24 vs 5.91 (HR 0.82; 95% CI 0.69–0.99, $p = 0.038$)
Folfirinox (folinic acid + 5FU + irinotecan + oxaliplatin) vs Gemcitabine, (Conroy et al: N Eng J Med 364:1817, 2011.)	342	11.1 vs 6.8 (HR 0.57; 95% CI 0.45–0.70, $p < 0.001$)
Nap-paclitaxel + gemcitabine vs gemcitabine, (Von Hoff et al: N Eng J Med 369:1691, 2013.)	861	8.5 vs 6.7 (HR 0.72; 95% CI 0.62–0.83, $p < 0.001$[a]

[a]The 2-year survival rate with this regimen is 9% and the 3+ year rate is 4%. Other studies have not reported on these parameters.

resection (no macroscopic or microscopic disease left after surgery); an R1 resection refers to residual disease likely left behind. Patients with smaller tumors and lymph node negative disease have a better survival (median of about 18–23 months with 5-year survival of about 20%).

Two approaches are being explored to try to improve on this.

(1) Postoperative adjuvant therapy. The standard of care is to use 6 months of adjuvant treatment with gemcitabine + capecitabine (referred to as the ESPAC4 trial). The median survival was 28 months (95% CI (23.5–31.5) for the combination of gemcitabine + capecitabine versus 25.5 months CI with (22.7–27.1) for the gemcitabine alone—hazard ratio 0.82 95% (0.6–0.98) ($p = 0.032$). Toxicities were manageable.

(2) A more experimental approach is the use of neoadjuvant chemotherapy (chemotherapy given before surgery) to try to shrink the tumor and normalize the patient's serum CA19-9 level. Studies of neoadjuvant chemotherapy are ongoing.

Locally Advanced Disease (30% of Patients) For patients with locally advanced disease, the median survival is also quite poor (6–10 months) because many of the patients die with local problems (portal vein thrombosis with bleeding varices, obstruction, sepsis, etc.). The approach has been to try to reduce the bulk of the disease with use of radiation therapy plus chemotherapy or chemotherapy alone, hoping the disease could become resectable. No standard therapy has been agreed upon, but experimental approaches are applying some of the treatments that show promise in advanced metastatic disease.

Advanced Metastatic Disease (60% of Patients) Only a few of the many phase III randomized trials in patients with advanced pancreatic cancer have led to meaningful increases in survival. We have learned that a regimen needs to have at least a 50% improvement in overall survival or 90% improvement in 1-year survival in a pilot trial to predict for any degree of success in large randomized phase III trials.

Patients with the best chance of receiving a benefit from treatment have a good performance status (functioning up and around at least 70% of the day), have a reasonable albumin level (≥3.0 g/dL), and a neutrophil/lymphocyte ratio of ≤5.0.

Single-agent gemcitabine achieves a median survival of 6 months and a 1-year survival rate of 18%. Table 79-4 details three combination regimens that have further improved survival modestly. Median overall survival still ranges from 6 to 11 months. However, 1-year survival is now approaching 35% for these combination regimens with some long-term 4+ year survivors.

Liposomal irinotecan has been approved by the U.S. Food and Drug Administration (FDA) in combination with 5 fluorouracil + leucovorin for patients whose tumors have progressed on gemcitabine based on improved overall survival. PARP inhibitors have clinical activity against pancreatic cancers having mutations in BRCA2 or PALB2 (i.e., defective DNA repair proteins). In addition, tumors with microsatellite instability often have more mutations and such tumors appear to have a higher response rate to immunotherapy with checkpoint inhibitors, anti-PD-1 (pembrolizumab, nivolumab), and anti-PD-L1 antibodies.

Other Potential Factors Influencing Survival Preclinical studies have suggested that vitamin D can inhibit the development and growth of cancer. In models of pancreatic cancer, synthetic analogs of vitamin D had an effect on both tumor cells and on the tumor microenvironment. Clinical studies are conflicting as to whether circulating levels of plasma 25-hydroxyvitaminD (25[OH]D) affect the incidence of pancreatic cancer. However, patients with prediagnostic levels of 25(OH)D that are in the normal range have a longer survival than those who have reduced levels (35% lower hazard for death).

FUTURE DIRECTIONS

Death from pancreatic cancer is often due to progressive inanition. The metabolic consequences of this cancer are being examined. The tumor can be fatal at a modest level of tumor burden based on the profound metabolic effects. Other promising areas of investigation include addressing the florid stromal reaction around the tumor cells (believed to act as a physical barrier to drug delivery and as an immune sanctuary for the tumor cells). This attack on the stroma is being done with enzymatic (hyaluronidase) and other (antisuper enhancer genes) approaches. Also, utilization of hypomethylating and histone deacetylase inhibitors to correct epigenetic defects in the tumor microenvironment are under active study.

Acknowledgment

Thank you to Jennifer Byrne, BA, for assistance in the preparation of this chapter, and Drs. Elizabeth Washington, Ron Korn, and Haiyong Han and the American Joint Committee on Cancer for providing the figures.

80 Neuroendocrine Tumors of the Gastrointestinal Tract and Pancreas

Robert T. Jensen

GENERAL FEATURES OF GASTROINTESTINAL NEUROENDOCRINE TUMORS

Gastrointestinal (GI) neuroendocrine tumors (NETs) are tumors derived from the diffuse neuroendocrine system of the GI tract, which is composed of amine- and acid-producing cells with different hormonal profiles, depending on the site of origin. NETs of the GI tract share many features with other NETs throughout the body and were historically divided into GI-NETs (in the GI tract) (also frequently called *carcinoid tumors*) and pancreatic neuroendocrine tumors (pNETs), although in newer pathologic classifications they are all classified as NETs **(Table 80-1)**. These tumors originally were classified as APUDomas (for *a*mine *p*recursor *u*ptake and *d*ecarboxylation), as were pheochromocytomas, NETs in other locations, melanomas, and medullary thyroid carcinomas, because they share certain cytochemical features as well as various pathologic, biologic, and molecular features. It was originally proposed that APUDomas had a similar embryonic origin from neural crest cells, but it is now known that the peptide-secreting cells are not of neuroectodermal origin.

TABLE 80-1 Comparison of the Criteria for the Tumor Category in the ENETS AJCC TNM Classifications of Pancreatic and Appendiceal NETs (Top Panel) and the WHO/ENETS Grading and Classification (Bottom Panel)

A. TNM Classification

	ENETS TNM	AJCC/UICC TNM
pNETs		
T1	Confined to pancreas, <2 cm	Confined to pancreas, <2 cm
T2	Confined to pancreas, 2–4 cm	Confined to pancreas, >2 cm
T3	Confined to pancreas, >4 cm, or invasion of duodenum or bile duct	Peripancreatic spread, but without major vascular invasion (truncus coeliacus, superior mesenteric artery)
T4	Invasion of adjacent organs or major vessels	Major vascular invasion
Appendiceal NETs		
T1	≤1 cm; invasion of muscularis propria	T1a, ≤1 cm; T1b, >1–2 cm
T2	≤2 cm and <3 mm invasion of subserosa/mesoappendix	>2–4 cm or invasion of cecum
T3	>2 cm or >3 mm invasion of subserosa/mesoappendix	>4 cm or invasion of ileum
T4	Invasion of peritoneum/ other organs	Invasion of peritoneum/other organs

B. Grading

CLASSIFICATION	GRADE	MITOTIC COUNT (per 10 HPF)	KI_{67} INDEX (%)
NET	G1	<2	≤2
NET	G2	2–20	3–20
NEC (small cell and large cell)	G3	>20	>20

Abbreviations: HPF, high-power field; NEC, neuroendocrine carcinoma; NET, neuroendocrine tumor.

CLASSIFICATION/PATHOLOGY/TUMOR BIOLOGY OF NETS

NETs generally are composed of monotonous sheets of small round cells with uniform nuclei, and mitoses are uncommon. They can be frequently recognized on routine histology; however, these tumors are now recognized principally by their histologic staining patterns due to shared cellular proteins. Historically, silver staining was used, and tumors were classified as showing an argentaffin reaction if they took up and reduced silver or as being argyrophilic if they did not reduce it. Currently, immunocytochemical localization of chromogranins (A, B, C) and synaptophysin are routinely used. Chromogranins are acidic monomeric soluble proteins found in the large secretory granules. Synaptophysin is an integral membrane glycoprotein of 38,000 molecular weight found in small vesicles of neurons and NET. Chromogranin A is the most widely used.

Ultrastructurally, these tumors possess electron-dense neurosecretory granules and frequently contain small clear vesicles that correspond to synaptic vesicles of neurons. NETs synthesize numerous peptides, growth factors, and bioactive amines that may be ectopically secreted, giving rise to a specific clinical syndrome **(Table 80-2)**. The diagnosis of the specific syndrome requires the clinical features of the disease (Table 80-2) and cannot be made from the immunocytochemistry results alone. The presence or absence of a specific clinical syndrome also cannot be predicted from the immunocytochemistry alone.

NETs of the GI tract (GI-NETs) have been classified according to their anatomic area of origin (i.e., foregut, midgut, hindgut) because tumors with similar areas of origin share functional manifestations, histochemistry, and secretory products **(Table 80-3)**. Foregut tumors generally have a low serotonin (5-HT) content, are argentaffin-negative but argyrophilic, occasionally secrete adrenocorticotropic hormone (ACTH) or 5-hydroxytryptophan (5-HTP), causing an atypical carcinoid syndrome **(Fig. 80-1)**; these are often multihormonal and may metastasize to bone. They may produce a clinical syndrome due to the secreted products. Midgut carcinoids are argentaffin-positive, have a high serotonin content, most frequently cause the typical carcinoid syndrome when they metastasize (Table 80-3, Fig. 80-1), release serotonin and tachykinins (substance P, neuropeptide K, substance K), rarely secrete 5-HTP or ACTH, and less commonly metastasize to bone. Hindgut carcinoids (rectum, transverse and descending colon) are argentaffin-negative, are often argyrophilic, rarely contain serotonin or cause the carcinoid syndrome (Fig. 80-1, Table 80-3), rarely secrete 5-HTP or ACTH, contain numerous peptides, and may metastasize to bone.

However, the classification of GI NETs into foregut, midgut, or hindgut even though widely used, has not proved useful for prognostic or therapeutic purposes. More general classifications have been developed that allow NETs with similar features in different locations to be compared, have proven prognostic and tumor management value, and are now recommended in all recent guidelines and have become an essential requirement for management of these patients. The World Health Organization (WHO), European Neuroendocrine Tumor Society (ENETS), and the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) have developed classification systems (Table 80-1). Although there are some differences between these different classification systems, each uses similar information, and it is now recommended that the basic data underlying the classification be included in all standard pathology reports. These classification systems divide NETs from all sites into those that are well differentiated (low grade [G1] or intermediate grade [G2]) and those that are poorly differentiated (high grade [G3] divided into either small-cell carcinoma or large-cell neuroendocrine carcinoma [NEC]) (Table 80-1). In these classification systems, both pNETs and GI-NETs (carcinoids) are classified as NETs, and the old term of carcinoid is equivalent to well-differentiated NETs of the GI tract. These classification systems are based on not only the differentiation of the NET, but also a grading system assessing proliferative indices (Ki_{67} and the mitotic count)

TABLE 80-2 Gastrointestinal Neuroendocrine Tumor Syndromes

NAME	BIOLOGICALLY ACTIVE PEPTIDE(S) SECRETED	INCIDENCE (NEW CASES/10^6 POPULATION/YEAR)	TUMOR LOCATION	MALIGNANT, %	ASSOCIATED WITH MEN 1, %	MAIN SYMPTOMS/SIGNS
I. Established Specific Functional Syndromes						
A. Carcinoid syndrome due to GI-NET						
Carcinoid syndrome	Serotonin, possibly tachykinins, motilin, prostaglandins	0.5–2	Midgut (75–87%) Foregut (2–33%) Hindgut (1–8%) Unknown (2–15%)	95–100	Rare	Diarrhea (32–84%) Flushing (63–75%) Pain (10–34%) Asthma (4–18%) Heart disease (11–41%)
B. Well-established functional pNET syndromes						
Zollinger-Ellison syndrome	Gastrin	0.5–1.5	Duodenum (70%) Pancreas (25%) Other sites (5%)	60–90	20–25	Pain (79–100%) Diarrhea (30–75%) Esophageal symptoms (31–56%)
Insulinoma	Insulin	1–2	Pancreas (>99%)	<10	4–5	Hypoglycemic symptoms (100%)
VIPoma (Verner-Morrison syndrome, pancreatic cholera, WDHA)	Vasoactive intestinal peptide	0.05–0.2	Pancreas (90%, adult) Other (10%, neural, adrenal, periganglionic)	40–70	6	Diarrhea (90–100%) Hypokalemia (80–100%) Dehydration (83%)
Glucagonoma	Glucagon	0.01–0.1	Pancreas (100%)	50–80	1–20	Rash (67–90%) Glucose intolerance (38–87%) Weight loss (66–96%)
Somatostatinoma	Somatostatin	Rare	Pancreas (55%) Duodenum/jejunum (44%)	>70	45	Diabetes mellitus (63–90%) Cholelithiasis (65–90%) Diarrhea (35–90%)
GRFoma	Growth hormone–releasing hormone	Unknown	Pancreas (30%) Lung (54%) Jejunum (7%) Other (13%)	>60	16	Acromegaly (100%)
ACTHoma	ACTH	Rare	Pancreas (4–16% all ectopic Cushing's)	>95	Rare	Cushing's syndrome (100%)
pNET causing carcinoid syndrome	Serotonin, ?tachykinins	Rare (<100 cases)	Pancreas (<1% all carcinoids)	60–88	Rare	Same as carcinoid syndrome above
pNET causing hypercalcemia	PTHrP Others unknown	Rare	Pancreas (rare cause of hypercalcemia)	84	Rare	Abdominal pain due to hepatic metastases
II. Rare Specific Functional Syndromes						
pNET secreting renin	Renin	Rare	Pancreas	Unknown	No	Hypertension
pNET secreting luteinizing hormone	Luteinizing hormone	Rare	Pancreas	Unknown	No	Anovulation, virilization (female); reduced libido (male)
pNET secreting erythropoietin	Erythropoietin	Rare	Pancreas	100	No	Polycythemia
pNET secreting IGF-II	Insulin-like growth factor II	Rare	Pancreas	Unknown	No	Hypoglycemia
pNET secreting GLP-1	Glucagon-like peptide-1	Rare	Pancreas	Unknown	No	Hypoglycemia, diabetes
pNET secreting enteroglucagon	Enteroglucagon	Rare	Pancreas, small intestine	Unknown	Rare	Small intestinal hypertrophy, intestinal stasis, malabsorption
pNET secreting Cholecytokinin	Cholecytokinin	Rare	Pancreas	Unknown	No	Diarrhea, gallstones, peptic ulcer, weight loss
III. Possible Specific Functional pNET Syndromes						
pNET secreting calcitonin	Calcitonin	Rare	Pancreas (rare cause of hypercalcitonemia)	>80	16	Diarrhea (50%)
pNET secreting neurotensin	Neurotensin	Rare	Pancreas (100%)	Unknown	No	Motility disturbances, vascular symptoms
pNET secreting pancreatic polypeptide (PPoma)	Pancreatic polypeptide	1–2	Pancreas	>60	18–44	Watery diarrhea
pNET secreting ghrelin	Ghrelin	Rare	Pancreas	Unknown	No	Effects on appetite, body weight
pNET secreting secretin	Secretin	Rare	Pancreas	Unknown	unknown	Watery diarrhea

(*Continued*)

TABLE 80-2 Gastrointestinal Neuroendocrine Tumor Syndromes (Continued)

NAME	BIOLOGICALLY ACTIVE PEPTIDE(S) SECRETED	INCIDENCE (NEW CASES/10^6 POPULATION/YEAR)	TUMOR LOCATION	MALIGNANT, %	ASSOCIATED WITH MEN 1, %	MAIN SYMPTOMS/SIGNS
IV. Nonfunctional Syndrome pNET						
PPoma/nonfunctional[a]	None	1–2	Pancreas (100%)	>60	18–44	Weight loss (30–90%) Abdominal mass (10–30%) Pain (30–95%)

[a]Pancreatic polypeptide–secreting tumors (PPomas) are listed in two places because most authorities classify these as not associated with a specific hormonal syndrome (nonfunctional); however, rare cases of watery diarrhea proposed to be due to PPomas have been reported.

Abbreviations: ACTH, adrenocorticotropic hormone; GRFoma, growth hormone–releasing factor secreting pancreatic endocrine tumor; IGF-II, insulin-like growth factor II; MEN, multiple endocrine neoplasia; pNET, pancreatic neuroendocrine tumor; PPoma, tumor secreting pancreatic polypeptide; PTHrP, parathyroid hormone–related peptide; VIPoma, tumor secreting vasoactive intestinal peptide; WDHA, watery diarrhea, hypokalemia, and achlorhydria syndrome.

(Table 80-1). Based on these proliferative indices, NETs are classified as low grade (G1), intermediate grade (G2), or high grade (G3) (Table 80-1). In addition to the grading system, a TNM (TNM-tumor staging, T=primary size, N=regional lymph node involvement, M=distant metastases) classification has been proposed that is based on the level of tumor invasion, tumor size, and tumor extent (Table 80-1). Because of the proven prognostic value of these classification and grading systems, as well as the fact that NETs with different classifications/grades respond differently to treatments, these classification systems are now essential for the management of all NETs.

GI-NETs may or may not be associated with a specific functional syndrome (Table 80-2). In the case of pNETs the type of functional syndrome present is used to classify them into nine well-established specific functional syndromes (Table 80-2), seven additional very rare specific functional syndromes (less than five cases described), five possible specific functional syndromes (pNETs secreting calcitonin, neurotensin, pancreatic polypeptide [PP], ghrelin) (Table 80-2), and nonfunctional pNETs. Other functional hormonal syndromes due to nonpancreatic tumors (usually intra-abdominal in location) have been described only rarely and are not included in (Table 80-2). These include secretion by intestinal and ovarian tumors of peptide tyrosine tyrosine (PYY), which results in altered motility and constipation, and ovarian tumors secreting renin or aldosterone causing alterations in blood pressure or somatostatin causing diabetes or reactive hypoglycemia. Each of the functional syndromes listed in Table 80-2 is associated with symptoms due to the specific hormone released. In contrast, nonfunctional pNETs release no products that cause a specific clinical syndrome. "Nonfunctional" is a misnomer in the strict sense because those tumors frequently ectopically secrete a number of peptides (PP, chromogranin A, ghrelin, neurotensin, α subunits of human chorionic gonadotropin, and neuron-specific enolase); however, they cause no specific clinical syndrome. The symptoms caused by nonfunctional pNETs are entirely due to the tumor per se. pNETs frequently ectopically secrete PP (60–85%), neurotensin (30–67%), calcitonin (30–42%), and to a lesser degree, ghrelin (5–65%). Whereas a few studies have proposed that their secretion can cause a specific functional syndrome, most studies support the conclusion that their ectopic secretion is not associated with a specific clinical syndrome, and thus they are listed in Table 80-2 as possible clinical syndromes. Because a large proportion of nonfunctional pNETs (60–90%) secrete PP, these tumors are often referred to as PPomas (Table 80-2). pNETs can secrete secretin (secretinoma) producing watery diarrhea; however, only two possible cases are described.

GI-NETs (carcinoids) can occur in almost any GI tissue (Table 80-3); however, at present, most (70%) have their origin in one of three sites: bronchus, jejunoileum, or colon/rectum. In the past, GI-NET (carcinoids) most frequently were reported in the appendix (i.e., 40%); however, at present they account for <5% (Table 80-3). Overall, the GI tract is the most common site for NETs, accounting for 64%, with the respiratory tract a distant second at 28%. Both race and sex can affect the frequency as well as the distribution of GI-NETs (carcinoids). African Americans have a higher incidence of carcinoids. Race is particularly important for rectal carcinoids, which are found in 41%

TABLE 80-3 GI-NET (Carcinoid) Location, Frequency of Metastases, and Association with the Carcinoid Syndrome

	LOCATION (% OF TOTAL)	INCIDENCE OF METASTASES	INCIDENCE OF CARCINOID SYNDROME
Foregut

Abbreviation: GI-NET, gastrointestinal neuroendocrine tumor.

Source: Location is from the PAN-SEER data (1973–1999), and incidence of metastases is from the SEER data (1992–1999), reported by IM Modlin et al: Cancer 97:934, 2003. Incidence of carcinoid syndrome is from 4349 cases studied from 1950 to 1971, reported by JD Godwin: Cancer 36:560, 1975.

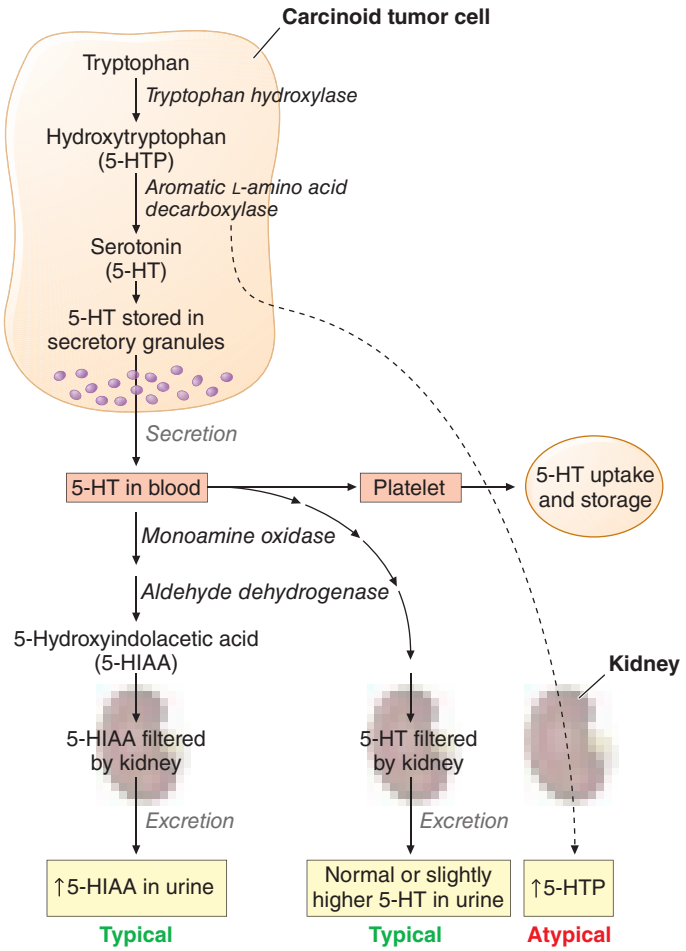

FIGURE 80-1 Synthesis, secretion, and metabolism of serotonin (5-HT) in patients with typical and atypical carcinoid syndromes. 5-HIAA, 5-hydroxyindolacetic acid.

of Asians/Pacific Islanders with NETs compared to 32% of American Indians/Alaskan natives, 26% of African Americans, and 12% of white Americans. Females have a lower incidence of small intestinal and pancreatic carcinoids.

The term *pancreatic neuroendocrine* or *endocrine tumor*, although widely used and therefore retained here, is also a misnomer, strictly speaking, because these tumors can occur either almost entirely in the pancreas (insulinomas, glucagonomas, nonfunctional pNETs, pNETs causing hypercalcemia) or at both pancreatic and extrapancreatic sites (gastrinomas, VIPomas [vasoactive intestinal peptide], somatostatinomas, GRFomas [growth hormone–releasing factor]). pNETs are also called islet cell tumors; however, the use of this term is discouraged because it is not established that they originate from the islets, and many can occur at extrapancreatic sites.

In addition to these classification/grading systems, a number of other factors have been identified that provide important prognostic information that can guide treatment **(Table 80-4)**.

The exact incidence of GI-NETs (carcinoids) or pNETs varies according to whether only symptomatic tumors or all tumors are considered. The incidence of clinically significant carcinoids is 7–13 cases/million population per year, whereas any malignant carcinoids at autopsy are reported in 21–84 cases/million population per year. The incidence of GI-NETs (carcinoids) is ~25–50 cases per million in the United States, which makes them less common than adenocarcinomas of the GI tract. However, their incidence has increased sixfold in the last 30 years. In an analysis of 35,825 GI-NETs (carcinoids) (2004) from the U.S. Surveillance, Epidemiology, and End Results (SEER) database which includes predominately malignant NETs, their incidence was 5.25/100,000 per year, and the 29-year prevalence was 35/100,000. Clinically significant pNETs have a prevalence of 10 cases/million population, with insulinomas, gastrinomas, and nonfunctional pNETs having an incidence of 0.5–2 cases/million population per year (Table 80-2). NF-pNETs are predominating, often making up 50–80% of the series, and increasingly found when asymptomatic. pNETs account for 1–10% of all tumors arising in the pancreas and 1.3% of tumors in the SEER database. VIPomas are 2–8 times less common, glucagonomas are 17–30 times less common, and somatostatinomas are the least common. In autopsy studies, 0.5–1.5% of all cases have a pNET; however, in <1 in 1000 cases was a functional tumor thought to occur.

Both GI-NETs (carcinoids) and pNETs commonly show malignant behavior (Tables 80-2 and 80-3). With pNETs, except for insulinomas in which <10% are malignant, 50–100% in different series are malignant. With GI-NETs (carcinoids), the percentage showing malignant behavior varies in different locations (Table 80-3). For the three most common sites of NET's occurrence, the incidence of metastases varies greatly from the jejunoileum (58%), lung/bronchus (6%), and rectum (4%) (Table 80-3). With both GI-NETs (carcinoids) and pNETs, a number of factors (Table 80-4) are important prognostic factors in determining survival and the aggressiveness of the tumor. Patients with pNETs (excluding insulinomas) generally have a poorer prognosis than do patients with GI-NETs (carcinoids). The presence of liver metastases is the single most important prognostic factor in single and multivariate analyses for both GI-NETs (carcinoids) and pNETs. Particularly important in the development of liver metastases is the size of the primary tumor. For example, with small intestinal carcinoids, which are the most common cause of the carcinoid syndrome due to metastatic disease in the liver (Table 80-2), metastases occur in 15–25% if the tumor is <1 cm in diameter, 58–80% if it is 1–2 cm in diameter, and >75% if it is >2 cm in diameter. Similar data exist for gastrinomas and other pNETs; the size of the primary tumor is an independent predictor of the development of liver metastases. The presence of lymph node metastases, their ratio or presence of extra-hepatic metastases; the depth of invasion; the rapid rate of growth; various histologic features (differentiation, mitotic rates, growth indices, vessel density, vascular endothelial growth factor [VEGF], CD10 metalloproteinase expression, abnormal expression of p53, retinoblastoma or SMAD, and low expression of p27 nuclear staining, low progesterone receptor expression); necrosis; presence of cytokeratin; elevated serum alkaline phosphatase levels; older age; presence of circulating tumor cells; increased uptake on ^{18}(F)-FDG-PET/CT scanning or low uptake (SUV/max) on ^{68}Ga-DOTANOC PET/CT scanning, and flow cytometric results, such as the presence of aneuploidy, are all important prognostic factors for the development of metastatic disease (Table 80-4). For patients with GI-NETs (carcinoids), additional associations with a worse prognosis include the development of the carcinoid syndrome (especially the development of carcinoid heart disease); male sex; the presence of a symptomatic tumor, a secondary malignancy, or greater increases in a number of tumor markers (5-hydroxyindolacetic acid [5-HIAA], neuropeptide K, chromogranin A), and the presence of various molecular features. With pNETs or gastrinomas, a worse prognosis is associated with female sex, overexpression of the Ha-*ras* oncogene or p53, the absence of Multiple Endocrine Neoplasia type 1 (MEN 1), presence of a NF-pNET, higher levels of various tumor markers (i.e., chromogranin A, gastrin, C-reactive protein), and presence of various histologic features (immunohistochemistry for c-KIT, low cyclin B1 or ATM, loss of PTEN/TSC-2, expression of fibroblast growth factor-13) and various molecular features (Table 80-4). The WHO, ENETs, and AJCC/UICC TNM classification systems and the grading systems (G1–G3) have important prognostic value and use in determining therapeutic management, that they are now generally routinely required.

A number of diseases due to various genetic disorders are associated with an increased incidence of NETs **(Table 80-5)**. Each one is caused by a loss of a possible tumor-suppressor gene. The most important is MEN 1, which is an autosomal dominant disorder due to a defect in a 10-exon gene on 11q13, which encodes for a 610-amino-acid nuclear protein, menin **(Chap. 381)**. Patients with MEN 1 develop hyperparathyroidism due to parathyroid hyperplasia in 95–100% of cases, pNETs in 80–100%, pituitary adenomas in 54–80%, adrenal adenomas in 27–36%, bronchial carcinoids in 8%, thymic carcinoids in 8% (predominately males), gastric carcinoids in 13–30% of patients with Zollinger-Ellison syndrome, skin tumors (angiofibromas [88%], collagenomas [72%]),

TABLE 80-4 Prognostic Factors in Neuroendocrine Tumors

I. Both GI-NETs (carcinoids) and pNETs
Symptomatic presentation (p <0.05)
Performance status (p <0.04)
Presence/extent of liver metastases (p <0.01)
Presence of lymph node metastases or lymph node positive ratio (p <0.001)
Development of bone or extrahepatic metastases (p <0.01)
Depth of invasion (p <0.001)
Rapid rate of tumor growth
Elevated serum alkaline phosphatase levels (p = 0.003)
Primary tumor site/site (p <0.005)
High serum chromogranin A level (p <0.01)
Presence of one or more circulating tumor cells (p <0.001)
Increased uptake on (18)F-FDG PET scanning
Low uptake (SUVmax) on (68)Ga-DOTANOC PET/CT scanning
Various histologic/molecular features
Tumor differentiation (p <0.001)
High growth indices (high Ki_{67} index, PCNA expression)
High mitotic counts (p <0.001)
Low progesterone receptor expression (p <0.001)
Necrosis present
Presence of cytokeratin 19 (p <0.02)
Vascular or perineural invasion (p <0.02)
Vessel density (low microvessel density, increased lymphatic density)
High CD10 metalloproteinase expression (in series with all grades of NETs)
Flow cytometric features (i.e., aneuploidy)
High VEGF expression (in low-grade or well-differentiated NETs only)
Abnormal expression of p53, Rb, SMADs
Loss of p27 expression(nuclear) (p <0.001)
WHO, ENETS, AJCC/UICC stage, and grade
Presence of a pNET rather than GI-NET associated with poorer prognosis (p = 0.0001)
Older age (p <0.01)
II. GI-NETs (carcinoids)
Location of primary: appendix < lung, rectum < small intestine < pancreas
Presence of carcinoid syndrome
Laboratory results (urinary 5-HIAA levels [p <0.01], plasma neuropeptide K [p <0.05], serum chromogranin A [p <0.01])
Presence of a second malignancy
Male sex (p <0.001)
Molecular findings (TGF-α expression [p <.05], chr 16q LOH or gain chr 4p [p <.05], gain in chr 14, loss of 3p13, loss of succinate dehydrogenase expression [ileal carcinoid], upregulation of Hoxc6), molecular profiling category (mutations, epigenetic changes, copy number-small intestinal NETs)
III. pNETs
Location of primary: duodenal (gastrinoma) better than pancreatic
Ha-*ras* oncogene or p53 overexpression
Female sex
MEN 1 syndrome absent
Presence of nonfunctional tumor (some studies, not all)
Various histologic features: IHC positivity for c-KIT, low cyclin B1 or ATM expression (p <0.01), loss of PTEN or of tuberous sclerosis-2 IHC, expression of fibroblast growth factor-13; high SSTR2 expression (p = .001);
Laboratory findings (increased chromogranin A in some studies; gastrinomas—increased gastrin level, increased CRP (p <0.001)
Molecular findings (increased HER2/*neu* expression [p = 0.032], chr 1q, 3p, 3q, or 6q LOH [p = 0.0004], EGF receptor overexpression [p = 0.034], gains in chr 7q, 17q, 17p, 20q; alterations in the VHL gene [deletion, methylation]; presence of FGFR4-G388R single-nucleotide polymorphism); loss of ATRX/DAXX or positive for alternative lengthening of telomeres (p <0.001); high nuclear surviving expression (p <0.01)
PHLDA3 LOH; altered miRNA expression (lnc miRNA-21, miRNA-196)

Abbreviations: 5-HIAA, 5-hydroxyindoleacetic acid; AJCC, American Joint Committee on Cancer; ATM, ataxia telangiectasia mutated kinase; ATRX, a-thalassemia/mental retardation X-linked; chr, chromosome; CRP, C-reactive protein; DAXX, death domain-associated protein; EGF, epidermal growth factor; FGFR, fibroblast growth factor receptor; GI-NET, gastrointestinal neuroendocrine tumor; IHC, immunohistochemistry; Ki_{67}, proliferation-associated nuclear antigen recognized by Ki_{67} monoclonal antibody; LOH, loss of heterozygosity; MEN, multiple endocrine neoplasia; NET, neuroendocrine tumors; PCNA, proliferating cell nuclear antigen; PHLDA3, Pleckstrin homology-like domain family A, member 3; pNET, pancreatic neuroendocrine tumor; PTEN, phosphatase and tensin homologue deleted from chromosome 10; Rb, retinoblastoma; SSTR2, somatostatin receptor subtype 2; TGF-α, transforming growth; factor α; TNM, tumor, node, metastasis; UICC, International Union Against Cancer; VEGF, vascular endothelial growth factor; WHO, World Health Organization.

central nervous system (CNS) tumors (meningiomas, ependymomas, schwannomas [<8%]), and smooth-muscle tumors (leiomyomas, leiomyosarcomas [1–7%]). Among patients with MEN 1, 80–100% develop nonfunctional pNETs (most are microscopic with 0–13% large/symptomatic), and functional pNETs occur in 20–80% in different series, with a mean of 54% developing Zollinger-Ellison syndrome, 18% insulinomas, 3% glucagonomas, 3% VIPomas, and <1% GRFomas or somatostatinomas. MEN 1 is present in 20–25% of all patients with Zollinger-Ellison syndrome, 4% of patients with insulinomas, and a low percentage (<5%) of patients with other pNETs.

TABLE 80-5 Genetic Syndromes Associated with an Increased Incidence of Neuroendocrine Tumors (NETs) (GI-NETs [Carcinoids] or pNETs)

SYNDROME	LOCATION OF GENE MUTATION AND GENE PRODUCT	NETS SEEN/ FREQUENCY
Multiple endocrine neoplasia type 1 (MEN 1)	11q13 (encodes 610-amino-acid protein, menin)	80–100% develop pNETs (microscopic), 20–80% (clinical): (nonfunctional > gastrinoma > insulinoma) GI-NETs (Carcinoids): gastric (13–30%), bronchial/thymic (8%)
von Hippel–Lindau disease	3q25 (encodes 213-amino-acid protein)	12–17% develop pNETs (almost always nonfunctional)
von Recklinghausen's disease (neurofibromatosis 1 [NF-1])	17q11.2 (encodes 2485-amino-acid protein, neurofibromin)	0–10% develop pNETs, primarily duodenal somatostatinomas (usually nonfunctional) Rarely insulinoma, gastrinoma
Tuberous sclerosis	9q34 (TSCI) (encodes 1164-amino-acid protein, hamartin), 16p13 (TSC2) (encodes 1807-amino-acid protein, tuberin)	0–9% develop pNETs (nonfunctional and functional [insulinoma, gastrinoma])

Abbreviations: GI, gastrointestinal; PNETs, pancreatic neuroendocrine tumors.

TABLE 80-6 Clinical Characteristics in Patients with Carcinoid Syndrome

	PERCENTAGE (RANGE)	
	AT PRESENTATION	DURING COURSE OF DISEASE
Symptoms/signs		
Diarrhea	32–93%	68–100%
Flushing	23–100%	45–96%
Pain	10%	34%
Asthma/wheezing	4–14%	3–18%
Pellagra	0–7%	0–5%
None	12%	22%
Carcinoid heart disease present	11–40%	14–41%
Demographics		
Male	46–59%	46–61%
Age		
Mean	57 years	59.2 years
Range	25–79 years	18–91 years
Tumor location		
Foregut	5–14%	0–33%
Midgut	57–87%	60–100%
Hindgut	1–7%	0–8%
Unknown	2–21%	0–26%

Three phacomatoses associated with NETs are von Hippel–Lindau disease (VHL), von Recklinghausen's disease (neurofibromatosis type 1 [NF-1]), and tuberous sclerosis (Bourneville's disease) (Table 80-5). VHL is an autosomal dominant disorder due to defects on chromosome 3p25, which encodes for a 213-amino-acid protein that interacts with the elongin family of proteins as a transcriptional regulator **(Chaps. 86, 309, 380, 381)**. In addition to cerebellar hemangioblastomas, renal cancer, and pheochromocytomas, 10–17% develop a pNET. Most are nonfunctional, although insulinomas and VIPomas have been reported. Patients with NF-1 (von Recklinghausen's disease) have defects in a gene on chromosome 17q11.2 that encodes for a 2845-amino-acid protein, neurofibromin, which functions in normal cells as a suppressor of the *ras* signaling cascade **(Chap. 86)**. Up to 10% of these patients develop an upper GI-NET (carcinoid), characteristically in the periampullary region (54%). Many are classified as somatostatinomas because they contain somatostatin immunocytochemically; however, they uncommonly secrete somatostatin and rarely produce a clinical somatostatinoma syndrome. NF-1 has rarely been associated with insulinomas and Zollinger-Ellison syndrome. NF-1 accounts for 48% of all duodenal somatostatinomas and 23% of all ampullary GI-NETs (carcinoids). Tuberous sclerosis is caused by mutations that alter either the 1164-amino-acid protein hamartin (TSC1) or the 1807-amino-acid protein tuberin (TSC2) **(Chap. 86)**. Both hamartin and tuberin interact in a pathway related to phosphatidylinositol 3-kinases and mammalian target of rapamycin (mTOR) signaling cascades. A few cases including nonfunctional and functional pNETs (insulinomas and gastrinomas) have been reported in these patients **(Table 80-6)**.

A few other syndromes involving GI-NETs have been described due to various mutations, but no inherited cases have been reported. Mahvash disease is associated with the development of α-cell hyperplasia, hyperglucagonemia, without features of the glucagonoma syndrome, the development of NF pNETs, and is due to inactivating mutations of the human glucagon receptor. The polycythemia-paraganglioma-somatostatinoma (SSoma) syndrome involves childhood polycythemia, later the development of norepinephrine-producing paragangliomas (mean age 17 years) then SSomas (mean age 29 years) with gallbladder disease. In 28% of the patients, a somatic mutation in hypoxia-inducible factor 2 alphas is found.

Most GI NETs (carcinoids) are sporadic, although as discussed above gastric carcinoids occur (type 2) in MEN1 syndrome, duodenal carcinoids (SSomas) occur in NF-1 and a small percentage of patients (<3%) with small intestinal carcinoids have a familial form of the disease, which in one family was due to mutations in the inositol polyphosphate multikinase gene (IMPK).

Mutations in common oncogenes (*ras, myc, fos, src, jun*) or common tumor-suppressor genes (*p53*, retinoblastoma susceptibility gene) are not commonly found in either pNETs or GI-NETs (carcinoids). However, frequent (70%) gene amplifications in *MDM2, MDM4,* and *WIPI* inactivating the p53 pathway are noted in well-differentiated pNETs, and the retinoblastoma pathway is altered in the majority of pNETs. In addition to these genes, additional alterations that may be important in their pathogenesis include changes in the *MEN1* gene, *p16/MTS1* tumor-suppressor gene, and *DPC4/Smad4* gene; amplification of the HER-2/*neu* protooncogene; alterations in transcription factors (Hoxc6 [GI carcinoids]), growth factors, and their receptors; methylation of a number of genes that probably results in their inactivation; and deletions of unknown tumor-suppressor genes as well as gains in other unknown genes. The clinical antitumor activity of everolimus, an mTOR inhibitor, and sunitinib, a tyrosine kinase inhibitor (PDGFR, VEGFR1, VEGFR2, c-KIT, FLT-3), support the importance of the mTOR-AKT pathway and tyrosine kinase receptors in mediating growth of malignant NETs (especially pNETs). The importance of the mTOR pathway in pNET growth is further supported by the finding that a single-nucleotide polymorphism (FGFR4-G388R, in fibroblast growth factor receptor 4) affects selectivity to the mTOR inhibitor and can result in significantly higher risk of advanced pNET stage and liver metastases (Table 80-4). Comparative genomic hybridization, genome-wide allelotyping studies, and genome-wide single-nucleotide polymorphism analyses have shown that chromosomal losses and gains are common in pNETs and GI-NETs (carcinoids), but they differ between these two NETs, and some have prognostic significance (Table 80-4). Mutations in the *MEN1* gene are probably particularly important. Loss of heterozygosity at the MEN 1 locus on chromosome 11q13 is noted in 93% of sporadic pNETs (i.e., in patients without MEN 1) and in 26–75% of sporadic GI-NETs (carcinoids). Mutations in the *MEN1* gene are reported in 31–34% of sporadic gastrinomas. Exomic sequencing of sporadic pNETs found that the most frequently altered gene was *MEN1*, occurring in 44% of patients, followed by mutations in 43% of patients in genes encoding for two subunits of a transcription/chromatin remodeling complex consisting of DAXX (death-domain-associated protein) and ATRX (α-thalassemia/mental retardation

syndrome X-linked) and in 15% of patients in the mTOR pathway. The presence of a number of these molecular alterations in pNETs or GI-NETs (carcinoids) correlates with tumor growth, tumor size, and disease extent or invasiveness and may have prognostic significance (Table 80-4).

GI NETs (carcinoids) have frequently loss of chromosome 18 (>60%) as well as losses on Chr 9p, 16q and chromosomal gains of 17q, 19p (57%) and lesser gains on 4q, 14q, and Chr 5, but the exact genes mediating possible effects on the tumor in these areas are still unclear. In contrast to pNETs, mutations in GI-NETs (carcinoids) are uncommon, and in one study of 180 small intestinal carcinoids, with exome and genome-sequencing analysis recurrent mutations were only observed in the CDKN1B gene (cyclin-dependent kinase inhibitor 1B [$p27^{Kip1}$]) in 8%. Integrative genomic analysis incorporating DNA methylation, show that small intestinal GI carcinoids commonly have epigenetic changes and three molecular subgroups with differing clinical course and outcomes have been identified (Table 80-4).

CHARACTERISTICS OF THE MOST COMMON GI-NETs (CARCINOIDS)

Appendiceal NETs (Carcinoids) Appendiceal NETs (carcinoids) occur in 1 in every 200–300 appendectomies, usually in the appendiceal tip, have an incidence of 0.15/100,000 per year, comprise 2–5% of all GI-NETs (carcinoids), and comprise 32–80% of all appendiceal tumors. The mean age at diagnosis is 38–51 years. Most (i.e., >90%) are <1 cm in diameter without metastases in older studies, but more recently, 2–35% have had metastases (Table 80-3). In the SEER data of 1570 appendiceal carcinoids, 62% were localized, 27% had regional metastases, and 8% had distant metastases. The risk of metastases increases with size, with those <1 cm having a 0 to <10% risk of metastases and those >2 cm having a 25–44% risk. Besides tumor size, other important prognostic factors for metastases include basal NET location, invasion of mesoappendix, poor differentiation, advanced stage or WHO/ENETS classification, older age, and positive resection margins. The 5-year survival is 88–100% for patients with localized disease, 78–100% for patients with regional involvement, and 12–28% for patients with distal metastases. In patients with tumors <1 cm in diameter, the 5-year survival is 95–100%, whereas it is 29% if tumors are >2 cm in diameter. Most tumors are well-differentiated G1 tumors (87%) (Table 80-1), with the remainder primarily well-differentiated G2 tumors (13%); with poorly differentiated G3 tumors uncommon (<1%). Their percentage of the total number of carcinoids decreased from 43.9% (1950–1969) to 2.4% (1992–1999). Appendiceal goblet cell (GC) NETs (carcinoids)/carcinomas are a rare subtype (<5%) that are mixed adeno-neuroendocrine carcinomas. They are malignant and are thought to comprise a distinct entity; they frequently present with advanced disease and are recommended to be treated as adenocarcinomas, not carcinoid tumors.

SMALL INTESTINAL NETs (CARCINOIDS)

Small intestinal (SI) NETs (carcinoids) have a reported incidence of 0.67/100,000 in the United States, 0.32/100,000 in England, and 1.12/100,000 in Sweden and comprise >50% of all SI tumors. There is a male predominance (1.5:1), and race affects frequency, with a lower frequency in Asians and greater frequency in African Americans. The mean age of presentation is 52–63 years, with a wide range (1–93 years). Familial SI carcinoid families exist but are very uncommon. SI NETs (carcinoids) are frequently multiple; 9–18% occur in the jejunum, 70–80% are present in the ileum, and 70% occur within 6 cm (2.4 in.) of the ileocecal valve. Forty percent are <1 cm in diameter, 32% are 1–2 cm, and 29% are >2 cm. They are characteristically well differentiated; however, they are generally invasive, with 1.2% being intramucosal in location, 27% penetrating the submucosa, and 20% invading the muscularis propria. Metastases occur in a mean of 47–58% (range 20–100%). Liver metastases occur in 38%, to lymph nodes in 37% and more distant in 20–25%. They characteristically cause a marked fibrotic reaction, which can lead to intestinal obstruction. Tumor size is an important variable in the frequency of metastases. However, even small NETs (carcinoids) of the small intestine (<1 cm) have metastases in 15–25% of cases, whereas the proportion increases to 58–100% for tumors 1–2 cm in diameter. Carcinoids also occur in the duodenum, with 31% having metastases. Duodenal tumors <1 cm rarely metastasize, whereas 33% of those >2 cm had metastases. SI NETs (carcinoids) are the most common cause (60–87%) of the carcinoid syndrome (Table 80-6). Important prognostic factors are listed in Table 80-4, and particularly important are the tumor extent, proliferative index by grading, and stage (Table 80-1). SI NETs (carcinoid) are well differentiated in 99% of cases with 61–72% being G1 and 11–37% being G2. The overall survival at 5 years is 55–75%; however, it varies markedly with disease extent, being 65–90% with localized disease, 66–72% with regional involvement, and 36–43% with distant disease.

Rectal NETs (Carcinoids) Rectal NETs (carcinoids) comprise 27% of all GI-NETs (carcinoids) and 16% of all NETs and are increasing in frequency. In Europe they comprise 5–14% of all NETs and in some Asian series (Japan, China, Korea) they comprise 60–89% of all NETs. In the U.S. SEER data, they currently have an incidence of 0.86/100,000 per year (up from 0.2/100,000 per year in 1973) and represent 1–2% of all rectal tumors. They are found in ~1 in every 1500/2500 proctoscopies/colonoscopies or 0.05–0.07% of individuals undergoing these procedures. Nearly all occur between 4 and 13 cm above the dentate line. Most are small, with 66–80% being <1 cm in diameter, and rarely metastasize (5%). Tumors between 1 and 2 cm can metastasize in 5–30%, and those >2 cm, which are uncommon, in >70%. Most invade only to the submucosa (75%), with 2.1% confined to the mucosa, 10% to the muscular layer, and 5% to adjacent structures. Histologically, most are well differentiated (98%) with 72% ENETS/WHO grade G1 and 28% grade G2 (Table 80-1). Overall survival is 88%; however, it is very much dependent of the stage, with 5-year survival of 91% for localized disease, 36–49% for regional disease, and 20–32% for distant disease. Risk factors are listed in Table 80-4 and particularly include tumor size, depth of invasion, presence of metastases, differentiation, and recent TNM classification and grade.

Bronchial NETs (Carcinoids) Bronchial NETs (carcinoids) comprise 25–33% of all well-differentiated NETs and 90% of all the poorly differentiated NETs found, likely due to a strong association with smoking. Their incidence ranges from 0.2 to 2/100,000 per year in the United States and European countries and is increasing at a rate of 6% per year. They are slightly more frequent in females and in whites compared with those of Hispanic/Asian/African descent, and are most commonly seen in the sixth decade of life, with a younger age of presentation for typical carcinoids (45 years) compared to atypical carcinoids (55 years).

A number of different classifications of bronchial GI-NETs (carcinoids) have been proposed. The principal factors used in classifying lung NETs include: morphology, presence or absence of necrosis, mitotic rate and size. In some studies, they are classified into four categories: typical carcinoid (also called bronchial carcinoid tumor, Kulchitsky cell carcinoma I [KCC-I]), atypical carcinoid (also called well-differentiated NEC [KC-II]), intermediate small-cell NEC, and small-cell neuroendocarcinoma (KC-III). Another proposed classification includes three categories of lung NETs: benign or low-grade malignant (typical carcinoid), low-grade malignant (atypical carcinoid), and high-grade malignant (poorly differentiated carcinoma of the large-cell or small-cell type). The WHO classification includes four general categories: typical carcinoid, atypical carcinoid, large-cell NEC, and small-cell carcinoma. The ratio of typical to atypical carcinoids is 8–10:1, with the typical carcinoids comprising 1–2% of lung tumors, atypical 0.1–0.2%, large-cell NETs 0.3%, and small-cell lung cancer 9.8% of all lung tumors. These different categories of lung NETs have different prognoses, varying from excellent for typical carcinoid to poor for small-cell NECs. The occurrence of large-cell and small-cell lung carcinoids, but not typical or atypical lung carcinoids, is related to tobacco use. The 5-year survival is very much influenced by the classification of the tumor, with survival of 92–100% for patients with a typical carcinoid, 61–88% with an atypical carcinoid, 13–57% with a large-cell neuroendocrine tumor, and 5% with a small-cell lung cancer. Typical/atypical lung carcinoids are generally well-differentiated with typical lung carcinoids sharing some homologies with G1 NETs, atypical

sharing some homologies with G2 NETs of the GI tract, whereas small cell and large cell lung NECs are poorly differentiated and correspond to the G3 NEC category of the GI Tract (Table 80-1).

Gastric NET (Carcinoids) Gastric NETs (carcinoids) account for 3 of every 1000 gastric neoplasms and 1.3–2% of all carcinoids, and their relative frequency has increased three- to fourfold over the last five decades (2.2% in 1950 to 9.6% in 2000–2007, SEER data). At present, it is unclear whether this increase is due to better detection with the increased use of upper GI endoscopy or to a true increase in incidence. Gastric NETs (carcinoids) are generally classified into three different categories, and this has important implications for pathogenesis, prognosis, and treatment. Each originates from gastric enterochromaffin-like (ECL) cells, one of the six types of gastric neuroendocrine cells, in the gastric mucosa. Two subtypes are associated with hypergastrinemic states, either chronic atrophic gastritis (type I) (70–80% of all gastric NETs [carcinoids]) or Zollinger-Ellison syndrome, which is almost always a part of the MEN 1 syndrome (type II) (5–6% of all cases). These tumors generally pursue a benign course, with type I uncommonly (<10%) associated with metastases, whereas type II tumors are slightly more aggressive, with 10–30% associated with metastases. Gastric carcinoids type 1 and type 2 are usually multiple, small, and infiltrate only to the submucosa. The third subtype of gastric NETs (carcinoids) (type III) (sporadic) occurs without hypergastrinemia (14–25% of all gastric carcinoids) and has an aggressive course, with 54–66% developing metastases. Sporadic carcinoids are usually single, large tumors; 50% have atypical histology, and they can be a cause of the carcinoid syndrome. Five-year survival is 99–100% in patients with type I, 60–90% in patients with type II, and 50% in patients with type III gastric NETs (carcinoids). Type 1 gastric carcinoids are usually grade G1 and well differentiated; type 2 are well-differentiated grade G1 or G2; and type 3 are characteristically NEC G3 with poor differentiation.

CLINICAL PRESENTATION OF NETs (CARCINOIDS)

GI/Lung NET (Carcinoid) Without the Carcinoid Syndrome

The age of patients at diagnosis ranges from 10 to 93 years, with a mean age of 63 years for the small intestine, 43–60 years for bronchial, and 66 years for the rectum. The presentation is diverse and is related to the site of origin and the extent of malignant spread. In the appendix, NETs (carcinoids) usually are found incidentally during surgery for suspected appendicitis. SI NETs (carcinoids) in the jejunoileum present with periodic abdominal pain (51%), intestinal obstruction with ileus/invagination (31%), an abdominal tumor (17%), or GI bleeding (11%). Because of the vagueness of the symptoms, the diagnosis usually is delayed ~2 years from onset of the symptoms, with a range up to 20 years. Duodenal, gastric, and rectal NETs (carcinoids) are most frequently found by chance at endoscopy. The most common symptoms of rectal carcinoids are melena/bleeding (39%), constipation (17%), and diarrhea (12%). Bronchial NETs (carcinoids) frequently are discovered as a lesion on a chest radiograph, and 31–43% of the patients are asymptomatic. Thymic NETs (carcinoids) present as anterior mediastinal masses, usually on chest radiograph or computed tomography (CT) scan. Ovarian and testicular NETs (carcinoids) usually present as masses discovered on physical examination or ultrasound. Metastatic NETs (carcinoids) in the liver frequently present as hepatomegaly in a patient who may have minimal symptoms and nearly normal liver function test results.

GI-NETs (CARCINOIDS) WITH SYSTEMIC SYMPTOMS DUE TO SECRETED PRODUCTS

GI/lung NETs (carcinoids) immunocytochemically can contain numerous GI peptides: gastrin, insulin, somatostatin, motilin, neurotensin, tachykinins (substance K, substance P, neuropeptide K), glucagon, gastrin-releasing peptide, vasoactive intestinal peptide (VIP), PP, ghrelin, other biologically active peptides (ACTH, calcitonin, growth hormone, GRF), prostaglandins, and bioactive amines (serotonin). These substances may or may not be released in sufficient amounts to cause symptoms. In various studies of patients with GI-NETs (carcinoids), elevated serum levels of PP were found in 43%, motilin in 14%, gastrin in 15%, and VIP in 6%. Foregut NETs (carcinoids) are more likely to produce various GI peptides than are midgut NETs (carcinoids). Ectopic ACTH production causing Cushing's syndrome is seen increasingly with foregut carcinoids (respiratory tract primarily) and, in some series, has been the most common cause of the ectopic ACTH syndrome, accounting for 64% of all cases. Acromegaly due to growth hormone–releasing factor release occurs with foregut NETs (carcinoids), as does the somatostatinoma syndrome, but rarely occurs with duodenal NETs (carcinoids). The most common systemic syndrome with GI-NETs (carcinoids) is the carcinoid syndrome, which is discussed in detail in the next section.

CARCINOID SYNDROME

Clinical Features The cardinal features from a number of series at presentation as well as during the disease course are shown in Table 80-6.

Flushing and diarrhea are the two most common symptoms, occurring in a mean of 69–70% of patients initially and in up to 78% of patients during the course of the disease. The characteristic flush is of sudden onset; it is a deep red or violaceous erythema of the upper body, especially the neck and face, often associated with a feeling of warmth and occasionally associated with pruritus, lacrimation, diarrhea, or facial edema. Flushes may be precipitated by stress; alcohol; exercise; certain foods, such as cheese; or certain agents, such as catecholamines, pentagastrin; and serotonin reuptake inhibitors. Flushing episodes may be brief, lasting 2–5 min, especially initially, or may last hours, especially later in the disease course. Flushing usually is associated with metastatic midgut NETs (carcinoids) but can also occur with foregut NETs (carcinoids). With bronchial NETs (carcinoids), the flushes frequently are prolonged for hours to days, reddish in color, and associated with salivation, lacrimation, diaphoresis, diarrhea, and hypotension. The flush associated with gastric NETs (carcinoids) can also be reddish in color, but with a patchy distribution over the face and neck, although the classic flush seen with midgut NETs (carcinoids) can also be seen with gastric NETs (carcinoids). It may be provoked by food and have accompanying pruritus.

Diarrhea usually occurs with flushing (85% of cases). The diarrhea usually is described as watery, with 60% of patients having <1 L/d of diarrhea. Steatorrhea is present in 67%, and in 46%, it is >15 g/d (normal <7 g). Abdominal pain may be present with the diarrhea or independently in 10–34% of cases.

Cardiac manifestations occur initially in 11–40% (mean 26%) of patients with carcinoid syndrome and in 14–41% (mean 30%) at some time in the disease course. The cardiac disease is due to the formation of fibrotic plaques (composed of smooth-muscle cells, myofibroblasts, and elastic tissue) involving the endocardium, primarily on the right side, although lesions on the left side also occur occasionally (mean 11%, range 0–25), especially if a patent foramen ovale exists. The dense fibrous deposits are most commonly on the ventricular aspect of the tricuspid valve and less commonly on the pulmonary valve cusps. They can result in constriction of the valves, and pulmonic stenosis is usually predominant, whereas the tricuspid valve is often fixed open, resulting in regurgitation predominating. Overall, in patients with carcinoid heart disease, 90–100% have tricuspid insufficiency, 43–59% have tricuspid stenosis, 50–81% have pulmonary insufficiency, 25–59% have pulmonary stenosis, and 11% (0–25%) left-side lesions. Up to 80% of patients with cardiac lesions develop heart failure. Lesions on the left side are much less extensive, occur in 30% at autopsy, and most frequently affect the mitral valve. Up to 80% of patients with cardiac lesions have evidence of heart failure. At diagnosis in various series, 27–43% of patients are in New York Heart Association class I, 30–40% are in class II, 13–31% are in class III, and 3–12% are in class IV. At present, carcinoid heart disease is reported to be decreasing in frequency and severity, with mean occurrence in 20% of patients and occurrence in as few as 3–4% in some reports. Whether this decrease is due to the widespread use of somatostatin analogues, which control the release of bioactive agents thought involved in mediating the heart disease, is unclear.

Other clinical manifestations include wheezing or asthma-like symptoms (8–18%), pellagra-like skin lesions (2–25%), and impaired

cognitive function. A variety of noncardiac problems due to increased fibrous tissue have been reported, including retroperitoneal fibrosis causing urethral obstruction, Peyronie's disease of the penis, intraabdominal fibrosis, and occlusion of the mesenteric arteries or veins.

Pathobiology Carcinoid syndrome occurred in 8% of 8876 patients with GI-NETs (carcinoids), with a rate of 1.7–18.4% in different studies. It occurs only when sufficient concentrations of products secreted by the tumor reach the systemic circulation. In 91–100% of cases, this occurs after distant metastases to the liver. Rarely, primary GI-NETs (carcinoids) with nodal metastases with extensive retroperitoneal invasion, pNETs (carcinoids) with retroperitoneal lymph nodes, or NETs (carcinoids) of the lung, testis or ovary with direct access to the systemic circulation can cause the carcinoid syndrome without hepatic metastases. All GI-NETs (carcinoids) do not have the same propensity to metastasize and cause the carcinoid syndrome (Table 80-3). Midgut NETs (carcinoids) account for 57–67% of cases of carcinoid syndrome, foregut NETs (carcinoids) for 0–33%, hindgut for 0–8%, and an unknown primary location for 2–26% (Tables 80-3 and 80-6).

One of the main secretory products of GI-NETs (carcinoids) involved in the carcinoid syndrome is serotonin (5-HT) (Fig. 80-1), which is synthesized from tryptophan. Up to 50% of dietary tryptophan can be used in this synthetic pathway by tumor cells, and this can result in inadequate supplies for conversion to niacin; hence, some patients (2.5%) develop pellagra-like lesions. Serotonin has numerous biologic effects, including stimulating intestinal secretion with inhibition of absorption, stimulating increases in intestinal motility, and stimulating fibrogenesis. In various studies, 56–88% of all GI-NETs (carcinoids) were associated with serotonin overproduction; however, 12–26% of the patients did not have the carcinoid syndrome. In one study, platelet serotonin was elevated in 96% of patients with midgut NETs (carcinoids), 43% with foregut tumors, and 0% with hindgut tumors. In 90–100% of patients with the carcinoid syndrome, there is evidence of serotonin overproduction. Serotonin is thought to be predominantly responsible for the diarrhea. Patients with the carcinoid syndrome have increased colonic motility with a shortened transit time and possibly a secretory/absorptive alteration that is compatible with the known actions of serotonin in the gut mediated primarily through 5-HT_3 and, to a lesser degree, 5-HT_4 receptors. Serotonin receptor antagonists (especially 5-HT_3 antagonists) relieve the diarrhea in many, but not all, patients. A tryptophan 5-hydroxylase inhibitor, telotristat (LX-10310), which inhibits serotonin synthesis in peripheral tissues, caused a decrease in bowel movement frequency in 40–50% of patients with the carcinoid syndrome. Additional studies suggest that tachykinins may be important mediators of diarrhea in some patients. In one study, plasma tachykinin levels correlated with symptoms of diarrhea. Serotonin does not appear to be involved in the flushing in most patients because serotonin receptor antagonists do not relieve flushing. In patients with gastric carcinoids, the characteristic red, patchy pruritic flush is thought due to histamine release because H_1 and H_2 receptor antagonists can prevent it. Numerous studies have shown that tachykinins (substance P, neuropeptide K) are stored in GI-NETs (carcinoids) and released during flushing. However, some studies have demonstrated that octreotide can relieve the flushing induced by pentagastrin in these patients without altering the stimulated increase in plasma substance P, suggesting that other mediators must be involved in the flushing. A correlation between plasma tachykinin levels (but not substance P levels) and flushing has been reported. Prostaglandin release could be involved in mediating either the diarrhea or flush, but conflicting data exist. Both histamine and serotonin may be responsible for the wheezing as well as the fibrotic reactions involving the heart, causing Peyronie's disease and intraabdominal fibrosis.

The exact mechanism of the heart disease remains unclear, although increasing evidence supports a central role for serotonin. Patients with heart disease have higher plasma levels of neurokinin A, substance P, plasma atrial natriuretic peptide (ANP), pro-brain natriuretic peptide, chromogranin A, and activin A as well as higher urinary 5-HIAA excretion.

The valvular heart disease caused by the appetite-suppressant drugs dexfenfluramine and benfluorex is histologically indistinguishable from that observed in carcinoid disease. Furthermore, ergot-containing dopamine receptor agonists used for Parkinson's disease (pergolide, cabergoline) cause valvular heart disease that closely resembles that seen in the carcinoid syndrome. Furthermore, in animal studies, the formation of valvular plaques/fibrosis occurs after prolonged treatment with serotonin as well as in animals with a deficiency of the 5-HIAA transporter gene, which results in an inability to inactivate serotonin. Metabolites of fenfluramine, as well as the dopamine receptor agonists, have high affinity for serotonin receptor subtype 5-HT_{2B} receptors, whose activation is known to cause fibroblast mitogenesis. Serotonin receptor subtypes 5-$HT_{1B,1D,2A,2B}$ normally are expressed in human heart valve interstitial cells. High levels of 5-HT_{2B} receptors are known to occur in heart valves and occur in cardiac fibroblasts and cardiomyocytes. Studies of cultured interstitial cells from human cardiac valves have demonstrated that these valvulopathic drugs induce mitogenesis by activating 5-HT_{2B} receptors and stimulating upregulation of transforming growth factor β and collagen biosynthesis. These observations support the conclusion that serotonin overproduction by GI-NETs (carcinoids) is important in mediating the valvular changes, possibly by activating 5-HT_{2B} receptors in the endocardium. Both the magnitude of serotonin overproduction and prior chemotherapy are important predictors of progression of the heart disease, whereas patients with high plasma levels of ANP have a worse prognosis. Plasma connective tissue growth factor levels are elevated in many fibrotic conditions; elevated levels occur in patients with carcinoid heart disease and correlate with the presence of right ventricular dysfunction and the extent of valvular regurgitation in patients with GI-NETs (carcinoids).

Patients may develop either a typical or, rarely, an atypical carcinoid syndrome (Fig. 80-1). In patients with the typical form, which characteristically is caused by midgut NETs (carcinoids), the conversion of tryptophan to 5-HTP by tryptophan hydroxylase is the rate-limiting step (Fig. 80-1). Once 5-HTP is formed, it is rapidly converted to 5-HT and stored in secretory granules of the tumor or in platelets. A small amount remains in plasma and is converted to 5-HIAA, which appears in large amounts in the urine. These patients have an expanded serotonin pool size, increased blood and platelet serotonin, and increased urinary 5-HIAA. Some GI-NETs (carcinoids) cause an atypical carcinoid syndrome that is thought to be due to a deficiency in the enzyme dopa decarboxylase; thus, 5-HTP cannot be converted to 5-HT (serotonin), and 5-HTP is secreted into the bloodstream (Fig. 80-1). In these patients, plasma serotonin levels are normal but urinary levels may be increased because some 5-HTP is converted to 5-HT in the kidney. Characteristically, urinary 5-HTP and 5-HT are increased, but urinary 5-HIAA levels are only slightly elevated. Foregut carcinoids are the most likely to cause an atypical carcinoid syndrome; however, they also can cause a typical carcinoid syndrome.

One of the most immediate life-threatening complications of the carcinoid syndrome is the development of a carcinoid crisis. This is more common in patients who have intense symptoms or have greatly increased urinary 5-HIAA levels (i.e., >200 mg/d). The crisis may occur spontaneously; however, it is usually provoked by procedures such as anesthesia, chemotherapy, surgery, biopsy, endoscopy, or radiologic examinations such as during biopsies, hepatic artery embolization, and vessel catheterization. It can be provoked by stress or procedures as mild as repeated palpation of the tumor during physical examination. Patients develop intense flushing, diarrhea, abdominal pain, cardiac abnormalities including tachycardia, hypertension, or hypotension, and confusion or stupor. If not adequately treated, this can be a terminal event.

DIAGNOSIS OF THE CARCINOID SYNDROME AND GI-NETs (CARCINOIDS)

The diagnosis of carcinoid syndrome relies on measurement of urinary or plasma serotonin or its metabolites in the plasma or urine. The measurement of urinary 5-HIAA is used most frequently. False-positive elevations may occur if the patient is eating serotonin-rich foods such as bananas, pineapples, walnuts, pecans, avocados, or hickory nuts or is taking certain medications (cough syrup containing guaifenesin, acetaminophen, salicylates, serotonin reuptake inhibitors, or L-dopa).

The normal range for daily urinary 5-HIAA excretion is 2–8 mg/d. Serotonin overproduction was noted in 92% of patients with carcinoid syndrome in one study, and in another study, 5-HIAA had 73% sensitivity and 100% specificity for carcinoid syndrome. Serotonin overproduction is *not* synonymous with the presence of clinical carcinoid syndrome because 12–26% of patients with serotonin overproduction do not have clinical evidence of the carcinoid syndrome.

Most physicians use only the urinary 24-h 5-HIAA excretion rate; even though a recent study shows an overnight urinary collection is just as accurate. Assessment of plasma and platelet serotonin levels and plasma 5-HIAA, if available, may provide additional information and/or substitute for the 24 h urinary 5-HIAA study. Platelet serotonin levels are more sensitive than urinary 5-HIAA but are not generally available. A single plasma 5-HIAA determination was found to have similar sensitivity/specificity to that with the 24-h urinary 5-HIAA assessment, suggesting this could replace the standard urinary collection because of its greater convenience and avoidance of incomplete or improper collections. It, however, could be affected by renal disease. Because patients with foregut NETs (carcinoids) may produce an atypical carcinoid syndrome, if this syndrome is suspected and the urinary 5-HIAA is minimally elevated or normal, other urinary metabolites of tryptophan, such as 5-HTP and 5-HT, should be measured (Fig. 80-1).

Flushing occurs in a number of other diseases, including systemic mastocytosis, chronic myeloid leukemia with increased histamine release, menopause, reactions to alcohol or glutamate, and side effects of chlorpropamide, calcium channel blockers, and nicotinic acid. None of these conditions causes increased urinary 5-HIAA.

The diagnosis of carcinoid tumor can be suggested by the carcinoid syndrome, recurrent abdominal symptoms in a healthy-appearing individual, or the discovery of hepatomegaly or hepatic metastases associated with minimal symptoms. Ileal NETs (carcinoids), which make up 25% of all clinically detected carcinoids, should be suspected in patients with bowel obstruction, abdominal pain, flushing, or diarrhea.

Serum chromogranin A levels are elevated in 56–100% of patients with GI-NETs (carcinoids), and the level correlates with tumor bulk. Serum chromogranin A levels are not specific for GI-NETs (carcinoids) because they are also elevated in patients with pNETs and other NETs. Furthermore, a major problem is caused by potent acid antisecretory drugs such as proton pump inhibitors (omeprazole and related drugs) because they almost invariably cause elevation of plasma chromogranin A levels; the elevation occurs rapidly (3–5 days) with continued use, and the elevated levels overlap with the levels seen in many patients with NETs. Plasma neuron-specific enolase levels are also used as a marker of GI-NETs (carcinoids) but are less sensitive than chromogranin A, being increased in only 17–47% of patients. Newer markers have been proposed including pancreastatin (a chromogranin A breakdown product), and activin A. The former is not affected by proton pump inhibitors; however, its sensitivity and specificity are not established. Plasma activin elevations are reported to correlate with the presence of cardiac disease with a sensitivity of 87% and specificity of 57%. Plasma levels of N-terminal pro brain natriuretic peptide moderately correlate with carcinoid heart disease severity.

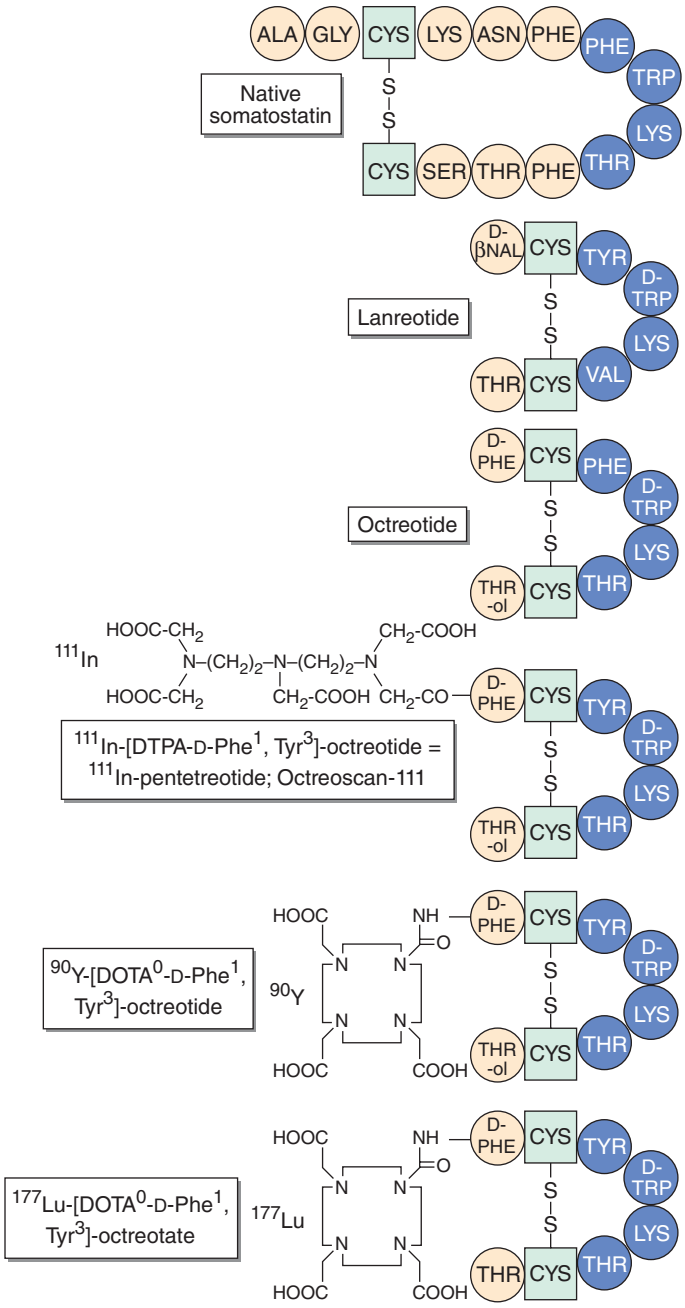

FIGURE 80-2 Structure of somatostatin and synthetic analogues used for diagnostic or therapeutic indications.

TREATMENT

Carcinoid Syndrome and Nonmetastatic Gastrointestinal Neuroendocrine Tumors (Carcinoids)

CARCINOID SYNDROME

Treatment includes avoiding conditions that precipitate flushing, dietary supplementation with nicotinamide, treatment of heart failure with diuretics, treatment of wheezing with oral bronchodilators, and control of the diarrhea with antidiarrheal agents such as loperamide and diphenoxylate. If patients still have symptoms, somatostatin analogues or less frequently, serotonin receptor antagonists, are the drugs of choice **(Fig. 80-2)**. An additional point dealt with in later sections, is the fact that most patients who develop the carcinoid syndrome have metastatic disease to the liver. Numerous antitumor therapies (liver-directed therapies, PRRT, surgery, chemotherapy/targeted drug therapies) also can ameliorate the severity of the carcinoid syndrome.

There are 14 subclasses of serotonin receptors, and antagonists for many are not available. The 5-HT$_1$ and 5-HT$_2$ receptor antagonists methysergide, cyproheptadine, and ketanserin have all been used to control the diarrhea but usually do not decrease flushing. The use of methysergide is limited because it can cause or enhance retroperitoneal fibrosis. Ketanserin diminishes diarrhea in 30–100% of patients. 5-HT$_3$ receptor antagonists (ondansetron, tropisetron, alosetron) can control diarrhea and nausea in up to 100% of patients and occasionally ameliorate the flushing. A combination of histamine H$_1$ and H$_2$ receptor antagonists (i.e., diphenhydramine and cimetidine or ranitidine) may control flushing in patients with foregut carcinoids. A phase 3 prospective, double-blind study provides evidence the peripheral tryptophan hydroxylase inhibitor, telotristat, will be useful to control the diarrhea in many of these patients.

Synthetic analogues of somatostatin (octreotide, lanreotide) are now the most widely used agents to control the symptoms of patients with

carcinoid syndrome (Figs. 80-1 and 80-2). These drugs are effective at relieving symptoms and decreasing urinary 5-HIAA levels in patients with this syndrome. Octreotide-LAR (10–30 mg i.m., monthly) and lanreotide-SR/autogel (Somatuline) (60–120 mg sc-deep, monthly) (sustained-release formulations allowing monthly injections) (Fig. 80-2), control symptoms in 74 and 68% of patients, respectively, with carcinoid syndrome and show a biochemical response in 51 and 64%, respectively. Patients with mild to moderate symptoms usually are treated initially with octreotide 50–100 μg SC every 8 h or lower doses or low doses of the long-acting formulations, and then receive higher doses as needed of the long-acting monthly depot forms (octreotide-LAR or lanreotide-autogel). Forty percent of patients escape control after a median time of 4 months, and the depot dosage may have to be increased as well as supplemented with the shorter-acting formulation, SC octreotide. Pasireotide (SOM230) is a somatostatin analogue with broader selectivity (high-affinity somatostatin receptors [sst_1, sst_2, sst_3, sst_5]) than octreotide/lanreotide (sst_2, sst_5). In a phase II study of patients with refractory carcinoid syndrome, pasireotide controlled symptoms in 27%.

Carcinoid heart disease is associated with a decreased mean survival (3.8 years), and therefore, it should be sought for and carefully assessed in all patients with carcinoid syndrome. Transthoracic echocardiography remains a key element in establishing the diagnosis of carcinoid heart disease and determining the extent and type of cardiac abnormalities. Treatment with diuretics and somatostatin analogues can reduce the negative hemodynamic effects and secondary heart failure. It remains unclear whether long-term treatment with these drugs or with the tryptophan hydroxylase inhibitor, telotristat, when it becomes available, will decrease the progression of carcinoid heart disease. Balloon valvuloplasty for stenotic valves or cardiac valve surgery may be required.

To prevent as well as treat patients with carcinoid crises, somatostatin analogues are recommended, although there is controversy of how effective they are and what dosage should be use. To prevent carcinoid crises development, treatment with somatostatin analogues is recommended prior to the possible precipitating event such as surgery, anesthesia, chemotherapy, and stress. It is generally recommended that octreotide 150–250 μg SC every 6–8 h be used 24–48 h before anesthesia and then continued throughout the procedure. Another commonly used protocol is to use 100 μg/h by continuous infusion with or without a preoperative bolus.

Currently, sustained-release preparations of both octreotide (octreotide-LAR [long-acting release], 10, 20, 30 mg) and lanreotide (lanreotide-PR [prolonged release, lanreotide-autogel], 60, 90, 120 mg) are available and widely used because their use greatly facilitates long-term treatment. Octreotide-LAR (30 mg/month) gives a plasma level ≥1 ng/mL for 25 days, whereas this requires 3–6 injections a day of the non-sustained-release form. Lanreotide-autogel (Somatuline) is given every 4–6 weeks.

Short-term side effects occur in up to one-half of patients. Pain at the injection site and side effects related to the GI tract (59% discomfort, 15% nausea, diarrhea) are the most common. They are usually short-lived and do not interrupt treatment. Important long-term side effects include gallstone formation, steatorrhea, and deterioration in glucose tolerance. The overall incidence of gallstones/biliary sludge varies from 5 to 66%, with 7% having symptomatic disease that required surgical treatment in one study.

Interferon α is reported to be effective in controlling symptoms of the carcinoid syndrome either alone or combined with hepatic artery embolization. With interferon α alone, the clinical response rate is 30–70%, and with interferon α with hepatic artery embolization, diarrhea was controlled for 1 year in 43% and flushing was controlled in 86%. Side effects develop in almost all patients, with the most frequent being a flu-like syndrome (80–100%), followed by anorexia and fatigue, even though these frequently improve with continued treatment. Other more severe side effects include bone marrow toxicity, hepatotoxicity, autoimmune disorders, and rarely CNS side effects (depression, mental disorders, visual problems).

Hepatic artery embolization alone or with chemotherapy (chemoembolization) has been used to control the symptoms of carcinoid syndrome. Embolization alone is reported to control symptoms in up to 76% of patients, and chemoembolization (5-fluorouracil, doxorubicin, cisplatin, mitomycin) controls symptoms in 60–75% of patients. Hepatic artery embolization can have major side effects, including nausea, vomiting, pain, and fever. In two studies, 5–7% of patients died from complications of hepatic artery occlusion.

Other drugs have been used successfully in small numbers of patients to control the symptoms of carcinoid syndrome. Parachlorophenylanine can inhibit tryptophan hydroxylase and therefore the conversion of tryptophan to 5-HTP. However, its severe side effects, including psychiatric disturbances, make it intolerable for long-term use. α-Methyldopa inhibits the conversion of 5-HTP to 5-HT, but its effects are only partial.

Peptide radioreceptor therapy (PRRT; using radiotherapy with radiolabeled somatostatin analogues), cytoreductive surgery, the use of radiolabeled microspheres, and other methods for treatment of advanced metastatic disease can facilitate control of the carcinoid syndrome (see below).

GI-NETS (CARCINOIDS) (NONMETASTATIC)

Surgery is the only potentially curative therapy. Because with most GI-NETs (carcinoids), the probability of metastatic disease increases with increasing size, in most guidelines, the therapeutic approach is determined accordingly. Furthermore, the grade of the tumor is having an increasingly important role in determining the therapeutic approach. With well-differentiated (G1/G2) GI-NETs the size of the primary NET plays an important role. With appendiceal NETs (carcinoids) <1 cm, simple appendectomy was curative in 103 patients followed for up to 35 years. With rectal NETs (carcinoids) <1 cm, local resection is curative. With SI NETs (carcinoids) <1 cm, there is not complete agreement. Because 15–69% of SI NETs (carcinoids) this size have metastases in different studies, most recommend a wide resection with en bloc resection of the adjacent lymph-bearing mesentery. If the tumor is >2 cm for rectal, appendiceal, or SI NETs (carcinoids), a full cancer operation should be done. This includes a right hemicolectomy for appendiceal NETs (carcinoids), an abdominoperineal resection or low anterior resection for rectal NETs (carcinoids), and an en bloc resection of adjacent lymph nodes for SI NETs (carcinoids). For appendiceal NETs (carcinoids) 1–2 cm in diameter, a simple appendectomy is proposed by some, whereas others favor a formal right hemicolectomy. For 1–2 cm rectal NETs (carcinoids), it is recommended that a wide, local, full-thickness excision be performed.

With well-differentiated (G1/G2) type I or II gastric NETs (carcinoids), which are usually <1 cm, endoscopic removal is recommended. In type I or II gastric carcinoids, if the tumor is >2 cm or if there is local invasion, some recommend total gastrectomy, whereas others recommend antrectomy in type I to reduce the hypergastrinemia, which has led to regression of the carcinoids in a number of studies. For types I and II gastric NETs (carcinoids) of 1–2 cm, there is no agreement, with some recommending endoscopic treatment followed by chronic somatostatin treatment and careful follow-up and others recommending surgical treatment. With type III gastric NETs (carcinoids) >2 cm, excision and regional lymph node clearance are recommended. Most tumors <1 cm are treated endoscopically. Type 1 and 2 gastric carcinoids tend to recur after endoscopic treatments so patients need to continue to be followed. Treatment of type 1 or 2 gastric carcinoids using a CCK_B (gastrin) receptor antagonist, netazepide (not yet FDA approved) decreased the size and number of gastric carcinoids. However, netazepide needed to be continued or they would return. Poorly differentiated G3 carcinoids of the GI tract are treated like G3 tumors in other locations, which involve primarily chemotherapy and will discussed in a later section on treatment of advanced/aggressive disease.

Resection of isolated or limited hepatic metastases may be beneficial and will be discussed in a later section on treatment of advanced disease.

PANCREATIC NEUROENDOCRINE TUMORS (pNETs)

Functional pNETs (F-pNETs) usually present clinically with symptoms due to the hormone-excess state (Table 80-2). Only late in the course of the disease does the tumor per se cause prominent symptoms such as abdominal pain. In contrast, all the symptoms due to nonfunctional pNETs (NF-pNET) are due to the tumor per se. The overall result of this is that some F-pNETs may present with severe symptoms with a small or undetectable primary tumor, whereas NF-pNETs usually present late in the disease course with large tumors, which are frequently metastatic. The mean delay between onset of continuous symptoms and diagnosis of a F-pNET syndrome is 4–7 years. Therefore, the diagnoses frequently are missed for extended periods.

TREATMENT

Pancreatic Neuroendocrine Tumor (General Points)

Treatment of pNETs requires two different strategies. First, treatment must be directed at the hormone-excess state such as the gastric acid hypersecretion in gastrinomas or the hypoglycemia in insulinomas. Ectopic hormone secretion usually causes the presenting symptoms and can cause life-threatening complications. Second, with all the tumors except insulinomas, >50% are malignant (Table 80-2); therefore, treatment must also be directed against the tumor per se. Because in many patients these tumors are not surgically curable due to the presence of advanced disease at diagnosis, surgical resection for cure, which addresses both treatment aspects, is often not possible.

GASTRINOMA (ZOLLINGER-ELLISON SYNDROME)

A gastrinoma is an NET that secretes gastrin; the resultant hypergastrinemia causes gastric acid hypersecretion (Zollinger-Ellison syndrome [ZES]). The chronic hypergastrinemia results in marked gastric acid hypersecretion and growth of the gastric mucosa with increased numbers of parietal cells and proliferation of gastric ECL cells. The gastric acid hypersecretion characteristically causes peptic ulcer disease (PUD), often refractory and severe, as well as diarrhea. The most common presenting symptoms are abdominal pain (70–100%), diarrhea (37–73%), gastroesophageal reflux disease (GERD) (30–35%), and 10–20% of patients have diarrhea only. Although peptic ulcers may occur in unusual locations, most patients have a typical duodenal ulcer. Important observations that should suggest this diagnosis include PUD with diarrhea; PUD in an unusual location or with multiple ulcers; PUD refractory to treatment or persistent; PUD associated with prominent gastric folds; PUD associated with findings suggestive of MEN 1 (endocrinopathy, family history of ulcer or endocrinopathy, nephrolithiases); and PUD without *Helicobacter pylori* present. *H. pylori* is present in >90% of idiopathic peptic ulcers but is present in <50% of patients with gastrinomas. Chronic unexplained diarrhea also should suggest ZES.

Approximately 20–25% of patients with ZES have MEN 1 (MEN1/ZES), and in most cases, hyperparathyroidism is present before the ZES develops. In older studies it was generally reported that almost all MEN/ZES presented with the hyperparathyroidism, but in a number of recent series up to one-third of these patients present with the ZES, and while the hyperparathyroidism is present it may be mild and difficult to diagnose without appropriate testing. These patients are treated differently from those without MEN 1 (sporadic ZES); therefore, MEN 1 should be sought in all patients with ZES by family history and by measuring plasma ionized calcium and prolactin levels and plasma hormone levels (parathormone, growth hormone).

Most gastrinomas (50–90%) in sporadic ZES are present in the duodenum, followed by the pancreas (10–40%) and other intraabdominal sites (mesentery, lymph nodes, biliary tract, liver, stomach, ovary). Rarely, the tumor may involve extraabdominal sites (heart, lung cancer). In MEN 1/ZES the gastrinomas are also usually in the duodenum (80–100%), followed by the pancreas (0–20%), and are almost always multiple. About 60–90% of gastrinomas are malignant (Table 80-2) with metastatic spread to lymph nodes and liver. Distant metastases to bone occur in 12–30% of patients with liver metastases.

Diagnosis The diagnosis of ZES requires the demonstration of inappropriate fasting hypergastrinemia, usually by demonstrating hypergastrinemia occurring with an increased basal gastric acid output (BAO) (hyperchlorhydria). More than 98% of patients with ZES have fasting hypergastrinemia, although in 40–60% the level may be elevated less than tenfold. Therefore, when the diagnosis is suspected, a fasting gastrin is usually the initial test performed. It is important to remember that potent gastric acid suppressant drugs such as proton pump inhibitors (PPIs) (omeprazole, esomeprazole, pantoprazole, lansoprazole, rabeprazole) can suppress acid secretion sufficiently to cause hypergastrinemia; because of their prolonged duration of action, these drugs have to be tapered or frequently discontinued for a week before the gastrin determination. Withdrawal of PPIs should be performed carefully because PUD complications can rapidly develop in some patients and is best done in consultation with GI units with experience in this area. The widespread use of PPIs can confound the diagnosis of ZES. First, by raising a false-positive diagnosis by causing hypergastrinemia in a patient being treated with idiopathic PUD (without ZES). Second, by leading to a false-negative diagnosis because at routine doses used to treat patients with idiopathic PUD, PPIs control symptoms in most ZES patients and thus mask the diagnosis. If ZES is suspected and the gastrin level is elevated, it is important to show that it is increased when gastric pH is ≤2.0 because physiologically hypergastrinemia secondary to achlorhydria (atrophic gastritis, pernicious anemia) is one of the most common causes of hypergastrinemia. Nearly all ZES patients have a fasting pH ≤2 when off antisecretory drugs. If the fasting gastrin is >1000 pg/mL (increased tenfold) and the pH is ≤2.0, which occurs in 40–60% of patients with ZES, the diagnosis of ZES is established after the possibility of retained antrum syndrome has been ruled out by history. In patients with hypergastrinemia with fasting gastrins <1000 pg/mL (<tenfold increased) and gastric pH ≤2.0, other conditions, such as *H. pylori* infections, antral G-cell hyperplasia/hyperfunction, gastric outlet obstruction, and, rarely, renal failure, can masquerade as ZES. To establish the diagnosis in this group, a determination of BAO and a secretin provocative test should be done. In patients with ZES without previous gastric acid–reducing surgery, the BAO is usually (>90%) elevated (i.e., >15 mEq/h). The secretin provocative test is usually positive, with the criterion of a >120-pg/mL increase over the basal level having the highest sensitivity (94%) and specificity (100%). Unfortunately the diagnosis of ZES is becoming increasing more difficult. This is due not only to the widespread use of PPIs (leading to false-positive results as well as masking ZES presentation), but also recent studies demonstrate than many of the commercial gastrin kits that are used by most laboratories to measure fasting serum gastrin levels are not reliable. In one study, 7 of the 12 tested commercial gastrin kits inaccurately assessed the true serum concentration of gastrin primarily because the antibodies used had inappropriate specificity for the different circulating forms of gastrin and were not adequately validated. Both underestimation and overestimation of fasting serum gastrin levels occurred using these commercial kits. To circumvent this problem, it is either necessary to use one of the five reliable kits identified or, alternatively, to refer the patient to a center with expertise in making the diagnosis in your area, or if this is not possible, to contact such a center and use the gastrin assay they recommend. An accurate gastrin assay is essential for accurate measurement of fasting serum gastrin level as well as for assessing gastrin levels during the secretin provocative test, and thus, the diagnosis of ZES cannot reliably be made without one.

TREATMENT

Zollinger-Ellison Syndrome

Gastric acid hypersecretion in patients with ZES can be controlled in almost every case by oral gastric antisecretory drugs. Because of their long duration of action and potency, which allows dosing once or twice a day, the PPIs (H^+, K^+-ATPase inhibitors) are the drugs of

choice. Histamine H_2-receptor antagonists are also effective, although more frequent dosing (q 4–8 h) and high doses are required. In patients with MEN1/ZES with hyperparathyroidism, correction of the hyperparathyroidism increases the sensitivity to gastric antisecretory drugs and decreases the basal acid output. Long-term treatment with PPIs (>15 years) has proved to be safe and effective, without development of tachyphylaxis. Although patients with ZES, especially those with MEN 1/ZES, more frequently develop gastric NETs (carcinoids), no data suggest that the long-term use of PPIs increases this risk in these patients. With long-term PPI use in ZES patients, vitamin B_{12} deficiency can develop; thus, vitamin B_{12} levels should be assessed during follow-up. Long-term PPI use may be associated with a number of side-effects including; an increased incidence of bone fractures; *Clostridium difficile* infections; dementia; hypomagnesemia; renal disease; and numerous drug interactions; however, at present, there is no report these are increased in ZES patients.

With the increased ability to control acid hypersecretion, >50% of patients who are not cured (>60% of patients) will die from tumor-related causes. At presentation, careful imaging studies are essential to localize the extent of the tumor to determine the appropriate treatment. A third of patients present with hepatic metastases, and in <15% of those patients, the disease is limited, so that surgical resection may be possible. Surgical short-term cure is possible in 60% of all patients without MEN 1/ZES or liver metastases (40% of all patients) and in 30% of patients long term. In patients with MEN 1/ZES, long-term surgical cure is rare without aggressive resection (i.e., Whipple resections), because the tumors are small, multiple, and frequently with lymph node metastases. At present the role of routine surgery for removal of the gastrinoma in MEN1/ZES patients is controversial for the above reason, with most guidelines recommending attempted gastrinoma resection only in MEN1/ZES patients with pNETs ≥1.5–2 cm in diameter. Surgical studies demonstrate that successful resection of the gastrinoma not only decreases the chances of developing liver metastases but also increases the disease-related survival rate. Therefore, all patients with gastrinomas without MEN 1/ZES or a medical condition that limits life expectancy should undergo surgery by a surgeon experienced in the treatment of these disorders.

INSULINOMAS

An insulinoma is an NET of the pancreas that is thought to be derived from beta cells that ectopically secrete insulin, which results in hypoglycemia. The average age of occurrence is 40–50 years old. The most common clinical symptoms are due to the effect of the hypoglycemia on the CNS (neuroglycemic symptoms) and include confusion, headache, disorientation, visual difficulties, irrational behavior, and even coma. Also, most patients have symptoms due to excess catecholamine release secondary to the hypoglycemia, including sweating, tremor, and palpitations. Characteristically, these attacks are associated with fasting.

Insulinomas are generally small (>90% are <2 cm) and usually not multiple (90%); only 5–15% are malignant, and they almost invariably occur only in the pancreas, distributed equally in the pancreatic head, body, and tail. They are associated with the MEN1 syndrome in 4%.

Insulinomas should be suspected in all patients with hypoglycemia, especially when there is a history suggesting that attacks are provoked by fasting, or with a family history of MEN 1. Insulin is synthesized as proinsulin, which consists of a 21-amino-acid α chain and a 30-amino-acid β chain connected by a 33-amino-acid connecting peptide (C peptide). In insulinomas, in addition to elevated plasma insulin levels, elevated plasma proinsulin levels are found, and C-peptide levels are elevated.

Diagnosis The diagnosis of insulinoma requires the demonstration of an elevated plasma insulin level at the time of hypoglycemia. A number of other conditions may cause fasting hypoglycemia, such as the inadvertent or surreptitious use of insulin or oral hypoglycemic agents, severe liver disease, alcoholism, poor nutrition, and other extrapancreatic tumors. Furthermore, postprandial hypoglycemia can be caused by a number of conditions that confuse the diagnosis of insulinoma. Particularly important here is the increased occurrence of hypoglycemia after gastric bypass surgery for obesity, which is now widely performed. A new entity, insulinomatosis, was described that can cause hypoglycemia and mimic insulinomas. It occurs in 10% of patients with persistent hyperinsulinemic hypoglycemia and is characterized by the occurrence of multiple macro-/microadenomas expressing insulin, and it is not clear how to distinguish this entity from insulinoma preoperatively. The most reliable test to diagnose insulinoma is a fast up to 72 h with serum glucose, C-peptide, proinsulin, and insulin measurements every 4–8 h. If at any point the patient becomes symptomatic or glucose levels are persistently <2.2 mmol/L (40 mg/dL), the test should be terminated, and repeat samples for the above studies should be obtained before glucose is given. Some 70–80% of patients will develop hypoglycemia during the first 24 h, and 98% by 48 h. In nonobese normal subjects, serum insulin levels should decrease to <43 pmol/L (<6 μU/mL) when blood glucose decreases to <2.2 mmol/L (<40 mg/dL) and the ratio of insulin to glucose is <0.3 (in mg/dL). In addition to having an insulin level >6 μU/mL when blood glucose is <40 mg/dL, some investigators also require an elevated C-peptide and serum proinsulin level, an insulin/glucose ratio >0.3, and a decreased plasma β-hydroxybutyrate level for the diagnosis of insulinomas. A commonly used set of criteria to make the diagnosis include: low blood glucose levels (≤2.2 mmol/L (≤40 mg/dL); concomitant insulin levels ≥6 U/L (≥ 36 pmol/L; ≥3 U/L by ICMA); C-peptide levels ≥200 pmol/L; proinsulin levels ≥5 pmol/L; β-hydroxybutyrate levels ≤2.7 mmol/L; and absence of sulfonylurea (metabolites) in the plasma and/or urine.

Surreptitious use of insulin or hypoglycemic agents may be difficult to distinguish from insulinomas. The combination of proinsulin levels (normal in exogenous insulin/hypoglycemic agent users), C-peptide levels (low in exogenous insulin users), antibodies to insulin (positive in exogenous insulin users), and measurement of sulfonylurea levels in serum or plasma will allow the correct diagnosis to be made. The diagnosis of insulinoma has been complicated by the introduction of specific insulin assays that do not also interact with proinsulin, as do many of the older radioimmunoassays (RIAs), and therefore give lower plasma insulin levels. The increased use of these specific insulin assays has resulted in increased numbers of patients with insulinomas having lower plasma insulin values (<6 μU/mL) than levels proposed to be characteristic of insulinomas by RIA. In these patients, the assessment of proinsulin and C-peptide levels at the time of hypoglycemia is particularly helpful for establishing the correct diagnosis. An elevated proinsulin level when the fasting glucose level is <45 mg/dL is sensitive and specific.

TREATMENT

Insulinomas

Only 5–15% of insulinomas are malignant; therefore, after appropriate imaging (see below), surgery should be performed. In different studies, 75–100% of patients are cured by surgery. Before surgery, the hypoglycemia can be controlled by frequent small meals and the use of diazoxide (150–800 mg/d). Diazoxide is a benzothiadiazide whose hyperglycemic effect is attributed to inhibition of insulin release. Its side effects are sodium retention and GI symptoms such as nausea. Approximately 50–60% of patients respond to diazoxide. Other agents effective in some patients to control the hypoglycemia include verapamil and diphenylhydantoin. Long-acting somatostatin analogues such as octreotide and lanreotide are acutely effective in 40% of patients. However, octreotide must be used with care because it inhibits growth hormone secretion and can alter plasma glucagon levels; therefore, in some patients, it can worsen the hypoglycemia.

For the 5–15% of patients with malignant insulinomas, these drugs or somatostatin analogues are used initially. In a small number of patients with malignant tumors, mammalian target of rapamycin (mTOR) inhibitors (everolimus, rapamycin) are reported to control the hypoglycemia. If they are not effective, various antitumor treatments such as hepatic arterial embolization, chemoembolization, chemotherapy, and peptide receptor radiotherapy with radiolabeled somatostatin analogues (PRRT) have been used and can be effective, particularly PRRT.

Insulinomas, which are usually benign (>90%) and intrapancreatic in location, are increasingly resected using a laparoscopic approach, which has lower morbidity rates. This approach requires that the insulinoma be localized on preoperative imaging studies.

GLUCAGONOMAS

A glucagonoma is NET of the pancreas that secretes excessive amounts of glucagon, which causes a distinct syndrome characterized by dermatitis, glucose intolerance or diabetes, and weight loss. Glucagonomas principally occur between 45 and 70 years of age. The tumor is clinically heralded by a characteristic dermatitis (migratory necrolytic erythema) (67–90%), accompanied by glucose intolerance (40–90%), weight loss (66–96%), anemia (33–85%), diarrhea (15–29%), and thromboembolism (11–24%). The characteristic rash usually starts as an annular erythema at intertriginous and periorificial sites, especially in the groin or buttock. It subsequently becomes raised, and bullae form; when the bullae rupture, eroded areas form. The lesions can wax and wane. The development of a similar rash in patients receiving glucagon therapy suggests that the rash is a direct effect of the hyperglucagonemia. A characteristic laboratory finding is hypoaminoacidemia, which occurs in 26–100% of patients.

Glucagonomas are generally large tumors at diagnosis (5–10 cm). Some 50–80% occur in the pancreatic tail. From 50 to 82% have evidence of metastatic spread at presentation, usually to the liver. Glucagonomas are rarely extrapancreatic, usually occur singly, and <3% are associated with the MEN1 syndrome.

Two new entities have been described that can also cause hyperglucagonemia and may mimic glucagonomas. Mahvash disease is due to an inactivating mutation (homozygous P86S mutation) of the human glucagon receptor. It is associated with the development of α-cell hyperplasia, hyperglucagonemia, and the development of nonfunctioning pNETs. Subsequently other patients with other inactivating mutations of the human glucagon receptor have been described with similar findings, leading to the suggestion that a hepato-pancreatic feedback regulation of the cells, possibly involving amino acids, may exist in humans. A second disease called *glucagon cell adenomatosis* can mimic glucagonoma syndrome clinically and is characterized by the presence of hyperplastic islets staining positive for glucagon instead of a single glucagonoma.

Diagnosis The diagnosis is confirmed by demonstrating an increased plasma glucagon level. Characteristically, plasma glucagon levels exceed 1000 pg/mL (normal is <150 pg/mL) in 90%; 7% are between 500 and 1000 pg/mL, and 3% are <500 pg/mL. A trend toward lower levels at diagnosis has been noted in the last decade. A plasma glucagon level >1000 pg/mL is considered diagnostic of glucagonoma. Other diseases causing increased plasma glucagon levels include cirrhosis, diabetic ketoacidosis, celiac disease, renal insufficiency, acute pancreatitis, hypercorticism, hepatic insufficiency, severe stress, and prolonged fasting or familial hyperglucagonemia, as well as danazol treatment. With the exception of cirrhosis, these disorders do not increase plasma glucagon >500 pg/mL.

Necrolytic migratory erythema is not pathognomonic for glucagonoma and occurs in myeloproliferative disorders, hepatitis B infection, malnutrition, short-bowel syndrome, inflammatory bowel disease, zinc deficiency, and malabsorption disorders.

TREATMENT

Glucagonomas

In 50–80% of patients, hepatic metastases are present, and so curative surgical resection is not possible. Surgical debulking in patients with advanced disease or other antitumor treatments may be beneficial as well as PRRT with radiolabeled somatostatin analogues (see below). Long-acting somatostatin analogues such as octreotide and lanreotide improve the skin rash in 75% of patients and may improve the weight loss, pain, and diarrhea, but usually do not improve the glucose intolerance.

SOMATOSTATINOMA SYNDROME

The somatostatinoma syndrome is due to an NET that secretes excessive amounts of somatostatin, which causes a distinct syndrome characterized by diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea. There is no general distinction in the literature between a tumor that contains somatostatin-like immunoreactivity (somatostatinoma) and does (11–45%) or does not (55–90%) produce a clinical syndrome (somatostatinoma syndrome) by secreting somatostatin. In a review of 173 cases of somatostatinomas, only 11% were associated with the somatostatinoma syndrome. The mean age is 51 years. Somatostatinomas occur primarily in the pancreas and small intestine, and the frequency of the symptoms and occurrence of the somatostatinoma syndrome differ in each. Each of the usual symptoms is more common in pancreatic than in intestinal somatostatinomas: diabetes mellitus (95% vs 21%), gallbladder disease (94% vs 43%), diarrhea (92% vs 38%), steatorrhea (83% vs 12%), hypochlorhydria (86% vs 12%), and weight loss (90% vs 69%). The somatostatinoma syndrome occurs in 30–90% of pancreatic and 0–5% of SI somatostatinomas. In various series, 43% of all duodenal NETs contain somatostatin; however, the somatostatinoma syndrome is rarely present (<2%). Somatostatinomas occur in the pancreas in 56–74% of cases, with the primary location being the pancreatic head. The tumors are usually solitary (90%) and large (mean size 4.5 cm). Liver metastases are common, being present in 69–84% of patients. Somatostatinomas are rare in patients with MEN 1, occurring in only 0.65%.

The existence of a somatostatinoma syndrome (SSoma syndrome) has been called into question. This occurred because in one review of 821 patients with duodenal or pancreatic NETs, a proportion of which showed predominant somatostatin expression, none had the SSoma syndrome leading to the conclusion it is either very rare or nonexistent. However, in other studies, a proportion of the patients with somatostatin positive pancreatic or duodenal NETs had number of the proposed features of the SSoma syndrome.

Somatostatin is a tetradecapeptide that is widely distributed in the CNS and GI tract, where it functions as a neurotransmitter or has paracrine and autocrine actions. It is a potent inhibitor of many processes, including release of almost all hormones, acid secretion, intestinal and pancreatic secretion, and intestinal absorption. Most of the clinical manifestations are directly related to these inhibitory actions.

Diagnosis In most cases, somatostatinomas have been found by accident either at the time of cholecystectomy or during endoscopy. The presence of psammoma bodies in a duodenal tumor should particularly raise suspicion. Duodenal somatostatin-containing tumors are increasingly associated with von Recklinghausen's disease (NF-1) (Table 80-5). Most of these tumors (>98%) do not cause the SSoma syndrome. The diagnosis of the SSoma syndrome requires the demonstration of elevated plasma somatostatin levels.

TREATMENT

Somatostatinomas

Pancreatic tumors are frequently (70–92%) metastatic at presentation, whereas 30–69% of SI somatostatinomas have metastases. Surgery is the treatment of choice for those without widespread hepatic metastases. Symptoms in patients with the SSoma syndrome are also improved by octreotide treatment.

VIPomas

VIPomas are NETs that secrete excessive amounts of vasoactive intestinal peptide (VIP), which causes a distinct syndrome characterized by large-volume diarrhea, hypokalemia, and dehydration. This syndrome also is called Verner-Morrison syndrome, pancreatic cholera, and WDHA syndrome for *w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria, which some patients develop. The mean age of patients with this syndrome is 49 years; however, it can occur in children, and when it does, it is usually caused by a ganglioneuroma or ganglioneuroblastoma.

The principal symptoms are large-volume diarrhea (100%) severe enough to cause hypokalemia (80–100%), dehydration (83%),

hypochlorhydria (54–76%), and flushing (20%). The diarrhea is secretory in nature, persisting during fasting, and is almost always >1 L/d and in 70% is >3 L/d. In a number of studies, the diarrhea was intermittent initially in up to half the patients. Most patients do not have accompanying steatorrhea (16%), and the increased stool volume is due to increased excretion of sodium and potassium, which, with the anions, accounts for the osmolality of the stool. Patients frequently have hyperglycemia (25–50%) and hypercalcemia (25–50%).

VIP is a 28-amino-acid peptide that is an important neurotransmitter, ubiquitously present in the CNS and GI tract. Its known actions include stimulation of SI chloride secretion as well as effects on smooth-muscle contractility, inhibition of acid secretion, and vasodilatory effects, which explain most features of the clinical syndrome.

In adults, 80–90% of VIPomas are pancreatic in location, with the rest due to VIP-secreting pheochromocytomas, intestinal carcinoids, and rarely ganglioneuromas. These tumors are usually solitary, 50–75% are in the pancreatic tail, and 37–68% have hepatic metastases at diagnosis. In children <10 years old, the syndrome is usually due to ganglioneuromas or ganglioblastomas and is less often malignant (10%).

Diagnosis The diagnosis requires the demonstration of an elevated plasma VIP level and the presence of large-volume diarrhea. A stool volume <700 mL/d is proposed to exclude the diagnosis of VIPoma. When the patient fasts, a number of diseases can be excluded that can cause marked diarrhea because the high volume of diarrhea is not sustained during the fast. Other diseases that can produce a secretory large-volume diarrhea include gastrinomas, chronic laxative abuse, carcinoid syndrome, systemic mastocytosis, rarely medullary thyroid cancer, diabetic diarrhea, sprue, and AIDS. Among these conditions, only VIPomas caused a marked increase in plasma VIP. Chronic surreptitious use of laxatives/diuretics can be particularly difficult to detect clinically. Hence, in a patient with unexplained chronic diarrhea, screens for laxatives should be performed; they will detect many, but not all, laxative abusers. Elevated plasma levels of VIP should not be the only basis of the diagnosis of VIPomas because they can occur with some diarrheal states including inflammatory bowel disease, post small bowel resection, and radiation enteritis. Furthermore, nesidioblastosis can mimic VIPomas by causing elevated plasma VIP levels, diarrhea, and even false-positive location in the pancreatic region on somatostatin receptor scintigraphy (SRS).

TREATMENT

VIPomas

The most important initial treatment in these patients is to correct their dehydration, hypokalemia, and electrolyte losses with fluid and electrolyte replacement. These patients may require >5 L/d of fluid and >350 mEq/d of potassium. Because 37–68% of adults with VIPomas have metastatic disease in the liver at presentation, a significant number of patients cannot be cured surgically. In these patients, long-acting somatostatin analogues such as octreotide and lanreotide (Fig. 80-2) are the drugs of choice.

Octreotide/lanreotide will control the diarrhea short- and long-term in 75–100% of patients. In nonresponsive patients, the combination of glucocorticoids and octreotide/lanreotide has proved helpful in a small number of patients. Other drugs reported to be helpful in small numbers of patients include prednisone (60–100 mg/d), clonidine, indomethacin, phenothiazines, loperamide, lidamidine, lithium, propranolol, and metoclopramide. Treatment of advanced disease with cytoreductive surgery, embolization, chemoembolization, chemotherapy, radiotherapy, radiofrequency ablation (RFA), and peptide receptor radiotherapy may be helpful (see below). Control of the diarrhea in VIPoma patients using the tyrosine kinase inhibitor, sunitinib, has been described in case reports.

NONFUNCTIONAL PANCREATIC NEUROENDOCRINE TUMORS (NF-pNETs)

NF-pNETs are NETs that originate in the pancreas and either secretes no products or their products do not cause a specific clinical syndrome. Their symptoms are due entirely to the tumor per se. NF-pNETs secrete chromogranin A (90–100%), chromogranin B (90–100%), α-HCG (human chorionic gonadotropin) (40%), neuron-specific enolase (31%), and β-HCG (20%), and because 40–90% secrete PP, they are also often called PPomas. A proportion also secrete ghrelin, neurotensin, calcitonin and other GI hormones/neurotransmitters, which are generally accepted as not causing a distinct clinical syndrome. Because the symptoms are due to the tumor mass, patients with NF-pNETs usually present late in the disease course with invasive tumors and hepatic metastases (64–92%), and the tumors are usually large (72% >5 cm). An increasing proportion of NF-PNETs are asymptomatic (up to 30–50%) and are found at screening for various nonspecific symptoms. NF-pNETs are usually solitary except in patients with MEN 1, in which case they are multiple. They occur primarily in the pancreatic head. Even though these tumors do not cause a functional syndrome, immunocytochemical studies show that they synthesize numerous peptides and cannot be distinguished from functional pNETs by immunocytochemistry. In MEN 1, 80–100% of patients have microscopic NF-pNETs, but they become large or symptomatic in a minority (0–13%) of cases. In VHL, 12–17% develop NF-pNETs, and in 4%, they are ≥3 cm in diameter.

The most common symptoms are abdominal pain (30–80%), jaundice (20–35%), and weight loss, fatigue, or bleeding. The average time from the beginning of symptoms to diagnosis is 5 years.

Diagnosis The diagnosis is established by histologic confirmation in a patient without either the clinical symptoms or the elevated plasma hormone levels of one of the established syndromes. The principal difficulty in diagnosis is to distinguish an NF-pNET from a nonendocrine pancreatic tumor, which is more common, as well as from a F-pNET. Even though chromogranin A levels are elevated in almost every patient, this is not specific for this disease as it can be found in F-pNETs, GI-NETs (carcinoids), and other neuroendocrine disorders, as well in patients without any of these, but being treated with PPIs. Plasma PP elevations should strongly suggest the diagnosis in a patient with a pancreatic mass because it is usually normal in patients with pancreatic adenocarcinomas. Elevated plasma PP is not diagnostic of this tumor because it is elevated in a number of other conditions, such as chronic renal failure, old age, inflammatory conditions, alcohol abuse, pancreatitis, hypoglycemia, postprandially, and diabetes. A positive somatostatin receptor scan in a patient with a pancreatic mass should suggest the presence of pNET/NF-pNET rather than a nonendocrine tumor.

TREATMENT

Nonfunctional Pancreatic Neuroendocrine Tumors (NF-pNETs)

Overall survival in patients with sporadic NF-pNET is 30–63% at 5 years, with a median survival of 6 years. Unfortunately, surgical curative resection can be considered only in a minority of these patients because 30–92% present with diffuse metastatic disease. Treatment needs to be directed against the tumor per se using the various modalities discussed below for advanced disease. Whereas the treatment of NF-pNETs in either MEN 1 patients or patients with VHL has remained controversial for a number of years, the treatment in sporadic cases has also become controversial. In these inherited disorders, most recommend surgical resection for any tumor >2–3 cm in diameter; however, there is controversy in patients with smaller NF-pNETs (≤1.5–2 cm), with most guidelines recommending careful surveillance of these patients. This approach is taken because patients with these inherited diseases are not curable without aggressive surgery with its associated mortality/morbidity, because of the multiplicity of the small NF-pNETs; studies show these patients with NF-NETs ≤2 cm have no increased mortality; and most are slow growing. Most of these are low- or intermediate-grade lesions, and <7% are malignant. Similarly in patients with sporadic NF-pNETs in the past almost all were operated on; however, because

of the generally benign course of those that are asymptomatic and ≤2 cm in diameter, increasingly they are not operated, but followed closely. No consensus exists on this point with the result that some advocate a non-operative approach with careful, regular follow-up, whereas others recommend an operative or laparoscopic.

GRFomas

GRFomas are NETs that secrete excessive amounts of growth hormone–releasing factor (GRF) that cause acromegaly. GRF is a 44-amino-acid peptide, and 25–44% of pNETs have GRF immunoreactivity, although it is uncommonly secreted. GRFomas are lung tumors in 47–54% of cases, pNETs in 29–30%, SI carcinoids in 8–10%; and up to 12% occur at other sites. Patients have a mean age of 38 years, and the symptoms usually are due to either acromegaly or the tumor per se. The acromegaly caused by GRFomas is indistinguishable from classic acromegaly. The pancreatic tumors are usually large (>6 cm), and liver metastases are present in 39%. They should be suspected in any patient with acromegaly and an abdominal tumor, a patient with MEN 1 with acromegaly, or a patient without a pituitary adenoma with acromegaly or associated with hyperprolactinemia, which occurs in 70% of GRFomas. GRFomas are an uncommon cause of acromegaly. GRFomas occur in <1% of MEN 1 patients. The diagnosis is established by performing plasma assays for GRF and growth hormone. Most GRFomas have a plasma GRF level >300 pg/mL (normal <5 pg/mL men, <10 pg/mL women). Patients with GRFomas also have increased plasma levels of insulin-like growth factor type I (IGF-I) similar to those in classic acromegaly. Surgery is the treatment of choice if diffuse metastases are not present. Long-acting somatostatin analogues such as octreotide and lanreotide are the agents of choice, with 75–100% of patients responding.

OTHER RARE PANCREATIC NEUROENDOCRINE TUMOR SYNDROMES

Cushing's syndrome (ACTHoma) due to a pNET occurs in 4–16% of all ectopic Cushing's syndrome cases. It occurs in 5% of cases of sporadic gastrinomas, almost invariably in patients with hepatic metastases, and is an independent poor prognostic factor. Paraneoplastic hypercalcemia due to pNETs releasing parathyroid hormone–related peptide (PTHrP), a PTH-like material, or unknown factor, is rarely reported. The tumors are usually large, and liver metastases are usually present. Most (88%) appear to be due to release of PTHrP. pNETs occasionally can cause the carcinoid syndrome and this may occur without the presence of liver metastases. A number of very rare pNET syndromes involving a few cases (less than five) have been described; these include a renin-producing pNET in a patient presenting with hypertension; pNETs secreting luteinizing hormone, resulting in masculinization or decreased libido; a pNET secreting erythropoietin, resulting in polycythemia; pNETs secreting IGF-II, causing hypoglycemia; pNETs secreting enteroglucagon, causing small intestinal hypertrophy, colonic/SI stasis, and malabsorption and a pNET secreting cholecystokinin (CCKoma) which can mimic ZES clinically with patients presenting with severe peptic ulcer disease, diarrhea, weight loss, and gallstones, but with a normal fasting gastrin level (Table 80-2). A number of other possible functional pNETs have been proposed, but most authorities classify these as unclear or as a nonfunctional pNET because in each case numerous patients have been described with similar plasma hormone elevations that do not cause any symptoms. These include pNETs secreting calcitonin, neurotensin (neurotensinoma), PP (PPoma), and ghrelin (Table 80-2).

TUMOR LOCALIZATION

Localization of the primary tumor and knowledge of the extent of the disease are essential to the proper management of all GI-NETs (carcinoids) and pNETs. Without proper localization studies, it is not possible to determine whether the patient is a candidate for surgical resection (curative or cytoreductive) or requires antitumor treatment, to determine whether the patient is responding to antitumor therapies, whether postresection recurrent disease is present or to appropriately classify/stage the patient's disease to assess prognosis.

Numerous tumor localization methods are used in both types of NETs, including cross-sectional imaging studies (CT, magnetic resonance imaging [MRI], trans-abdominal ultrasound), selective angiography, SRS, and positron emission tomography. In pNETs, endoscopic ultrasound (EUS) and functional localization by measuring venous hormonal gradients are also reported to be useful. Bronchial carcinoids are usually detected by standard chest radiography and assessed by CT. Rectal, duodenal, colonic, and gastric carcinoids are usually detected by GI endoscopy. Because of their wide availability, CT and MRI are generally initially used to determine the location of the primary NETs and the extent of disease. NETs are hypervascular tumors, and with both MRI and CT, contrast enhancement is essential for maximal sensitivity, and it is recommended that generally triple-phase scanning be used. The ability of cross-sectional imaging and, to a lesser extent, SRS to detect NETs is a function of NET size. With CT and MRI, <10% of tumors <1 cm in diameter are detected, 30–40% of tumors 1–3 cm are detected, and >50% of tumors >3 cm are detected. Many primary GI-NETs (carcinoids) are small, as are insulinomas and duodenal gastrinomas, and are frequently not detected by cross-sectional imaging, whereas most other pNETs present late in the course of their disease and are large (>4 cm). Selective angiography is more sensitive, localizing 60–90% of all NETs; however, it is now used infrequently. For detecting liver metastases, CT and MRI are more sensitive than ultrasound, and with recent improvements, 5–25% of patients with liver metastases will be missed by CT and/or MRI.

pNETs, as well as GI-NETs (carcinoids), frequently (>80%) overexpress high-affinity sst in both the primary tumors and the metastases. Of the five types of somatostatin receptors ($sst_{1–5}$), radiolabeled octreotide binds with high affinity to sst_2 and sst_5, has a lower affinity for sst_3, and has a very low affinity for sst_1 and sst_4. Between 80 and 100% of well-differentiated (G1, G2 grades) GI-NETs (carcinoids) and pNETs possess sst_2, and many also have some of the other four sst subtypes. Interaction with these receptors can be used to treat these tumors as well as to localize NETs by using radiolabeled somatostatin analogues (i.e. somatostatin receptor imaging [SRI]). In contrast, only 50–70% of poorly differentiated (G3 grade) NETs have sst2 receptors. In the United States, (^{111}In-DTPA-D-Phe^1) octreotide (octreoscan) (Fig. 80-2) is still generally used with gamma camera detection using single-photon emission computed tomography (SPECT) imaging. Using gallium-68-labeled somatostatin analogues and positron emission tomography (^{68}Ga-PET/CT) detection has greater sensitivity than using ^{111}In-labeled somatostatin analogues (^{111}In-SPECT/CT) **(Fig. 80-3)**. It (NEWSPOT) is now approved for use in the United States. Because of its sensitivity and ability to localize tumor throughout the body, SRI is the initial imaging modality of choice for localizing both the primary tumor and metastatic NETs. SRI localizes tumor in 73–95% of patients with GI-NETs (carcinoids) and in 56–100% of patients with pNETs, except insulinomas. Insulinomas are usually small and have low densities of sst receptors, resulting in SRI being positive in only 12–50% of patients with insulinomas. SRS identifies >90–95% of patients with liver metastases due to NETs. Figure 80-3 shows an example with SRI of the increased sensitivity of ^{68}Ga-PET/CT over ^{111}In-SPECT-CT and CT scanning to localize both the primary NET and liver/bone metastases in a patient with a metastatic small intestinal carcinoid (GI-NET). Occasional false-positive responses with SRI can occur (12% in one study) because numerous other normal tissues as well as diseases can have high densities of sst receptors, including granulomas (sarcoid, tuberculosis, etc.), thyroid diseases (goiter, thyroiditis), activated lymphocytes (lymphomas, wound infections), splenunculi, increased osteoblastic activity, meningiomas, and increased physiological uptake in the pancreatic uncinate process (^{68}Ga-DOTATAE PET/CT). If liver metastases are identified by SRI (performed without hybrid CT), to plan the proper treatment, either a CT or an MRI (with contrast enhancement) is recommended to assess the size and exact location of the metastases, because SRI does not provide information on tumor size. For pNETs in the pancreas, EUS is highly sensitive, localizing 77–100% of insulinomas, which occur almost exclusively within the pancreas. EUS is less sensitive for extrapancreatic tumors. It is increasingly used in patients with MEN 1, and to a lesser extent VHL, to detect small pNETs not seen with other modalities or for serial pNET assessments to determine size changes or rapid growth in patients in

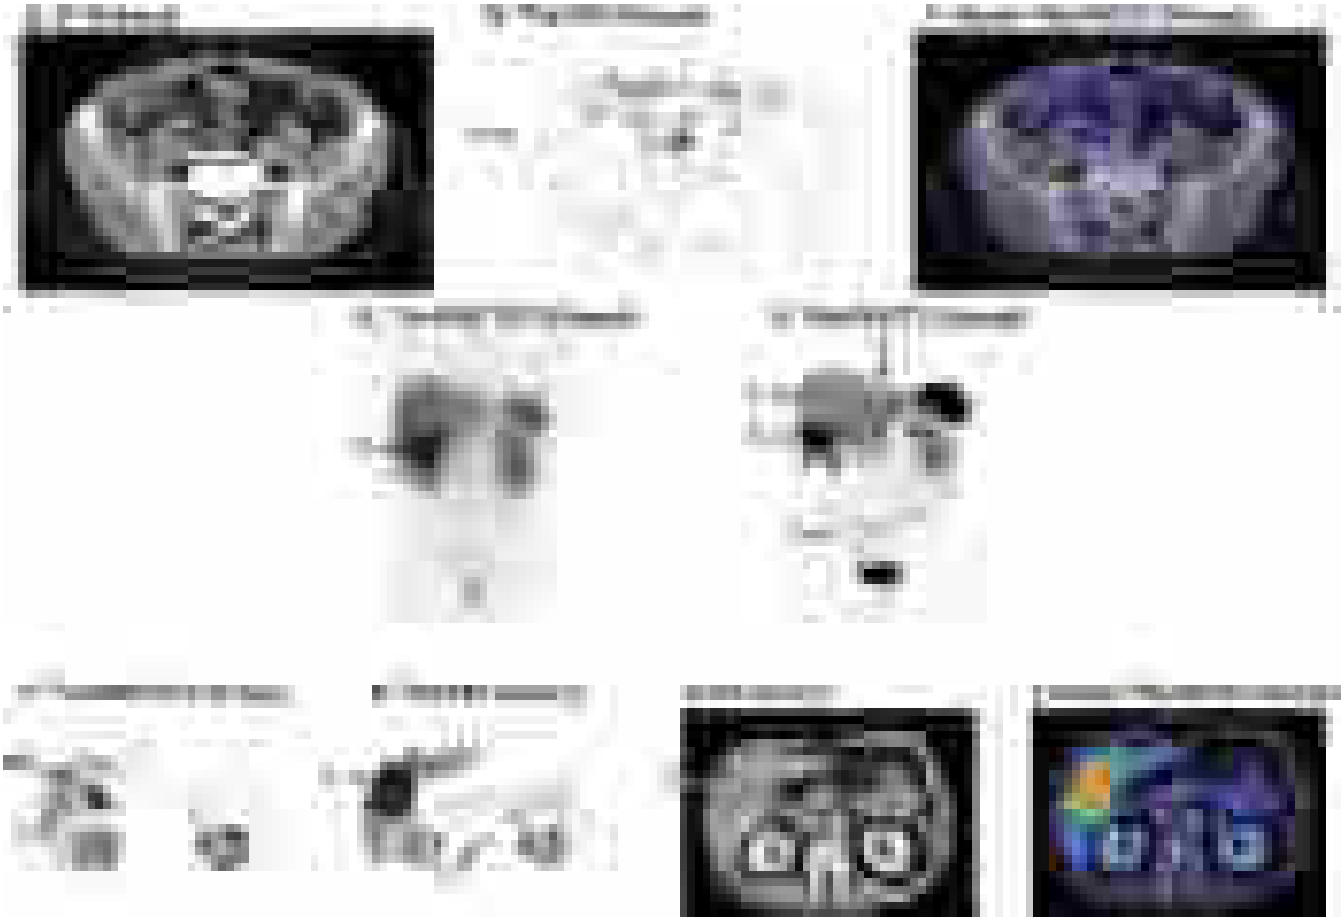

FIGURE 80-3 Enhanced sensitivity of ^{68}Ga-PET/CT to localize lesions in patient with a metastatic small intestinal carcinoid (GI-NET). Panels ***A–C*** show the ability of the ^{68}Ga-PET (transverse images) to localize the primary (T) when the CT is negative. Panels ***D*** and ***E*** (coronal views—maximum intensity projections) show the greater resolution and ability to localize more metastatic lesions (T) in the liver and bone of ^{68}Ga-PET than the ^{111}In-SPECT/CT scanning, which has been generally used in the United States until recently. Panels ***F-I*** (transverse images) show the increased sensitivity of ^{68}Ga-PET over the ^{111}In-SPECT/CT scanning in identifying the extent of the liver metastases as well as identifying bone metastasis. GB, gallbladder; T, tumor; Transv, transverse images. *(Results kindly provided by Prof. Anders Sundin, Department of Radiology, Uppsala University Hospital, Uppsala, Sweden.)*

whom surgery is deferred. EUS with cytologic evaluation also is used frequently to distinguish an NF-pNET from a pancreatic adenocarcinoma or another nonendocrine pancreatic tumor. Not infrequently patients present with liver metastases due to an NET and the primary site is unclear. Occult small intestinal NETs (carcinoids) are increasingly detected by double-balloon enteroscopy or capsule endoscopy.

Insulinomas frequently overexpress receptors for glucagon-like peptide-1 (GLP-1), and radiolabeled GLP-1 analogues have been developed that can detect occult insulinomas not localized by other imaging modalities. This study is only performed in a few specialty centers. Functional localization by measuring hormonal gradients is now uncommonly used with gastrinomas (after intra-arterial secretin injections) but is still frequently used in insulinoma patients in whom other imaging studies are negative (assessing hepatic vein insulin concentrations post-intra-arterial calcium injections). Functional localization measuring hormone gradients in insulinomas or gastrin gradients in gastrinoma is a sensitive method, being positive in 80–100% of patients. The intra-arterial calcium test may also allow differentiation of the cause of the hypoglycemia and indicate whether it is due to an insulinoma or a nesidioblastosis. The latter entity is becoming increasingly important because hypoglycemia after gastric bypass surgery for obesity is increasing in frequency, and it is primarily due to nesidioblastosis, although it can occasionally be due to an insulinoma.

PET and use of hybrid scanners such as CT and SRI has sensitivity because of the greater resolution of PET scanning. PET scanning with ^{18}F-fluoro-DOPA in patients with carcinoids or with ^{11}C-5-HTP in patients with pNETs or GI-NETs (carcinoids) has greater sensitivity than cross-sectional imaging studies and may be used increasingly in the future. PET/CT scanning using ^{18}F-FDG is receiving increasing attention in patients with NETs. It was initially thought that this would not be useful in NETs with the majority being well differentiated (G1, G2 grades, >85–98%) and having a low proliferative rate. However, ^{18}F-FDG PET/CT can identify higher grade NETs, and is particularly helpful for imaging G3 NETs, which are more frequently negative with SRS. There ^{18}F-FDG positivity can not only provide imaging information on location and tumor size, but also prognostic information because the relative survival of patients with the different NET grades is G1>G2>G3.

TREATMENT

Advanced and /or Aggressive Disease (Diffuse Metastatic Disease)

The single most important prognostic factor for survival is the presence of liver metastases **(Fig. 80-4*A, B, D, and E*)**. For patients with foregut carcinoids without hepatic metastases, the 5-year survival in one study was 95%, and with distant metastases, it was 20% (Fig. 80-4***A, B***). With gastrinomas, the 5-year survival without liver metastases is 98%; with limited metastases in one hepatic lobe, it is 78%; and with diffuse metastases, 16%. In a large study of 156 patients (67 pNETs, rest carcinoids), the overall 5-year survival rate was 77%; it was 96% without liver metastases, 73% with liver metastases, and 50% with distant disease.

The recent introduction and validation of the prognostic value of the different classification and grading systems (WHO, ENETS, the American Joint Committee on Cancer/International Union Against

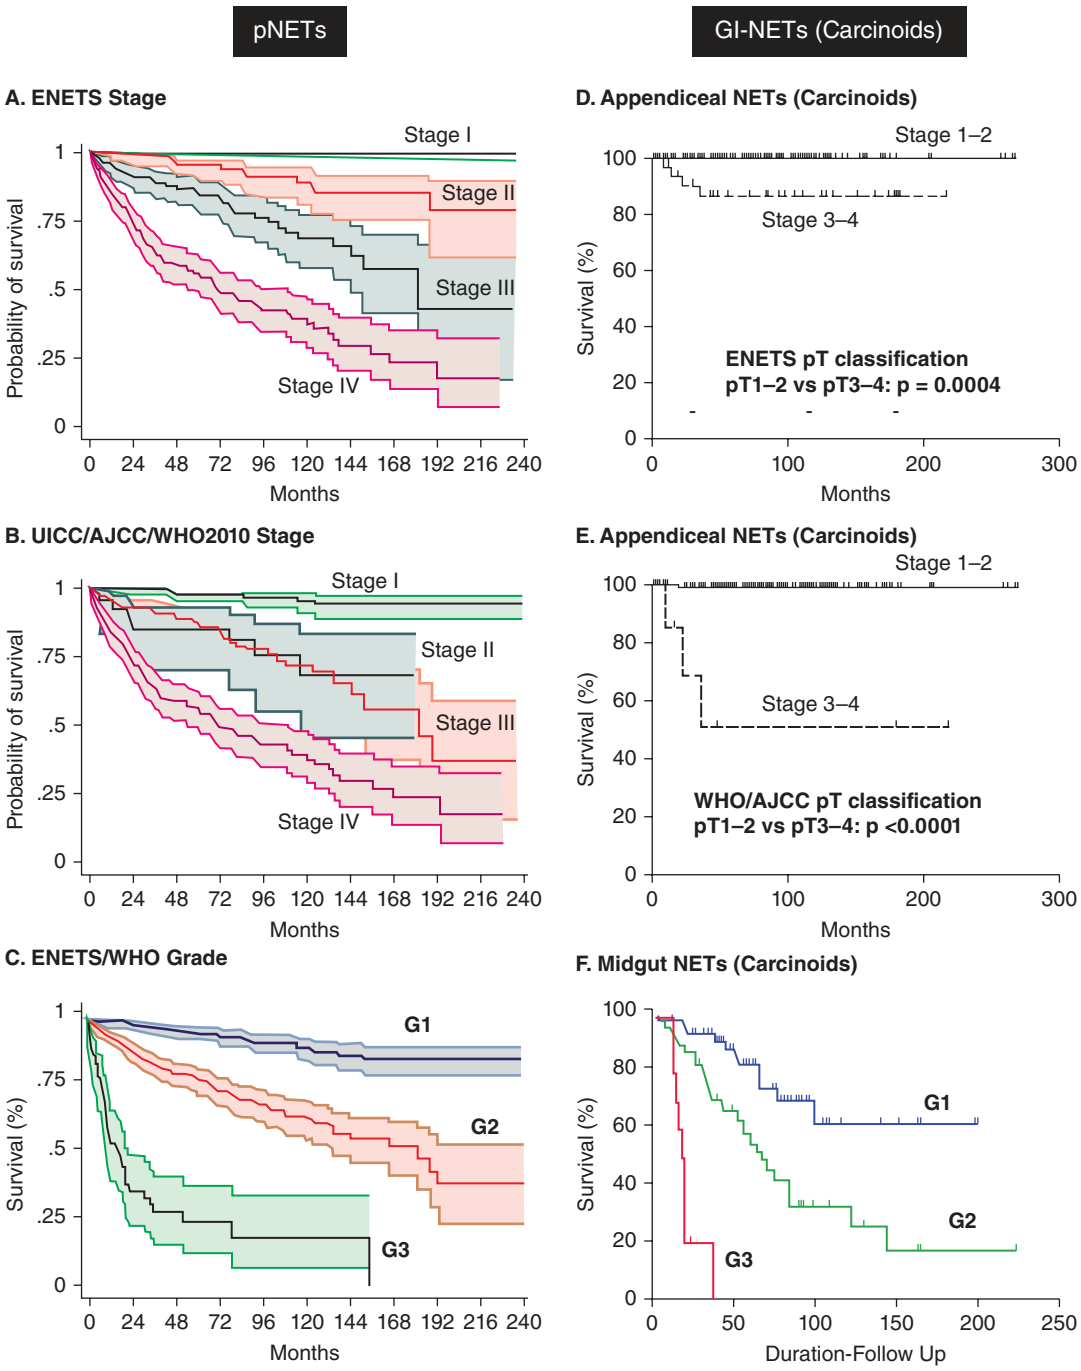

FIGURE 80-4 Survival (Kaplan-Meier plots) of patients with pancreatic neuroendocrine tumors (pNETs; n = 1072) (***A–C***) or gastrointestinal neuroendocrine tumors (GI-NETs; carcinoids) (appendix, n = 138; midgut, n = 238) (***D–F***) stratified according to recent proposed classification and grading systems. *(Panels A–C are drawn from data in G Rindi et al: J Natl Cancer Inst 104:764, 2012; panels D and E are drawn from data in M Volante et al: Am J Surg Pathol 37:606, 2013; and panel F is drawn from data in MS Khan: Br J Cancer 108:1838, 2013.)*

Cancer [AJCC/UICC]) are proving essential to stratify patients into different risk groups. A particular important prognostic factor is whether the NET is well differentiated (G1/G2) or poorly differentiated (<1% of all NETs) (G3) **(Fig. 80-4*C, F*)**. In various series overall, well-differentiated NETs, which are aggressive tumors, have a 5-year survival of 50–80%, whereas poorly differentiated NETs survival of only 0–15% at 5 years (Fig. 80-4*C, F*).

Therefore, treatment for advanced metastatic disease is an important challenge. A number of different modalities are reported to be effective, including cytoreductive surgery (surgically or by RFA), treatment with chemotherapy, somatostatin analogues, interferon α, hepatic embolization alone or with chemotherapy (chemoembolization), molecular targeted therapy, radiotherapy with radiolabeled beads/microspheres, PRRT, and liver transplantation.

SPECIFIC ANTITUMOR TREATMENTS

Cytoreductive surgery is considered if either all of the visible metastatic disease or at last 90% is thought resectable; however, unfortunately, this is possible in only the 9–22% of patients who present with limited hepatic metastases. Although no randomized studies have proven that it extends life, results from a number of studies suggest that it may increase survival; therefore, it is recommended, if possible. RFA can be applied to NET liver metastases if they are limited in number (usually <5) and size (usually <3.5 cm in diameter). It can be used at the time of surgery (either general or laparoscopic) or using radiologic guidance. Response rates are >80%, the responses can last up to 3 years, the morbidity rate is low, and this procedure may be particularly helpful in patients with F-pNETs that are difficult to control medically. Although RFA has not been established in

a controlled trial, both the European and North American Neuroendocrine Tumor Society guidelines (ENETS, NANETS) state it can be an effective antitumor treatment for both refractory functional syndromes and for palliative treatment.

Although there are no controlled, long-term trials, palliative surgical resection of the small intestinal primary and surrounding tumor is generally recommended in most guidelines and expert opinion reviews for patients with midgut carcinoids with carcinoid syndrome, who almost invariably have unresectable live metastases. Systematic analysis of existing data supports the conclusion surgical resection of the primary prevents complications (obstruction, etc.) and also prolongs survival in some studies. At the time of this resection, a cholecystectomy is recommended to possible biliary complications from long-term somatostatin therapy.

Chemotherapy plays a different role in the treatment of patients with pNETs and GI-NETs (carcinoids). Chemotherapy continues to be widely used in the treatment of patients with advanced pNETs with moderate success (response rates 20–70%). However, in general, its results in patients with metastatic GI-NETs (carcinoids) have been disappointing, with response rates of 0–30% with various two- and three-drug combinations, and thus, it is infrequently used in these patients. An important distinction in patients with pNETs is whether the tumor is well differentiated (G1/G2) or poorly differentiated (G3). The chemotherapeutic approach is different for these two groups. The current regimen of choice for patients with well-differentiated pNETs is the combination of streptozotocin and doxorubicin with or without 5-fluorouracil. Streptozotocin is a glucosamine nitrourea compound originally found to have cytotoxic effects on pancreatic islets, and later in studies with doxorubicin with or without 5-fluorouracil, it produced response rates of 20–45% in advanced pNETs. Streptozotocin causes considerable morbidity, with 70–100% of patients developing side effects (most prominent being nausea/vomiting in 60–100% or leukopenia/thrombocytopenia) and 15–70% of patients developing some degree of renal dysfunction (primarily proteinuria and/or decreased creatinine clearance). The combination of temozolomide (TMZ) with capecitabine is receiving increased attention as a possible alternative to streptozotocin-based therapies. Experience is still limited with this protocol and it is being evaluated in a number of current studies; however, analysis of larger retrospective studies shows responded rates from 48 to 70%. The use of TMZ or another alkylating agent in advanced pNETs is supported by some, but not all, studies that show low levels of the DNA repair enzyme O^6-methylguanine DNA methyltransferase in pNETs correlate with the sensitivity to TMZ. Grade G3 NETs are primarily treated by chemotherapy (see below).

In addition to the effectiveness in controlling the functional hormonal state, long-acting somatostatin analogues such as octreotide and lanreotide are increasingly used for their antiproliferative effects. Whereas somatostatin analogues rarely decrease tumor size (i.e., 0–17%), these drugs have tumoristatic effects, stopping additional growth in 26–95% of patients with NETs. In a randomized, double-blind study in patients with metastatic midgut carcinoids (PROMID study), octreotide-LAR demonstrated a marked lengthening of time to progression (14.3 vs 6 months, $p = 0.000072$). This improvement was seen in patients with limited liver involvement. This study did not assess whether such treatment will extend survival. A double-blind, randomized, placebo-controlled, phase III study in patients with well-differentiated, metastatic, inoperable pNETs (45%) or GI-NETs (carcinoids) (55%) (CLARINET study) showed that monthly treatment with lanreotide-autogel reduced tumor progression or death by 53%. Somatostatin analogues can induce apoptosis in GI-NETs (carcinoids), which probably contributes to their tumoristatic effects. Treatment with somatostatin analogues is generally well-tolerated, with most side effects being mild and uncommonly leading to stopping the drug. Potential long-term side effects include diabetes/glucose intolerance, steatorrhea, and the development of gallbladder sludge/gallstones (10–80%), although only 1% of patients develop symptomatic gallbladder disease. Because of these phase III studies, somatostatin analogues are generally recommended as first-line treatment for patients with well-differentiated metastatic NETs.

Interferon α, similar to somatostatin analogues, is effective at controlling the hormonal excess symptoms of NETs and has antiproliferative effects in NETs, which primarily result in disease stabilization (30–80%), with a decrease in tumor size in <15% of patients. Interferon can inhibit DNA synthesis, block cell cycle progression in the G_1 phase, inhibit protein synthesis, inhibit angiogenesis, and induce apoptosis. Interferon α treatment results in side effects in the majority of patients, with the most frequent being a flu-like syndrome (80–100%), anorexia with weight loss, and fatigue. These side effects frequently decrease in severity with continued treatment. In addition, patients become accommodated to the symptoms. More serious side effects include hepatotoxicity (31%), hyperlipidemia (31%), bone marrow toxicity, thyroid disease (19%), and rarely CNS side effects (depression, mental/visual disorders). ENETS 2016 guidelines conclude that in patients with well-differentiated NETs that are slowly progressive, interferon α treatment should be considered if the tumor is somatostatin receptor negative or if somatostatin or targeted therapy (everolimus, sunitinib) treatment fails.

Molecular targeted medical treatment with either an mTOR inhibitor (everolimus) or a tyrosine kinase inhibitor (sunitinib) is now approved treatment in the United States and Europe for patients with metastatic unresectable pNET, each supported by a phase III, double-blind, prospective, placebo-controlled trial. Furthermore, a Phase 3 double-blind study (RADIANT-4) also demonstrated the effectiveness of everolimus in advanced, non-functional NETs of the lung or GI-tract. In this study involving patients with advanced, progressive well differentiated, NF-lung/GI-NETs, everolimus significantly (p <0.000001) improved progression-free survival and led to FDA approval for its use.

mTOR is a serine-threonine kinase that plays an important role in proliferation, cell growth, and apoptosis in both normal and neoplastic cells. Activation of the mTOR cascade is important in mediating NET cell growth. A number of mTOR inhibitors have shown promising antitumor activity in NETs including everolimus and temsirolimus, with the former undergoing two phase III trials (RADIANT-3/RADIANT-4) studies in patients with advance progressive NETs (RADIANT-3=pNETs, RADIANT-4=lung, GI NF-NETs). In the RADIANT-III study which involved 410 patients with advanced, progressive pNETs, everolimus caused significant improvement in progression-free survival (11 vs 4.6 months, $p < 0.001$) and increased by a factor of 3.7 the proportion of patients progression-free at 18 months (37% vs 9%). Everolimus treatment was associated with frequent side effects, causing a twofold increase in adverse events, with the most frequent being grade 1 or 2. Grade 3 or 4 side effects included hematologic, GI (diarrhea), stomatitis, or hypoglycemia occurring in 3–7% of patients. Most grade 3 or 4 side effects were controlled by dose reduction or drug interruption. Similar side-effects were found in the RADIANT-4 study. The ENETS 2016 guidelines conclude that everolimus, similar to sunitinib (below), can be considered as a first-line treatment in well-differentiated pNETs that are unresectable especially if somatostatin analogues are not an option. However, these guidelines recommended that somatostatin analogues be the initial treatment because of their low incidence of side-effects. In patients with GI-NETs, the ENET 2016 guidelines recommended that everolimus could be recommended as second-line therapy after somatostatin analogues.

Like other normal and neoplastic cells, NETs frequently possess multiple types of the 20 different tyrosine kinase (TK) receptors that are known and mediate the action of different growth factors. Numerous studies demonstrate that TK receptors in normal and neoplastic tissues as well as NETs are especially important in mediating cell growth, angiogenesis, differentiation, and apoptosis. Whereas a number of TK inhibitors show antiproliferative activity in NETs, only sunitinib has undergone a phase III controlled trial. Sunitinib is

an orally active small-molecule inhibitor of TK receptors (PDGFRs, VEGFR-1, VEGFR-2, c-KIT, FLT-3). In a phase III study in which 171 patients with progressive, metastatic, nonresectable pNETs were treated with sunitinib (37.5 mg/d) or placebo, sunitinib treatment caused a doubling of progression-free survival (11.4 vs 4.5 months, $p < 0.001$), an increase in objective tumor response rate (9% vs 0%, $p = 0.007$), and an increase in overall survival. Sunitinib treatment was associated with an overall threefold increase in side effects, although most were grade 1 or 2. The most frequent grade 3 or 4 side effects were neutropenia (12%) and hypertension (9.6%), which were controlled by dose reduction or temporary interruption. There is no consensus regarding the order of sunitinib or everolimus use in patients with advanced, well-differentiated, progressive pNETs.

In patients with liver-predominant metastatic disease, a number of locoregional strategies have been used including: transarterial arterial embolization (TAE) alone or with chemotherapeutic agents (TACE); and selective internal radiation therapy (SIRT) or radioembolization. TACE/TAE can be effective because the blood supply to normal liver tissue is primarily from the portal vein whereas tumors receive 70–80% of their supply from the hepatic artery. Occlusion of selective branches of the hepatic artery is now generally performed radiologically. Contraindications include >50–75% liver involvement by tumor, portal vein thrombosis, post-biliary reconstructive surgery, liver failure, and a poor performance rating. Results include a symptomatic response rate of 50–100%, and an objective response rate of 25–86% with a mean duration of response of 6–45 months. Complications include a postembolization syndrome with pain, nausea/vomiting and fever in 10–80% with <6% mortality. SIRT using yttrium-90 (^{90}Y) glass or resin microspheres is a relatively newer approach being evaluated in patients with unresectable NET liver metastases. The treatment requires careful evaluation for vascular shunting before treatment and a pretreatment angiogram to evaluate placement of the catheter and is generally is reserved for patients without extrahepatic metastatic disease and with adequate hepatic reserve. One of two types of ^{90}Y microspheres is used: either microspheres with a 20- to 60-μm diameter and 50 Bq/sphere (SIR-Spheres) or glass microspheres (TheraSpheres) with a 20- to 30-μm diameter and 2500 Bq/sphere. The ^{90}Y-microspheres are delivered to the liver by intraarterial injection from percutaneously placed catheters. The response rate varied from 50 to 61% (partial or complete), tumor stabilization occurred in 22–41%, 60–100% had symptomatic improvement, and overall survival varied from 25 to 70 months. Side effects include postembolization syndrome (pain, fever, nausea/vomiting [frequent]), which is usually mild, although grade 2 (43%) or grade 3 (1%) symptoms can occur; radiation-induced liver disease (<1%); and radiation pneumonitis (<1%). Contraindications to use include excess shunting to the GI tract or lung, inability to isolate the liver arterial supply, and inadequate liver reserve. Because of the limited data available in the ENETS 2012 guidelines, treatment with SIRTs is considered experimental.

PRRT for NETs with radiolabeled somatostatin analogues is now being increasing considered for patients with advanced NETs. The success of this approach is based on the finding that somatostatin sst are overexpressed or ectopically expressed by 60–100% of all NETs, which allows the targeting of cytotoxic, radiolabeled somatostatin receptor ligands. Three different radionuclides have been used including: high doses of [^{111}In-DTPA-D-Phe^1] octreotide, which emits γ-rays, internal conversion, and Auger electrons; ^{90}yttrium, which emits high-energy β-particles coupled by a DOTA chelating group to octreotide or octreotate; and ^{177}lutetium-coupled analogues, which emit both (Fig. 80-2). At present, the ^{177}lutetium-coupled analogues are the most widely used and although not approved for general use in any country, they are frequently available in speciality centers on a special or compassionate basis. A double-blind, prospective, randomized trial (NETTER-1 Study) (using 177Lu-Dotatate [Lutathera]) has supported the efficacy and safety of this approach in patients with advanced inoperable, progressive midgut GI-NETs (carcinoids). In this trial, which included 229 patients with grade G1,2 metastatic midgut carcinoids, a marked increased in progressive-free survival ($p < 0.0001$) was seen with PRRT treatment with a ^{177}Lu-labeled-somatostatin-analog, with an acceptable safety profile and with a suggestion of an improved survival, although final survival analysis is not yet complete. In a number of retropective, non-blinded trials, ^{111}Indium-, ^{90}yttrium-, and ^{177}lutetium-labeled compounds caused tumor stabilization in patients with advanced, progressive NETs in 41–81%, 44–88%, and 23–51%, respectively, and a decrease in tumor size in 8–30%, 6–37%, and 38%, respectively, of patients. In one large study involving 504 patients with malignant NETs, ^{177}lutetium-labeled analogues produced a reduction of tumor size of >50% in 30% of patients (2% complete) and tumor stabilization in 51% of patients. The ENETS 2016, NANETS, Nordic 2010, and European Society for Medical Oncology (ESMO) guidelines list PRRT as an experimental or investigational treatment at present.

The use of liver transplantation has been abandoned for treatment of most metastatic tumors to the liver. However, for metastatic NETs, it is still a consideration by many centers although its use is controversial. An analysis of data from a number of centers showed that the overall 5-year survival is 47–58%, but varies widely in different studies from 36 to 97%; the 5-year disease-free survival was usually 20–30%, but varied from 9 to 77%, with a postoperative mortality <15%. With pNETs the 5-year survival rate varies from 30 to 50% and for GI-NETs from 60 to 90%. In various studies, important prognostic factors for a poor outcome include a major resection performed in addition at the time of the liver transplant; poor tumor differentiation; hepatomegaly; age >45 years; a primary NET in the duodenum or pancreas; the presence of extrahepatic metastatic disease or extensive liver involvement (>50%); Ki_{67} proliferative index >10%; and abnormal E-cadherin staining. The ENETS 2016 guidelines conclude that liver transplantation should be viewed as an option in highly selected patients, preferably in young patients with functional syndromes demonstrating early resistance to medical therapies.

The management and treatment of patients with G3 NETs (Ki_{67} >20) (WHO classification as NECs) has undergone a number of changes because of some important new insights. It is now realized that G3 NETs are heterogeneous and this has resulted in a proposal that they be divided into at least two categories; this division has important management ramifications because it is proposed they be treated differently. In reviews of G3 patients from a number of centers, a group of patients have G3 grading but with well-differentiated morphology (usually with a Ki_{67} 20–55) and it is proposed these be called G3 NET. These G3 NET patients have a better prognosis than poorly differentiated G3 tumors (usually with Ki_{67} >55), which are proposed to be called G3 NEC tumors. Pathology studies show that G3 NETs frequently have loss of ATRX/DAXX, whereas the G3 NEC poorly differentiated tumors have abnormal expression of p53, retinoblastoma and/or SMAD4. Most patients with G3 NETs have regional or distant metastases at the time of diagnosis and surgery is rarely curative, with the result that chemotherapy is usually recommended. This new subclassification has therapeutic implications because it is proposed to treat the G3 NET tumors similar to treatment for well-differentiated G2 tumors, whereas for G3 NEC tumors, treatment with cisplatin-based regimens with etoposide or other agents (vincristine, paclitaxel) is recommended. The response rates with this protocol are 40–70%; however, responses are generally short-lived (<12 months). This chemotherapy regimen can be associated with significant toxicity including GI toxicities (nausea, vomiting), myelosuppression.

81 Renal Cell Carcinoma

Robert J. Motzer

Renal cell carcinomas account for 90–95% of malignant neoplasms arising from the kidney. Notable features include diagnosis without symptoms, resistance to cytotoxic agents, infrequent responses to biologic response modifiers such as interleukin (IL)-2, robust activity of antiangiogenesis-targeted agents, and a variable clinical course for patients with metastatic disease, including anecdotal reports of spontaneous regression. The remaining 5–10% of malignant neoplasms arising from the kidney are transitional cell carcinomas (urothelial carcinomas) originating in the lining of the renal pelvis. See Chap. 82 for transitional cell carcinomas.

EPIDEMIOLOGY

The incidence of renal cell carcinoma rose for three decades but has now reached a plateau of ~63,000 cases annually in the United States, resulting in >14,000 deaths per year. It is the ninth most common cancer overall in the United States, seventh most common in males, and tenth most common in females; the male-to-female ratio is 2:1. Though this malignancy may be diagnosed at any age, it is uncommon in those aged <45 years, and incidence peaks between the ages of 50 and 70 years. Many factors have been investigated as possible contributing causes; associations include cigarette smoking, obesity, and hypertension. Risk is also increased for patients who have acquired cystic disease of the kidney associated with end-stage renal disease and for those with tuberous sclerosis.

Most cases of renal cell carcinoma are sporadic, although familial forms have been reported (Table 81-1). One such form is associated with von Hippel-Lindau (VHL) syndrome, an autosomal dominant disorder. Genetic studies identified the *VHL* gene on the short arm of chromosome 3. Approximately 35% of individuals with VHL disease develop clear cell renal cell carcinoma. Other *VHL*-associated neoplasms include retinal hemangioma, hemangioblastoma of the spinal cord and cerebellum, pheochromocytoma, and neuroendocrine tumors and cysts. Birt-Hogg-Dubé syndrome is a rare human autosomal dominant genetic disorder characterized by fibrofolliculomas (benign tumors arising in hair follicles), pulmonary cysts, and kidney tumors. The renal tumors are usually of the chromophobe type, but they can exist as hybrids with other cell types. This disorder is associated with mutations in the *FLCN* gene, which codes for folliculin.

PATHOLOGY AND GENETICS

Renal cell neoplasia represents a heterogeneous group of tumors with distinct histopathologic, genetic, and clinical features ranging from benign to high-grade malignant (Table 81-2). They are classified on the basis of morphology and histology. Categories include clear cell carcinoma (70% of cases), papillary tumors (10%), chromophobe tumors (≤5%), oncocytomas (5–10%), collecting duct or Bellini duct tumors (<1%), and translocation carcinoma (<1%). Papillary tumors tend to be bilateral and multifocal. Chromophobe tumors have a more indolent clinical course, and oncocytomas are considered benign neoplasms. In contrast, Bellini duct carcinomas, which are thought to arise from the collecting ducts within the renal medulla, are rare but often very aggressive. Medullary carcinoma has histopathologic and clinical features similar to those of Bellini duct carcinoma, but it is associated with sickle cell trait.

Clear cell tumors, the predominant histology, are found in >80% of patients who develop metastases. Clear cell tumors arise from the epithelial cells of the proximal tubules and usually show chromosome 3p deletions. Deletions of 3p21–26 (where the *VHL* gene maps) are identified in patients with familial as well as sporadic tumors. *VHL* encodes a tumor suppressor protein that is involved in regulating the transcription of vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and a number of other hypoxia-inducible proteins. Inactivation of *VHL* leads to overexpression of

TABLE 81-1 Hereditary Renal Cell Tumors

SYNDROME	CHROMOSOME(S)	GENE	PROTEIN	KIDNEY TUMOR TYPE	ADDITIONAL FINDINGS
von Hippel-Lindau syndrome	3p25	*VHL*	von Hippel-Lindau protein	Clear cell	Hemangioblastoma of the retina and central nervous system; pheochromocytoma; pancreatic and renal cysts; neuroendocrine tumors
Hereditary papillary RCC	7p31	*MET*	MET	Papillary (type I)	
Hereditary leiomyomatosis and RCC	1q42	*FH*	Fumarate hydratase	Papillary (non–type I)	Leiomyoma; uterine leiomyoma/leiomyosarcoma

TABLE 81-2 Classification of Epithelial Neoplasms Arising from the Kidney

CARCINOMA TYPE	CHARACTERISTICS GROWTH PATTERN	CELL OF ORIGIN	CYTOGENETICS
Clear cell	Acinar or sarcomatoid	Proximal tubule	3p-, 5q+, 14q-
Papillary	Papillary or sarcomatoid	Proximal tubule	+7, +17, –Y
Chromophobe	Solid, tubular, or sarcomatoid	Distal tubules/cortical collecting duct	Whole arm losses (1, 2, 6, 10, 13, 17, and 21)
Oncocytic	Tumor nests	Cortical collecting duct	–1, –14, –Y; rearrangement involving 11q13; or normal karyotype
Collecting duct	Papillary or sarcomatoid	Medullary collecting duct	Variable or undetermined
MiTF Translocation[a]	Clear and papillary	Undetermined	Gene fusions involving Xp11 (*TFE3*) or t(6;11) (*MALAT1-TFEB*)

[a]Microphthalmia transcription factor gene family.

these agonists of the VEGF and PDGF receptors, which promote tumor angiogenesis and tumor growth. Agents that inhibit proangiogenic growth factor activity show antitumor effects. Enormous genetic variability has been documented in tumors within individual patients. Although the tumors have a clear clonal origin and often contain *VHL* mutations in common, different portions of the primary tumor and different metastatic sites may have wide variation in genetic lesions they contain. This tumor heterogeneity may underlie the emergence of treatment resistance.

While *VHL* is the gene most frequently mutated in clear cell renal cell carcinoma (52% of cases), other genes are implicated as well: *PBRM1* in 40% of cases, *SETD2* in 15% of cases, and *BAP1* in 15% of cases. These three genes, all part of the chromatin remodeling/histone methylation pathway, are also located within a 50-Mb region on the short arm of chromosome 3p. Mutations in *BAP1* have been linked to shorter survival in renal cancer. In a subset of clear cell renal cell carcinomas, alterations have been found in components of the mammalian target of rapamycin (mTOR) pathway, spurring the study of mTOR inhibitors in renal cancer.

Approximately 10% of renal cell carcinomas are of the papillary subtype, where the most common copy-number events are gain of chromosome 7 (where MET is located) and chromosome 17. Alterations in MET are associated with type I papillary renal cell carcinoma, whereas type II papillary tumors are characterized by NFR2-antioxidant response element alterations. In the chromophobe subtype, which comprises ≤5% of cases of renal cell carcinoma, two mutations have been noted: TP53 in 32% of cases and PTEN in 9%.

CLINICAL PRESENTATION

The presenting signs and symptoms include hematuria, flank or abdominal pain, and a flank or abdominal mass. Other symptoms are fever, weight loss, anemia, and a varicocele. The tumor is most commonly detected as an incidental finding on a radiograph. Widespread use of radiologic cross-sectional imaging procedures (computed tomography [CT], ultrasound, magnetic resonance imaging [MRI]) contributes to earlier detection, including incidental renal masses detected during evaluation for other medical conditions. The increasing number of incidentally discovered low-stage tumors has contributed to an improved 5-year survival for patients with renal cell carcinoma and increased use of nephron-sparing surgery (partial nephrectomy). A spectrum of paraneoplastic syndromes has been associated with these malignancies, including erythrocytosis, hypercalcemia, nonmetastatic hepatic dysfunction (Stauffer's syndrome), and acquired dysfibrinogenemia. Erythrocytosis is noted at presentation in only ~3% of patients. Anemia, a sign of metastatic disease, is more common. Kidney cancer was called the "internist's tumor" since it was often discovered from the initial presentation of a paraneoplastic syndrome. This was more common before the era of modern imaging, as was initial presentation by the classic triad of hematuria, flank pain, and a palpable abdominal mass.

The standard evaluation of patients with suspected renal cell tumors includes a CT scan of the abdomen and pelvis, chest radiograph, urine analysis, and urine cytology. If metastatic disease is suspected from the chest radiograph, a CT of the chest is warranted. MRI is useful in evaluating the inferior vena cava in cases of suspected tumor involvement or invasion by thrombus, or when intravenous contrast administration given with CT is prohibited by impaired renal function. In clinical practice, any solid renal masses should be considered malignant until proven otherwise; a definitive diagnosis is required. If no metastases are demonstrated, surgery is indicated, even if the renal vein or inferior vena cava is invaded. The differential diagnosis of a renal mass includes cysts, benign neoplasms (adenoma, angiomyolipoma, oncocytoma), inflammatory lesions (pyelonephritis or abscesses), and other primary or metastatic cancers. Other malignancies that may involve the kidney include transitional cell carcinoma of the renal pelvis, sarcoma, lymphoma, and Wilms' tumor. All of these are less common causes of renal masses than is renal cell cancer.

STAGING AND PROGNOSIS

Staging is based on the American Joint Committee on Cancer (AJCC) staging system **(Fig. 81-1)**. Stage I tumors are ≤7 cm in greatest diameter and confined to the kidney, stage II tumors are >7 cm and confined to the kidney, stage III tumors extend through the renal capsule but are confined to Gerota's fascia (IIIa) or involve a single hilar lymph node (N1), and stage IV disease includes tumors that have invaded adjacent organs or involve multiple lymph nodes or distant metastases. Sixty-five percent of patients present with stage I or II disease, 15–20% with stage III, and 15–20% with stage IV. The 5-year survival rate is currently 74% across all renal cell carcinomas, but it varies by stage: 81% for stage I, 74% for stage II, 53% for stage III, and 8% for stage IV.

Prognostic risk models are helpful for counseling patients, and for anticipating survival rates when designing a clinical trial. The most widely used prognostic model, developed by investigators at Memorial Sloan Kettering Cancer Center, incorporated five factors shown to correlate with worse survival in advanced renal cell carcinoma: poor performance status, high serum lactate dehydrogenase, high serum calcium, low hemoglobin concentration, and <1-year interval from diagnosis to treatment. Patients with zero risk factors had significantly longer median survival (30 months) than those with one or two risk factors (14 months) and those with three to five risk factors (5 months).

TREATMENT

Renal Cell Carcinoma

LOCALIZED TUMOR

The standard management for stage I or II tumors and selected cases of stage III disease is radical or partial nephrectomy. A radical nephrectomy involves en bloc removal of Gerota's fascia and its contents, including the kidney, the ipsilateral adrenal gland in some cases, and adjacent hilar lymph nodes. Open, laparoscopic, or robotic surgical techniques may be used to perform radical nephrectomy. The role of a regional lymphadenectomy is controversial. Extension into the renal vein or inferior vena cava (stage III disease) does not preclude resection even if cardiopulmonary bypass is required. If the tumor is resected, half of these patients have prolonged survival.

Nephron-sparing approaches via open or laparoscopic surgery may be appropriate for patients who have impaired renal function or only one kidney, depending on the size and location of the lesion. A nephron-sparing approach can also be used for patients

FIGURE 81-1 Renal cell carcinoma staging. TNM, tumor, node, metastasis.

with bilateral tumors. Partial nephrectomy techniques are applied electively to resect small masses for patients with a normal contralateral kidney. Radical nephrectomy can lead to an increased risk for chronic kidney disease and is associated with increased risks of cardiovascular morbidity and mortality. When compared with radical nephrectomy, partial nephrectomy can achieve preserved renal function, and reduced frequency of late cardiovascular events.

Adjuvant therapy with interferon-α or radiation therapy following this surgery does not improve outcome, even in cases with a poor prognosis. Adjuvant trials with sunitinib, an orally administered antiangiogenesis inhibitor, do not consistently show a benefit in prolonging time to relapse following nephrectomy.

METASTATIC DISEASE

Surgery has a limited role for patients with metastatic disease. Long-term survival may occur in patients who relapse after nephrectomy in a solitary site that is removed. One indication for nephrectomy with metastases at initial presentation is to alleviate pain or hemorrhage of a primary tumor. Also, a cytoreductive nephrectomy before systemic treatment improves survival for carefully selected patients with stage IV tumors. The most common sites of distant metastases are the lungs, lymph nodes, liver, bone, and brain. These tumors may follow an unpredictable and protracted clinical course. It may be best to document progression before considering systemic treatment.

Radiation therapy is generally used for palliation of bone or brain metastases. The types of radiotherapy most commonly used are external beam therapy and stereotactic radiotherapy. In select cases, stereotactic ablative radiotherapy to a metastatic site may result in local control with relatively minimal toxicity.

Metastatic renal cell carcinoma is refractory to cytotoxic chemotherapy. Cytokine therapy with IL-2 or interferon-α produces regression in 10–15% of patients. IL-2 produces durable complete remission in a small proportion of cases. In general, cytokine therapy is considered unsatisfactory for most patients due to high levels of toxicity and the unpredictability of response.

The situation changed dramatically when two large-scale randomized trials established a role for antiangiogenic therapy, as predicted by the genetic studies. These trials separately evaluated two orally administered antiangiogenic agents, sorafenib and sunitinib, that inhibited receptor tyrosine kinase signaling through the VEGF and PDGF receptors. Both showed efficacy as second-line treatment following progression during cytokine treatment, resulting in approval by regulatory authorities for the treatment of metastatic renal cell carcinoma. A randomized phase III trial comparing sunitinib to interferon-α showed superior efficacy for sunitinib with an acceptable safety profile. This trial resulted in a change in the standard first-line treatment from interferon to sunitinib.

These were followed by eight new systemic agents for metastatic renal cell carcinoma **(Table 81-3)**: pazopanib, axitinib, cabozantinib, and lenvatinib, also tyrosine kinase inhibitors; the antiangiogenic bevacizumab that inhibits the VEGF ligand; the mTOR inhibitors temsirolimus and everolimus; and nivolumab that inhibits PD-1. While the improvements in 5-year renal cancer survival rates over the past decades (50% in the mid-1970s, 57% in the late 1980s, and 74% for 2005–2012) can be attributed to widespread imaging leading to earlier discovery of tumors, the new agents are likely playing a part as well.

Pazopanib was compared to sunitinib in a randomized first-line phase III trial. Efficacy was similar, and there was less fatigue and skin toxicity, resulting in better quality-of-life scores for pazopanib compared with sunitinib. Temsirolimus and everolimus show activity in patients with untreated poor-prognosis tumors and in sunitinib/sorafenib-refractory tumors. Patients benefit from the sequential use of axitinib and everolimus following progression with sunitinib or pazopanib first-line therapy. Nivolumab, cabozantinib, and lenvatinib plus everolimus were compared to everolimus in randomized trials and showed that patients lived longer with each of these agents compared to patients treated with everolimus.

Biomarkers are needed to select appropriate treatment for individual patients and to get quicker confirmation of whether treatment is working. However, though a number of predictive biomarker candidates have been tested in metastatic renal cell carcinoma patients receiving various systemic therapies, none have been validated for clinical use.

GLOBAL CONSIDERATIONS

Worldwide, ~340,000 patients are diagnosed every year with malignant tumors arising from the kidney, resulting in >140,000 deaths annually. Kidney cancer is the ninth most common cancer in men and the fourteenth most common cancer in women. Higher incidence is observed in developed countries, including the United States, Northern Europe, Eastern Europe, and Australia. Relatively low rates are reported in southeast Asia and Africa. The incidence of kidney cancer has been steadily increasing over the past four decades. Mortality trends have stabilized in Europe and the United States but not in less developed countries. This is likely related to access to and availability of optimal therapies. Treatment guidelines for both localized and metastatic renal cancer are similar between U.S. and European documents, and contingent on the access to adequate health care and availability of targeted drugs to treat metastases.

TABLE 81-3 Approved Systemic Therapies for Metastatic Renal Cell Carcinoma

CLASS	DRUG	FIRST FDA APPROVAL FOR RCC	ORIGINALLY APPROVED FOR	CURRENTLY USED FOR
Cytokines	High-dose interleukin-2[a]	1992	Advanced RCC	Advanced RCC first-line
	Interferon-α	2009	Advanced RCC, in combination with bevacizumab	Advanced RCC, in combination with bevacizumab first-line
Antiangiogenic: tyrosine kinase inhibitors	Sorafenib	2005	Advanced RCC second-line	Advanced RCC third-line or later
	Sunitinib	2006	Advanced RCC second-line	Advanced RCC first-line
	Pazopanib	2009	Advanced RCC first-line or after cytokine therapy	Advanced RCC first-line

82 Cancer of the Bladder and Urinary Tract

Noah M. Hahn

GLOBAL CONSIDERATIONS

Within the United States, urothelial carcinoma of the bladder and urinary tract are most closely related to tobacco smoking history. However, within developing countries water supplies contaminated with arsenic or schistosomiasis parasites also are major carcinogenic contributors.

INTRODUCTION

Cancers of the urinary tract including the bladder, renal pelvis, ureter, and urethra occur frequently, and they represent the second most common class of genitourinary cancers. Bladder cancer alone represents the fifth most common cancer diagnosis annually in the United States with >76,000 new cases and 16,000 deaths every year. Because cancers of the renal pelvis are often lumped in with all kidney cancers, the true incidence and mortality from nonbladder urinary tract cancers are less precise. While less frequent than bladder cancer, an additional 20,000 new cases and 5000 deaths are estimated every year. While significant advances in therapy options and improvements in patient outcomes have rapidly occurred in many cancers in the past decade, progress in urinary tract cancers has lagged. Fortunately, an accelerated understanding of the molecular underpinnings of bladder and urinary tract cancer biology has led to a significant increase in clinical trials with the first U.S. Food and Drug Administration (FDA) approval of a new drug for advanced bladder and urinary tract cancers in over 25 years with many more expected to follow. This chapter reviews the established, current, and emerging evidence that serves as the basis for the rapidly evolving standards of care for patients with bladder and urinary tract cancers.

CLINICAL EPIDEMIOLOGY AND RISK FACTORS

Bladder cancer typically affects older patients with a median age at diagnosis of 73 years. Males are four times more frequently affected than females. Similarly, bladder cancer is more common in Caucasians than in Asian patients. Singular inheritable genetic risk factors are rare in patients with bladder or urinary tract cancers. Patients with defects in mismatch repair genes leading to microsatellite instability (*MLH1, MSH2, MSH6*, etc.) as part of the familial cancer Lynch syndrome are at particular risk of upper urinary tract cancers of the renal pelvis and ureter. Additionally, patients with Cowden disease (*PTEN* mutations) or retinoblastoma (*RB1* mutations) are at increased risk for developing bladder cancer.

Historically, associations have existed between environmental toxic exposures and higher rates of developing bladder cancer. Carcinogenic agents associated with increased risk of bladder cancer have included the aromatic amines benzidine and beta-naphthylamine that can be present in industrial dyes as well as arsenic that can be found in some drinking water supplies in underdeveloped countries. Other chemicals in the leather, paint, rubber, textiles, and printing industries have been associated with bladder cancer. More recently, associations with exposures to hair dyes and hair sprays in workers in the hairstyling field have been suggested. Additionally, much concern has been raised regarding use of the antidiabetic medication, pioglitazone, and bladder cancer risk. Extensive review of population data by leading

bladder cancer experts has produced mixed associations. An association between chronic inflammatory states and the development of squamous bladder cancer clearly exists in underdeveloped countries in patients chronically infected with the parasitic disease schistosomiasis and in paraplegic patients with chronic indwelling catheters. Above and beyond each of these associations, however, smoking of tobacco products (cigarettes, cigars, pipes, etc.) has been and continues to remain the overwhelming leading risk factor for development of bladder cancer. Among new bladder cancer diagnoses, 90% of cases occur in current or former smokers. Toxicologists have estimated that over 70 confirmed carcinogenic toxins are present within tobacco smoke. It is estimated that one-third of bladder cancer cases could be prevented through simple modification of lifestyle choices, in particular cessation of smoking.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

Occasionally, patients will present with flank pain in association with an upper tract renal pelvis or ureter cancer or due to hydronephrosis in association with a bladder tumor obstructing the orifice of the ureter within the bladder. Only in rare cases do patients present with significant cachexia and widespread metastatic disease. For most patients, painless hematuria (either gross or microscopic) represents the initial manifestation of an underlying urinary tract cancer. In females, hematuria due to malignancy can often be mistaken for a urinary tract infection or menstrual bleeding. While treatment with antibiotics is warranted if a concurrent urinary tract infection is noted on initial urinalysis, persistent hematuria requires further workup. Painless hematuria in males is almost always abnormal and should be worked up. Initial investigations in patients of either sex should include urine cytology and visual examination of the bladder by cystoscopy. Cytology is successful in identifying cancer in only 50% of individuals with high-grade bladder cancers. In addition to urine cytology, radiographic evaluation of the kidneys and upper urinary tract by CT urogram should be performed. Because of the increased sensitivity and reduced IV contrast loads, CT urograms have largely replaced IV pyelograms as the preferred upper urinary tract imaging modality. A magnetic resonance (MR) urogram may be substituted in patients with poor renal function. Additional diagnostic testing of the urine to assess for cancer-associated chromosomal changes by fluorescent in situ hybridization, increased levels of nuclear mitotic proteins, increased bladder tumor–associated antigens, or higher levels of staining on cells shed by the bladder may identify some cancers missed by traditional cytology testing. However, they may also produce abnormal results in patients who do not have cancer. For now, these adjunct molecular tests are primarily utilized in detecting recurrent cancer in patients with a prior diagnosis of urinary tract cancer. Small tumors, particularly flat noninvasive tumors of the bladder, may be detected at higher rates with the use of blue light cystoscopy or narrow-band imaging cystoscopy. Both blue light and narrow-band imaging cystoscopies are now used routinely in the initial workup and subsequent monitoring of patients with bladder cancer. For patients with no bladder abnormalities in whom upper tract tumors are suspected, visualization of the upper urinary tracts and renal pelvises should be performed by ureteroscopy or retrograde pyelography.

In all patients with abnormalities noted in the bladder or upper urinary tracts, complete endoscopic resection for histologic diagnosis and staging should be performed when possible via either transurethral resection of bladder tumor (TURBT) or endoscopic resection of upper tract tumors.

HISTOLOGY

Urothelial carcinoma, formerly referred to as *transitional cell carcinoma*, is the most common urinary tract cancer histology that is observed in ~90% of cases. Squamous, glandular, micropapillary, plasmacytoid, sarcomatoid, and other variant features can often be found in portions of urothelial carcinoma tumors; however, pure variant histologies are rare. The presence of some variant histologies including micropapillary and plasmacytoid has been associated with worse surgical outcomes compared to urothelial carcinoma. Nonurothelial variant histologies including squamous cell carcinoma, adenocarcinoma, small-cell carcinoma, and carcinosarcoma collectively account for ≤10% of urinary tract tumors. Examples of traditional urothelial carcinoma and some of the variant histologies are shown in Fig. 82-1.

MOLECULAR BIOLOGY

Clinically, urothelial carcinoma of the bladder displays a biphasic phenotype characterized by (1) low-grade papillary tumors that frequently recur but rarely invade or metastasize and (2) high-grade sometimes flat tumors that invade early leading to lethal metastatic disease. In both of these phenotypes, loss of portions of chromosomes 9q and 9p by loss of heterozygosity analyses is an early molecular event, whose exact significance is not clear. Potential candidate regulatory genes in these

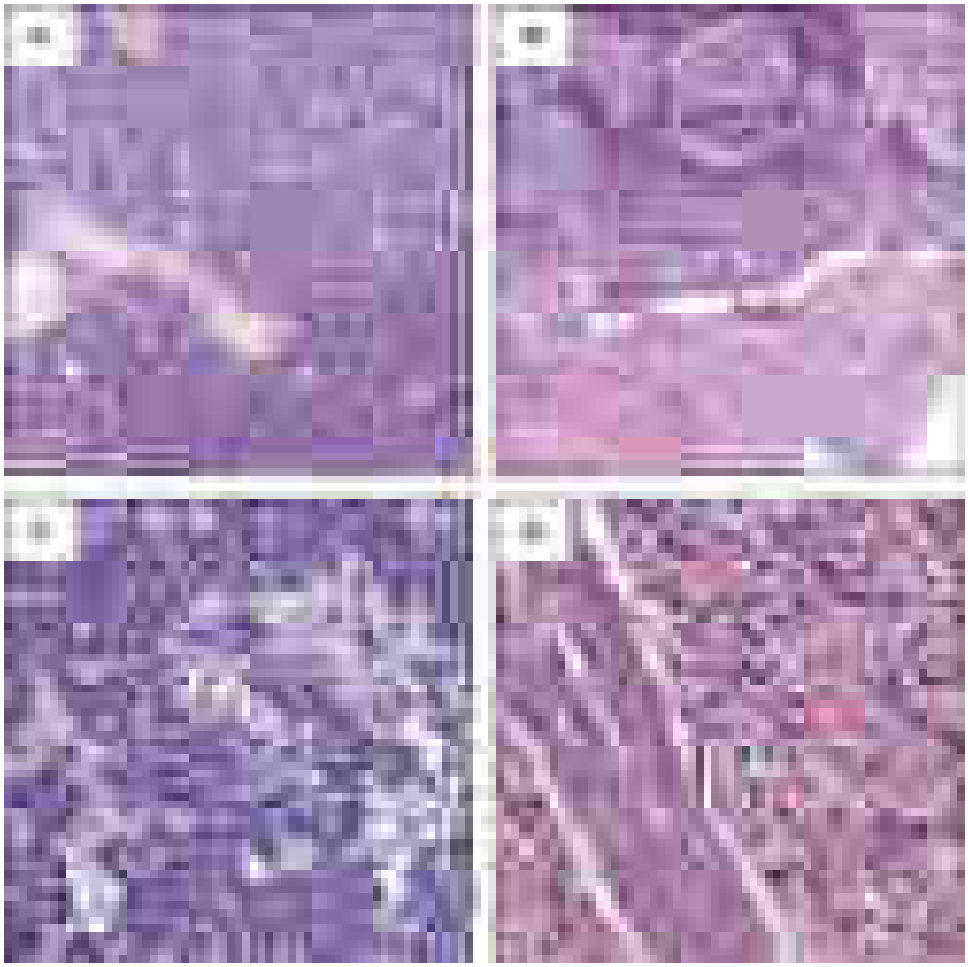

FIGURE 82-1 Bladder and urinary tract cancer histologies. ***A.*** Urothelial carcinoma; ***B.*** squamous cell carcinoma; ***C.*** small-cell carcinoma; ***D.*** plasmacytoid variant. *(Courtesy of Alex Baras, MD, PhD, Johns Hopkins University Department of Pathology.)*

genomic regions include *CDNK2A* and *TSC1*. Early investigations have demonstrated that low-grade tumors are characterized by alterations in the *RAS/RAF* signaling pathway with activating *FGFR3* mutations or gene fusions present in 60–80% of patients. In contrast, the high-grade invasive phenotype is notable for early deleterious mutations in *TP53* and *RB1*, alterations in *CDH1*, and increased expression of *VEGFR2*. In urothelial carcinoma of the renal pelvis and ureter, 10–20% of cases may be associated with Lynch syndrome hereditary defects in the *MLH1*, *MSH2*, *or MSH6* mismatch repair genes leading to microsatellite instability and frequent DNA mutations. Testing for germline mutations in these genes is recommended in patients with upper urinary tract urothelial carcinoma under the age of 60 at diagnosis, with a first-degree relative with a Lynch syndrome–associated cancer diagnosed under the age of 50, or with two first-degree relatives with a Lynch syndrome–associated cancer regardless of the age at diagnosis.

As genomic analysis technologies have improved, so has our understanding of the molecular biology unique to urothelial carcinoma. In 2014, the initial bladder cancer results of The Cancer Genome Atlas (TCGA) project were published. This effort comprehensively analyzed gene mutations, fusions, expression, copy number variations, methylation, and microRNA across the genome of patients with bladder urothelial carcinoma treated with surgery. While this data set will continue to be analyzed for years to come, the initial findings include (1) genomic alterations in genes (e.g., *FGFR3*, *EGFR*, *ERBB2*, *ERBB3*, *PIK3CA*, *TSC1*, etc.) targetable by currently approved drugs or drugs in development in 69% of patients; (2) genomic alterations in chromatin modifying genes (*KDM6A*, *MLL2*, *CREBBP*, *EP300*, etc.) in 89% of patients; (3) hypermethylation of tumor suppressor genes in 34% of patients; and (4) the identification by RNA sequencing of four distinct intrinsic molecular subtypes (luminal 1, luminal 2, basal 3, and basal 4) closely resembling luminal and basal subclassifications of breast cancers. These initial bladder TCGA findings have led to clinical trial designs enriching for patients with specific gene mutation profiles as well as interrogation of candidate biomarkers according to intrinsic molecular subtypes.

STAGING AND OUTCOMES BY STAGE

The staging of bladder cancer is dependent on the depth of invasion within the bladder wall, involvement of lymph nodes, and spread to surrounding and distant organs as depicted in Fig. 82-2. Approximately 75% of bladder cancer presents with non–muscle-invasive bladder cancer (NMIBC), 18% with disease invading into or through the muscular wall of the bladder, and only 3% presenting with metastatic spread to distant organs. NMIBC is defined by tumors that involve only the immediate epithelial layer of cells (carcinoma in situ [CIS] and Ta) or that only penetrate into the connective tissue below the urothelium (T1) but not into the muscular layer known as the *muscularis propria*. Muscle-invasive bladder cancer (MIBC) is defined by tumors that invade into the muscularis propria (T2), through the muscularis propria to involve the surrounding serosa (T3), or into immediately adjacent pelvic organs such as the rectum, prostate, vagina, or cervix (T4). Lymph node staging is classified according to involvement of a solitary node within the true pelvis (N1), multiple nodes involved in the true pelvis (N2), or involvement of the common iliac nodes (N3). Any disease that has spread beyond the true pelvis is considered metastatic (M1). The staging of bladder cancer is driven primarily by the T-stage of the tumor with stages 0a–III defined entirely by the T-stage in the absence of nodal or metastatic disease. Conversely, involvement of either nodal or distant metastases qualifies as stage IV disease. Clinical outcomes of patients with bladder cancer correlate closely with staging at diagnosis with 5-year overall survival rates of 80% for disease confined to the bladder (stage I–II), 35–50% for disease that penetrates through the bladder (stage III), and only 10–20% for disease extending to surrounding organs, lymph nodes, or metastatic sites (stage IV).

TREATMENT APPROACHES

Early-Stage Disease For NMIBC, removal of all visible tumors by TURBT in the operating room is considered the mainstay of surgical treatment. Risk of recurrence can be classified as low, intermediate, or high depending on the presence of features summarized in Table 82-1. For patients with low-risk disease meta-analyses have demonstrated a 12% reduction in early relapses when a single chemotherapy treatment of mitomycin C, epirubicin, or gemcitabine was instilled directly into the bladder (intravesical therapy) within 24 hours of the TURBT. For patients with intermediate- or high-risk tumors, weekly intravesical instillations for 6 consecutive weeks of the attenuated mycobacterium strain known as *Bacille-Calmette Guerin* (BCG) reduce the risk of recurrence at 12 months from 56 to 29%. In addition, BCG treatment has been shown to decrease the rate of progression to MIBC by 27%. Intravesical BCG is generally well tolerated. Side effects can include dysuria, urinary frequency, bladder spasms, hematuria, and, in rare cases (<5%), a systemic inflammatory response that can mimic disseminated BCG infection. Following a 6-week induction BCG schedule, additional maintenance BCG treatments given according to the Southwest Oncology Group schedule further reduce the risk of recurrent NMIBC compared to induction BCG alone. In patients with

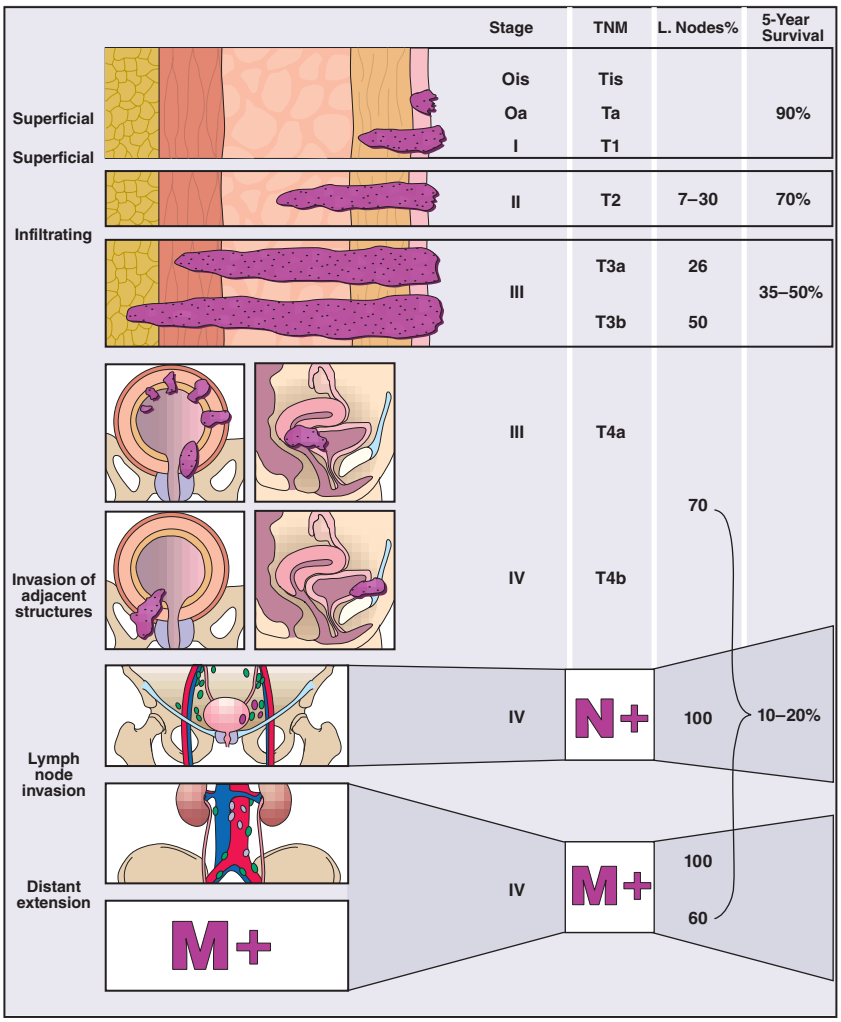

FIGURE 82-2 Bladder cancer staging. TNM, tumor, node metastasis. *(Reprinted with permission from HI Scher, JE Rosenberg, RJ Motzer: Bladder and renal cell carcinomas, in DL Kasper et al [eds]: Harrison's Principles of Internal Medicine, 19th ed. New York, McGraw-Hill, Chap. 114, 2015.)*

TABLE 82-1 Non–Muscle-Invasive Bladder Cancer Recurrence Risk Groups

RISK GROUP	CHARACTERISTICS
Low risk	Initial tumor, solitary tumor, low grade, <3 cm, no CIS
Intermediate risk	All tumors not defined in the two adjacent categories (between the category of low and high risk)
High risk	Any of the following: • T1 tumor • High-grade • CIS • Multiple and recurrent and large (>3 cm) Ta low-grade tumors (all conditions must be met for this point on Ta low-grade tumors)

Abbreviation: CIS, carcinoma in situ.

NMIBC that recurs long after initial BCG treatment, a repeat course of BCG can be considered. For patients with recurrence after a second induction course of BCG or with relapsed NMIBC within 6 months of initial BCG exposure, surgical removal of the entire bladder by cystectomy is recommended due to the high risk of progression to MIBC and potentially metastatic disease. For patients who are not fit enough for or who refuse cystectomy, non-BCG alternative intravesical agents (mitomycin C, gemcitabine, docetaxel, valrubicin) can achieve temporary tumor responses.

In patients with urothelial carcinoma of the renal pelvis or ureter, endoscopic tissue acquisition and staging are more challenging than primary tumors located in the bladder. Tumors possessing all of the following are considered low risk: solitary tumor, low grade, size <1 cm, no invasive component on imaging. Low-risk tumors can successfully be treated by laser ureteroscopic ablation or surgical resection and reanastomosis of the remaining ureter ends in tumors that cannot be successfully eradicated endoscopically.

Muscle-Invasive Disease In patients with urothelial carcinoma of the bladder that invades into or through the muscularis propria but with no evidence of metastatic spread, more aggressive therapy options summarized in Table 82-2 are required to achieve cure. In carefully selected patients with no evidence of CIS or hydronephrosis, bladder-sparing combined modality therapy with concurrent chemotherapy and radiation can achieve cure in ~65% of patients. Various chemotherapy regimens have been utilized in combination with radiation including cisplatin, carboplatin, 5-fluorouracil, mitomycin C, paclitaxel, and gemcitabine. It is important to note that a maximal debulking of all visible tumor by TURBT is required prior to initiation of combined modality therapy. In patients who achieve a complete response to combined modality therapy, regular cystoscopic monitoring of the bladder is required with salvage cystectomy offered to patients who develop MIBC in follow-up.

TABLE 82-2 Treatment Approaches to MIBC Patients

TREATMENT	PATIENT SELECTION	CLINICAL OUTCOMES
Bladder-sparing chemoradiation	No CIS, no hydronephrosis, maximal TURBT required	65% cure, 55% bladder intact, highly dependent on patient selection
Bladder-sparing partial cystectomy	Solitary tumors in dome of bladder are ideal	Variable, highly dependent on patient selection
Cystectomy	Any MIBC patient	50% cure with surgery alone, highly dependent on pathologic stage
Neoadjuvant cisplatin-based chemotherapy	Cisplatin-eligible MIBC patients	5–10% improvement in overall survival compared to cystectomy alone
Adjuvant cisplatin-based chemotherapy	Cisplatin-eligible high-risk postcystectomy MIBC patients (pT3-4, N+)	Similar improvement as neoadjuvant treatment, data less robust, many patients not suitable for adjuvant treatment

Abbreviations: CIS, carcinoma in situ; MIBC, muscle-invasive bladder cancer; TURBT, transurethral resection of bladder tumor.

In a similar fashion, bladder-sparing partial cystectomy can be performed in a very small subset of MIBC patients. The ideal patient for partial cystectomy is the patient with a solitary, clinical T2 urothelial carcinoma in the dome of the bladder. In such patients, the tumor and immediate surrounding urothelium can be resected with reconstruction of the remaining bladder to maintain near physiologic urinary function.

In the majority of patients, however, resection of the entire bladder is required. In males, a cystoprostatectomy with removal of the bladder, prostate, and pelvic lymph nodes is performed while in females an anterior exenteration with removal of the bladder, uterus, ovaries, cervix, and pelvic lymph nodes is performed. With the bladder removed, three options exist to re-route the urine outflow. In an ileostomy, the bilateral ureters are connected to a portion of ileum that is brought through an incision in the abdominal wall to create a stoma that drains urine into an affixed bag outside of the body. In a continent urinary reservoir or "Indiana pouch," the ureters are connected to a portion of ileum that has been separated on both ends from the rest of the small bowel transit to form a urinary reservoir. The remaining small bowel is reanastomosed, and the urinary reservoir is brought up just beneath the abdominal wall muscles with patients catheterizing the urinary reservoir several times per day via a small stoma tract. Last, in a neobladder, the same urinary reservoir described previously is brought down into the pelvis and is anastomosed to the remaining urethra to provide the opportunity to the patient to void urine through the urethra. The choice of which urinary reconstruction to perform is affected not only by patient choice but also by anatomic tumor considerations and urologist experience with each procedure. Regardless of the type of surgery performed, all patients undergo a significant catabolic change in their metabolism following removal of the bladder. While many MIBC patients are affected by weight loss preoperatively, it is not uncommon for postcystectomy patients to lose an additional 10–15 lb in the first month postoperatively. In addition, patients can experience long-term nutritional changes such as low B_{12} levels due to alterations in small bowel physiology caused by all of the urinary diversion options.

Despite aggressive surgery, only half of patients undergoing cystectomy are cured by surgery alone. Therefore, many clinical trials have investigated the role of systemic chemotherapy before (neoadjuvant) or after (adjuvant) surgery. Meta-analyses have shown a 5–10% absolute overall survival advantage when combination chemotherapy regimens utilizing cisplatin have been used before surgery. A similar benefit exists with cisplatin-based combination chemotherapy given after surgery. However, the data in the adjuvant setting are based on smaller, older trials. Furthermore, in the postoperative setting, some patients may not recover sufficiently from their surgery within a time frame optimal for chemotherapy administration. Importantly, non–cisplatin-containing chemotherapy regimens have proven inferior to cisplatin-containing regimens. Therefore, if patients are not suitable candidates for cisplatin administration due to poor functional status or comorbidities (e.g., poor renal function), patients should proceed directly to surgery and forego neoadjuvant therapy.

For patients with high-risk urothelial carcinoma of the upper urinary tract, resection of the kidney and ureter (including the ureter bladder cuff) by nephroureterectomy is preferred. Segmental ureterectomy may be appropriate in patients with decreased renal function in which nephron-sparing outcomes are critical to prevent the need for dialysis. Similarly, in CIS patients, administration of BCG therapy via a nephrostomy tube can be considered to preserve intact renal function. In retrospective series, the use of cisplatin-based neoadjuvant chemotherapy has been associated with a pathologic complete response at surgery of 14% in upper tract urothelial carcinoma patients. While adjuvant chemotherapy can be considered in patients with locally advanced stages (T3, T4, or node positive), due to the removal of a kidney at surgery and subsequent associated drop in renal function, many postoperative upper tract patients cannot receive cisplatin-based regimens.

Metastatic Disease For patients with metastatic urothelial carcinoma regardless of primary tumor origin, systemic chemotherapy is

the most established standard of care. In a randomized phase 3 clinical trial, the combination of methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) demonstrated an improvement in median overall survival from 8.2 to 12.5 months compared to single-agent cisplatin. In a head-to-head randomized phase 3 clinical trial, the combination of cisplatin and gemcitabine (CG) demonstrated similar overall survival compared to MVAC with a more favorable side-effect profile. Since 2000, treatment with either MVAC or CG has remained the standard for first-line treatment of patients with metastatic urothelial carcinoma with adequate renal function and functional status suitable for cisplatin therapy. For patients with lymph node only metastases and good functional status, cure is achieved in 15–20% of such patients. Unfortunately, only ~5% of metastatic patients fulfill both these criteria. For most patients, chemotherapy may prolong survival, but disease resistance proving lethal eventually develops. Furthermore, approximately half of patients with urothelial carcinoma have renal insufficiency, comorbidities, or frail functional status, and are not candidates for cisplatin treatment. In cisplatin-ineligible patients, carboplatin-based chemotherapy regimens are most often used with median overall survival rates decreased to 9.3 months.

Following front-line chemotherapy treatment, second-line chemotherapy regimens have shown modest 10–20% response rates, but no overall survival benefit. In recent years, exponential development of novel immunotherapy approaches has occurred for patients with urothelial carcinoma. The immune checkpoint targets programmed cell death protein 1 (PD-1) and programmed death ligand 1 (PD-L1) have demonstrated the most encouraging clinical benefits. In normal physiology, PD-1/PD-L1 are upregulated in response to inflammation to dampen and prevent an overactive inflammatory response. In cancers including urothelial carcinoma, however, PD-1/PD-L1 are often upregulated on the tumor surface or immune cells in the tumor microenvironment. Upregulated PD-1/PD-L1 in this situation serves as a mechanism of immune escape that facilitates tumor growth. Atezolizumab (an anti–PD-L1 antibody) was the first drug approved in the United States for metastatic urothelial carcinoma in over two decades based on a response rate of 15% in postplatinum patients. Subsequently, pembrolizumab (an anti–PD-1 antibody) demonstrated an improvement in overall survival from 7.4 to 10.3 months compared to standard second-line chemotherapy options. Multiple other PD-1/PD-L1 agents have demonstrated clinical responses in urothelial carcinoma. In addition, clinical trials investigating immunotherapy, chemotherapy, and radiation combinations are ongoing. Last, leveraging the molecular knowledge gained from the TCGA project, clinical trials are also investigating the role of molecularly targeted therapies in patients with metastatic urothelial carcinoma harboring specific genetic alterations predictive of clinical benefit (e.g., activating *FGFR3* mutations or gene fusions). Collectively, these new emerging options for metastatic urothelial carcinoma patients offer hope for improved outcomes for patients with urothelial carcinoma of all stages in the future.

83 Benign and Malignant Diseases of the Prostate

Howard I. Scher, James A. Eastham

Benign and malignant changes in the prostate increase with age. Autopsies of men in the eighth decade of life show hyperplastic changes in >90% and malignant changes in >70% of individuals. The high prevalence of these diseases among the elderly, who often have competing causes of morbidity and mortality, mandates a risk-adapted approach to diagnosis and treatment. This can be achieved by considering these diseases as a series of states. Each state represents a distinct clinical milestone for which therapy(ies) may be recommended based on disease extent, current symptoms, the risk of developing symptoms, or the risk of death from disease in relation to death from other causes within a given time frame. For benign proliferative disorders, symptoms of urinary frequency, infection, and potential for obstruction are weighed against the side effects and complications of medical or surgical intervention. For prostate malignancies, the likelihood that a clinically significant cancer is present in the gland and the concomitant risk of symptoms or death from cancer are balanced against the morbidities of the recommended treatments and preexisting comorbidities.

ANATOMY AND PATHOLOGY

The prostate is located in the pelvis and is surrounded by the rectum, the bladder, the periprostatic and dorsal vein complexes and neurovascular bundles that are responsible for erectile function, and the urinary sphincter that is responsible for passive urinary control. The prostate is composed of branching tubuloalveolar glands arranged in lobules surrounded by fibromuscular stroma. The acinar unit includes an epithelial compartment made up of epithelial, basal, and neuroendocrine cells and separated by a basement membrane, and a stromal compartment that includes fibroblasts and smooth-muscle cells. Prostate-specific antigen (PSA) and prostatic acid phosphatase (PAP) are produced in the epithelial cells. Both prostate epithelial cells and stromal cells express androgen receptors (ARs) and depend on androgens for growth. Testosterone, the major circulating androgen, is converted by the enzyme 5α-reductase to dihydrotestosterone in the gland.

The periurethral portion of the gland increases in size during puberty and after the age of 55 years due to the growth of nonmalignant cells in the transition zone of the prostate that surrounds the urethra. Most cancers develop in the peripheral zone, and cancers in this location may be palpated during a digital rectal examination (DRE).

PROSTATE CANCER

In 2017, ~161,360 prostate cancer cases were diagnosed and 26,730 men died from prostate cancer in the United States. The absolute number of prostate cancer deaths has decreased in the past 10 years, attributed by some to the widespread use of PSA-based detection strategies. However, the paradox of management is that although 1 in 6 men will eventually be diagnosed with prostate cancer, and the disease remains the second leading cause of cancer deaths in men, only 1 man in 30 with prostate cancer will die of his disease.

EPIDEMIOLOGY

Epidemiologic studies show that the risk of being diagnosed with prostate cancer increases 2.5-fold if one first-degree relative is affected and fivefold if two or more are affected. Current estimates are that 40% of early-onset and 5–10% of all prostate cancers are hereditary. Prostate cancer affects ethnic groups differently. Matched for age, African-American males have a higher incidence and present at a more advanced stage with higher-grade, more aggressive tumors. A high risk in families has been linked to the HPC1 (hereditary prostate cancer 1) susceptibility locus in *RNASEL*. Genome-wide association studies (GWAS) have identified >40 prostate cancer susceptibility loci that are estimated to explain up to 25% of prostate cancer risk. Among

the genes implicated in variations in incidence and outcome are single-nucleotide polymorphisms (SNPs) in the vitamin D receptor in African-Americans and variants in the AR, CYP3A4, both involved in the deactivation of testosterone, as well as CYP17, which is involved in steroid biosynthesis.

The prevalence of autopsy-detected cancers is similar around the world, while the incidence of clinical disease varies. Thus, environmental and dietary factors may play a role in prostate cancer growth and progression. High consumption of dietary fats, such as α-linoleic acid or polycyclic aromatic hydrocarbons that form when red meats are cooked, is believed to increase risk. Similar to breast cancer in Asian women, the risk of prostate cancer in Asian men increases when they move to Western environments. Protective factors include consumption of the isoflavonoid genistein (which inhibits 5α-reductase), cruciferous vegetables with isothiocyanate sulforaphane, lycopene found in tomatoes, and inhibitors of cholesterol biosynthesis (e.g., statin drugs). The development of prostate cancer is a multistep process. One early change is hypermethylation of the GSTP1 gene promoter, which leads to loss of function of a gene that detoxifies carcinogens. The finding that many prostate cancers develop adjacent to a lesion termed PIA (proliferative inflammatory atrophy) suggests a role for inflammation. Not smoking, regular exercise, and maintaining a healthy body weight may reduce the risk of progression.

DIAGNOSIS AND TREATMENT BY CLINICAL STATE

The prostate cancer continuum—from the appearance of a preneoplastic and invasive lesion that is localized to the gland, to a metastatic lesion causing symptoms and, ultimately, mortality—can span decades. To limit overdiagnosis of clinically insignificant cancers, and for disease management in general, competing risks are considered in the context of a series of clinical states **(Fig. 83-1)**. The states are defined operationally on the basis of whether or not a cancer diagnosis has been established and, for those with a diagnosis, whether or not metastases are detectable on imaging studies and the measured level of testosterone in the blood. With this approach, an individual resides in only one state and remains in that state until he has progressed. At each assessment, the decision to offer treatment and the specific form of treatment are based on the risk posed by the cancer relative to competing causes of morbidity and mortality that may be present in that individual. It follows that the more advanced the disease, the greater the need for treatment.

For those without a cancer diagnosis, the decision to undergo testing to detect a cancer is based on the individual's estimated life expectancy and, separately, the probability that a clinically significant cancer may be present. For those with a prostate cancer diagnosis, the clinical states model considers the probability of developing symptoms or dying from the disease. Thus, a patient with localized tumor that has been surgically removed remains in the state of localized disease as long as the PSA remains undetectable. The time within a state then becomes a measure of the efficacy of an intervention, though the effect may not be assessable for years. Because many men with active cancer are not at risk for developing metastases, symptoms, or death, the clinical states model allows a distinction between *cure*—the elimination of all cancer cells, the primary therapeutic objective of treatment for most cancers—and *cancer control*, by which the tempo of the illness is determined to be so slow or has been altered to the point where it is unlikely to cause symptoms, to metastasize, or to shorten a patient's life expectancy. Importantly, from a patient standpoint, both outcomes can be considered equivalent therapeutically, assuming the patient has not experienced symptoms of the disease or the treatment needed to control it. Even when a recurrence is documented, immediate therapy is not always necessary. Rather, as at the time of diagnosis, the need for intervention is based on the tempo of the illness as it unfolds in the individual, relative to the risk-to-benefit ratio of the intervention being considered.

NO CANCER DIAGNOSIS

Prevention No agent is currently approved for the prevention of prostate cancer. The results from several large double-blind, randomized chemoprevention trials have established 5α-reductase inhibitors (5ARI) as the predominant therapy to reduce the future risk of a prostate cancer diagnosis. The Prostate Cancer Prevention Trial (PCPT), in which men aged >55 years received placebo or the 5ARI finasteride, which inhibits the type 1 isoform, showed a 25% (95% confidence interval 19–31%) reduction in prostate cancer incidence from 24% with placebo to 18% with finasteride. In REDUCE (Reduction by Dutasteride of Prostate Cancer Events trial), a reduction in incidence from 25% with placebo to 20% with dutasteride was found ($p = 0.001$). Dutasteride inhibits both the type 1 and type 2 5ARI isoforms. While both studies met their endpoint, there was concern that most of the cancers that were prevented were low-risk and that there was a slightly higher rate of clinically significant cancers (those with higher Gleason score) in the treatment arm. Neither drug is approved for prostate cancer prevention. In comparison, the Selenium and Vitamin E Cancer Prevention Trial (SELECT), which enrolled African-American men aged ≥50 years and others aged ≥55 years, showed no difference in cancer incidence in patients receiving vitamin E (4.6%) or selenium (4.9%) alone or in combination (4.6%) relative to placebo (4.4%). A similar lack of benefit for vitamin E, vitamin C, and selenium was seen in the Physicians Health Study II.

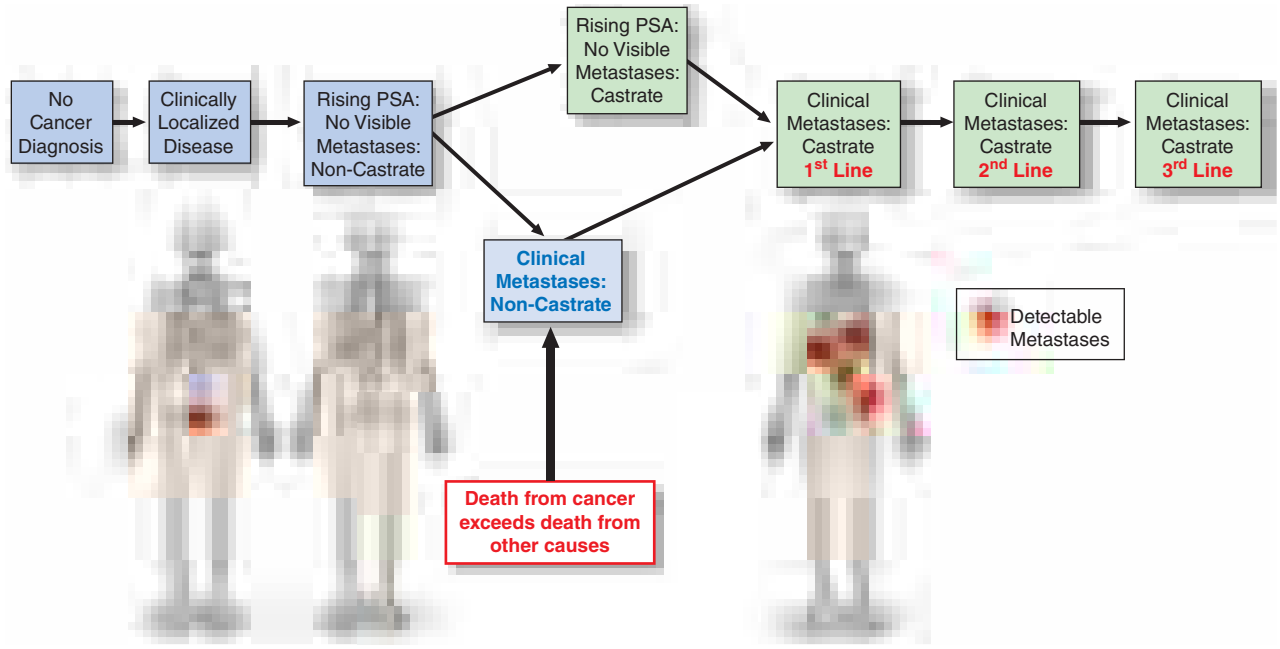

FIGURE 83-1 Clinical states of prostate cancer. PSA, prostate-specific antigen.

Screening/Early Detection and Diagnosis The need to pursue a diagnosis of prostate cancer must balance the benefit from detecting and treating clinically significant cancers that, left untreated, would adversely affect patients' quality and duration of life against the morbidity associated with overdiagnosis and overtreatment of clinically insignificant cancers that are highly prevalent in the general population. The balance is best approached through shared decision making between the patient and physician. Considerations for whether to pursue a diagnosis include symptoms, an abnormal DRE, or more typically, a change in or an elevated serum PSA. Genetic risk is also considered. The urologic history should focus on symptoms of outlet obstruction, continence, potency, or change in ejaculatory pattern.

PHYSICAL EXAMINATION The DRE focuses on prostate size and consistency and abnormalities within or beyond the gland. Many cancers occur in the peripheral zone and may be palpated on DRE. Carcinomas are characteristically hard, nodular, and irregular, while induration may also be due to benign prostatic hyperplasia (BPH) or calculi. Overall, 20–25% of men with an abnormal DRE have prostate cancer.

PROSTATE-SPECIFIC ANTIGEN PSA (kallikrein-related peptidase 3; *KLK3*) is a kallikrein-related serine protease that causes liquefaction of seminal coagulum. It is produced by both nonmalignant and malignant epithelial cells and, as such, is prostate-specific, not prostate cancer–specific. Serum levels may also increase from prostatitis and BPH. Serum levels are not significantly affected by DRE, but the performance of a cystoscopy or prostate biopsy can increase PSA levels up to tenfold for 8–10 weeks. PSA circulating in the blood is inactive and mainly occurs as a complex with the protease inhibitor α_1-antichymotrypsin and as free (unbound) PSA forms. The formation of complexes between PSA, α_2-macroglobulin, or other protease inhibitors is less significant. Free PSA is rapidly eliminated from the blood by glomerular filtration with an estimated half-life of 12–18 h. Elimination of PSA bound to α_1-antichymotrypsin is slow (estimated half-life of 1–2 weeks) as it too is largely cleared by the kidneys. Levels should be undetectable after about 6 weeks if the prostate has been completely removed (radical prostatectomy). Immunohistochemical staining for PSA can be used to establish a prostate cancer diagnosis.

PSA testing was approved by the U.S. Food and Drug Administration (FDA) in 1994 for early detection of prostate cancer, and the widespread use of the test has played a significant role in the proportion of men diagnosed with early-stage cancers: more than 70–80% of newly diagnosed cancers are clinically organ confined. The level of PSA in blood is strongly associated with the risk and outcome of prostate cancer. A single PSA measured at age 60 is associated (area under the curve [AUC] of 0.90) with lifetime risk of death from prostate cancer. Most (90%) prostate cancer deaths occur among men with PSA levels in the top quartile (>2 ng/mL), although only a minority of men with PSA >2 ng/mL will develop lethal prostate cancer. Despite this and mortality rate reductions reported from large randomized prostate cancer screening trials, routine use of the test remains controversial.

In 2012, the United States Preventive Services Task Force (USPSTF) published a review of the evidence for PSA-based screening for prostate cancer and made a clear recommendation against screening. By giving a grade of "D" in the recommendation statement that was based on this review, the USPSTF concluded that "there is moderate or high certainty that this service has no net benefit or that the harms outweigh the benefits." In 2013, the American Urological Association (AUA) updated their consensus statement regarding prostate cancer screening. They concluded that the quality of evidence for the benefits of screening was moderate for men aged 55–69 years. For men outside this age range, evidence was lacking for benefit, but the harms of screening, including overdiagnosis and overtreatment, remained. The AUA recommends shared decision-making for men aged 55–69 years considering PSA-based screening, a target age group for whom benefits may outweigh harms. Outside this age range, PSA-based screening as a routine was not recommended. The entire guideline is available at *http://www.auanet.org/guidelines/early-detection-of-prostate-cancer-(2013-reviewed-and-validity-confirmed-2015)*. As of 2017, the USPSTF has issued a draft of a revised recommendation with a grade of "C" for PSA-based prostate cancer screening for men aged 55–69. They recommend shared decision-making for men aged 55–69 and do not recommend screening for men aged ≥70; this is now roughly in agreement with the 2013 AUA guideline. The USPSTF notes that the increased use of active surveillance (observation with selective delayed treatment) for low-risk prostate cancer has reduced the risks of screening.

We believe that implementation of the following three guidelines will further improve PSA screening outcomes in the United States and will have a greater practical impact on men's health than the USPSTF and AUA recommendations that are based almost solely on age. First, avoid PSA tests in men with little to gain. There is no rationale for recommending PSA screening in asymptomatic men with a short life expectancy. Hence, men aged >75 years should only be tested in special circumstances, such as higher than median PSAs measured before age 70 or excellent overall health. In addition, because a baseline PSA is a strong predictor of the future risk of lethal prostate cancer, men with low PSAs, for example <1 ng/mL, can undergo testing less frequently, perhaps every 5 years, with screening possibly ending at age 60 if the PSA remains at ≤1 ng/mL. Men with PSAs that are above age median but below biopsy thresholds can be counseled about their elevated risk and actively encouraged to return for regular screening and more comprehensive risk assessment. Second, do not treat those who do not need treatment. High proportions of men with screen-detected prostate cancer do not need immediate treatment and can be managed by active surveillance. Third, refer men who do need treatment to high-volume centers. Although it is clearly not feasible to restrict treatment exclusively to high-volume centers, shifting treatment trends so that more patients are treated at such centers by high-volume providers will improve cancer control and decrease complications. The goal of prostate cancer screening should be to maximize the benefits of PSA testing and minimize its harms. Following the three rules outlined here should continue to improve the ratio of harms to benefits from PSA screening.

The PSA criteria used to recommend a diagnostic prostate biopsy have evolved over time. However, based on the commonly used cut-point for prostate biopsy (a total PSA ≥4 ng/mL), most men with a PSA elevation do not have histologic evidence of prostate cancer at biopsy. In addition, many men with PSA levels below this cut-point harbor cancer cells in their prostate. Information from the Prostate Cancer Prevention Trial demonstrates that there is no PSA below which the risk of prostate cancer is zero. Thus, the PSA level establishes the likelihood that a man will harbor cancer if he undergoes a prostate biopsy. The goal is to increase the sensitivity of the test for younger men more likely to die of the disease and to reduce the frequency of detecting cancers of low malignant potential in elderly men more likely to die of other causes. Patients with symptomatic prostatitis should have a course of antibiotics before biopsy. However, the routine use of antibiotics in an asymptomatic man with an elevated PSA level is strongly discouraged.

SECOND-LINE SCREENING TESTS The 4Kscore® Test (OPKO Lab, Nashville, TN) measures four prostate-specific kallikreins (total PSA, free PSA, intact PSA, and human kallikrein 2). The results are combined with clinical information in an algorithm that estimates an individual's percent risk of being found to harbor an aggressive prostate cancer should that individual opt for a prostate biopsy. The 4Kscore test has also been shown to identify the likelihood than an individual will develop aggressive prostate cancer, defined as high grade prostate cancer pathology and/or poor prostate cancer clinical outcomes, within 20 years.

Prostate Health Index (PHI™, Innovative Diagnostic Laboratory, Richmond, VA) is a blood test that estimates the risk of having prostate cancer. The PHI test is a combination of the free PSA, total PSA, and the [-2]proPSA isoform of free PSA. These three tests are combined in a formula that calculates the PHI score. The PHI score is a better predictor of prostate cancer than the total PSA test alone or the free PSA test alone.

PROSTATE BIOPSY A diagnosis of cancer is established by an image-guided needle biopsy. Direct visualization by transrectal ultrasound (TRUS), magnetic resonance imaging (MRI), or fusion of the ultrasound and MRI images ensures that all areas of the gland including suspicious areas are sampled. Contemporary schemas advise an extended-pattern 12-core biopsy that includes sampling from the peripheral zone as

well as a lesion-directed palpable nodule or suspicious image-guided sampling. Because a prostate biopsy is subject to sampling error, men with an abnormal PSA and negative biopsy are frequently advised to undergo additional testing which may include a 4Kscore Test, PHI, prostate MRI, and/or repeat biopsy.

PATHOLOGY Each core of the biopsy is examined for the presence of cancer, and the amount of cancer is quantified based on the length of the cancer within the core and the percentage of the core involved. Of the cancers identified, >95% are adenocarcinomas; the rest are squamous or transitional cell tumors or, rarely, carcinosarcomas. Metastases to the prostate are rare, but in some cases colon cancers or transitional cell tumors of the bladder invade the gland by direct extension.

When prostate cancer is diagnosed, a measure of histologic aggressiveness is assigned using the *Gleason grading system*, in which the dominant and secondary glandular histologic patterns are scored from 1 (well-differentiated) to 5 (undifferentiated) and summed to give a total score of 2–10 for each tumor. The most poorly differentiated area of tumor (i.e., the area with the highest histologic grade) often determines biologic behavior. The presence or absence of perineural invasion and extracapsular spread are also recorded.

Over the years, the Gleason grading system has undergone several changes. Currently, Gleason total scores 2–5 are no longer assigned and in practice the lowest total score is now assigned a 6, although the scale continues to range from 2 to 10. This leads to a logical yet incorrect assumption on the part of patients that their Gleason 6 cancer is in the middle of the scale, triggering the fear that their cancer is serious and the assumption that treatment is necessary despite Gleason score 6 actually being favorable risk. To address these issues, a new 5-grade group system has been developed:

Grade Group 1 (Gleason score ≤6)
Grade Group 2 (Gleason score 3+4 = 7)
Grade Group 3 (Gleason score 4+3 = 7)
Grade Group 4 (Gleason score 4+4 = 8)
Grade Group 5 (Gleason scores 9 and 10)

The new system simplifies the grading of prostate cancer, appropriately classifies the lowest risk as Grade Group 1 (rather than Gleason score 6), and accurately predicts prognosis.

PROSTATE CANCER STAGING The TNM (tumor, nodes, metastasis) staging system includes categories for cancers that are identified solely on the basis of an abnormal PSA (T1c), those that are palpable but clinically confined to the gland (T2), and those that have extended outside the gland (T3 and T4) **(Table 83-1, Fig. 83-2)**. DRE alone is inaccurate in determining the extent of disease within the gland, the presence or absence of capsular invasion, involvement of seminal vesicles, and extension of disease to lymph nodes. Because of the inadequacy of DRE for staging, the TNM staging system was modified to include the results of imaging. Unfortunately, no single test has proven to accurately indicate the stage or the presence of organ-confined disease, seminal vesicle involvement, or lymph node spread.

TRUS is the imaging technique most frequently used to assess the primary tumor, but its chief use is directing prostate biopsies, not staging. No TRUS finding consistently indicates cancer with certainty. Computed tomography (CT) lacks sensitivity and specificity to detect extraprostatic extension and is inferior to MRI in visualization of lymph nodes. In general, MRI is superior to CT to detect cancer in the prostate and to assess local disease extent. T1-weighted MRI produces a high signal in the periprostatic fat, periprostatic venous plexus, perivesicular tissues, lymph nodes, and bone marrow. T2-weighted MRI demonstrates the internal architecture of the prostate and seminal vesicles. Most cancers have a low signal, while the normal peripheral zone has a high signal, although the technique lacks sensitivity and specificity. MRI is also useful for the planning of surgery and radiation therapy.

Radionuclide bone scans (bone scintigraphy) are used to evaluate spread to osseous sites. This test is sensitive but relatively nonspecific because areas of increased uptake are not always related to metastatic disease. Healing fractures, arthritis, Paget's disease, and other conditions will also cause abnormal uptake. True-positive bone scans are uncommon when the PSA is <10 ng/mL unless the tumor is high-grade.

TABLE 83-1 TNM Classification

TNM (tumor, nodes, metastasis) Staging System for Prostate Cancer[a]	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Localized Disease	
T1	Clinically inapparent tumor, neither palpable nor visible by imaging
T1a	Tumor incidental histologic finding in ≤5% of resected tissue; not palpable
T1b	Tumor incidental histologic finding in >5% of resected tissue
T1c	Tumor identified by needle biopsy (e.g., because of elevated PSA)
T2	Tumor confined within prostate[b]
T2a	Tumor involves half of one lobe or less
T2b	Tumor involves more than one half of one lobe, not both lobes
T2c	Tumor involves both lobes
Local Extension	
T3	Tumor extends through the prostate capsule[c]
T3a	Extracapsular extension (unilateral or bilateral)
T3b	Tumor invades seminal vesicles
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles such as external sphincter, rectum, bladder, levator muscles, and/or pelvic wall
Metastatic Disease	
N1	Positive regional lymph nodes
M1	Distant metastases

[a]Revised from SB Edge et al (eds): *AJCC Cancer Staging Manual*, 7th ed. New York, Springer, 2010. [b]Tumor found in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, is classified as T1c. [c]Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2.

Abbreviation: PSA, prostate-specific antigen.

TREATMENT

LOCALIZED DISEASE OR CLINICALLY LOCALIZED DISEASE

Cancers are those that appear to be nonmetastatic after staging studies are performed. Patients with clinically localized disease are managed by radical prostatectomy, radiation therapy, or active surveillance. Choice of therapy requires the consideration of several factors: the presence of symptoms, the probability that the untreated tumor will adversely affect the quality or duration of survival and thus require treatment, and the probability that the tumor can be cured by single-modality therapy directed at the prostate versus requiring both local and systemic therapy to achieve cure.

Data from the literature (such as the ProtecT trial) do not provide clear evidence for the superiority of any one form of local therapy relative to another. This is due to the lack of prospective randomized trials, referral bias and physician bias, variation in the experience of the treating teams, and differences in trial endpoints and the definitions of cancer control. Often, PSA relapse–free survival is used because an effect on metastatic progression or survival may not be apparent for years. For many patients, however, a PSA recurrence does not necessarily mean that the disease will cause symptoms or shorten survival. After radical surgery to remove all prostate tissue, PSA should become undetectable in the blood within 6 weeks. If PSA remains or becomes detectable after radical prostatectomy, the patient is considered to have persistent or recurrent disease. After radiation therapy, in contrast, PSA does not become undetectable because the remaining nonmalignant elements of the gland continue to produce PSA even if all cancer cells have been eliminated. Similarly, cancer control is not well defined for a patient managed by active surveillance because PSA levels may continue to rise in the absence of therapy. Other outcomes are time to objective progression (local or systemic), cancer-specific survival, and overall survival; however, these outcomes may take years to assess.

The more extensive the local disease, the higher the probability of regional lymph node involvement even when imaging studies are

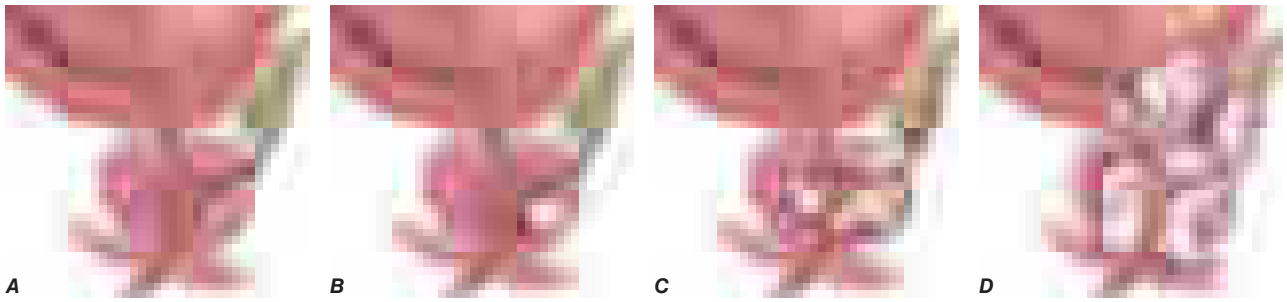

FIGURE 83-2 T stages of prostate cancer. ***A.*** T1—Clinically inapparent tumor, neither palpable nor visible by imaging; ***B.*** T2—Tumor confined within prostate; ***C.*** T3—Tumor extends through prostate capsule and may invade the seminal vesicles; ***D.*** T4—Tumor is fixed or invades adjacent structures. Eighty percent of patients present with local disease (T1 and T2), which is associated with a 5-year survival rate of 100%. An additional 12% of patients present with regional disease (T3 and T4 without metastases), which is also associated with a 100% survival rate after 5 years. Four percent of patients present with distant disease (T4 with metastases), which is associated with a 30% 5-year survival rate. (Three percent of patients are ungraded.) *(Data from AJCC, http://seer.cancer.gov/statfacts/html/prost.html. Figure © Memorial Sloan-Kettering Cancer Center Medical Graphics; used with permission.)*

normal, the lower the probability of local control, and the higher the probability of systemic relapse. More important is that within the categories of T1, T2, and T3 disease are cancers with a range of prognoses. Some T3 tumors are curable with therapy directed solely at the prostate, and some T1 lesions have a high probability of systemic relapse that requires the integration of local and systemic therapy to achieve cure. For T1c cancers in particular, stage alone is inadequate to predict outcome and select treatment; other factors must be considered.

To better assess risk and guide treatment selection, many groups have developed prognostic models or nomograms that use a combination of the initial clinical T stage, biopsy Gleason score, the number of biopsy cores in which cancer is detected, and baseline PSA. Some use discrete cut-points (PSA <10 or ≥10 ng/mL; Gleason score of ≤6, 7, or ≥8); others employ nomograms that use PSA and Gleason score as continuous variables. More than 100 nomograms have been reported to predict (a) the probability that a clinically significant cancer is present, (b) disease extent (organ-confined vs non–organ-confined, node-negative or -positive), or (c) the probability of treatment success for specific local therapies using pretreatment variables. Considerable controversy exists over what constitutes "high risk" based on a predicted probability of success or failure. In these situations, nomograms and predictive models can only go so far. Exactly what probability of success or failure would lead a physician to recommend and a patient to seek alternative approaches is controversial. As an example, it may be appropriate to recommend radical surgery for a younger patient with a low probability of cure. Nomograms are being refined continually to incorporate additional clinical parameters, biologic determinants, and year of treatment, which can also affect outcomes, making treatment decisions a dynamic process.

The frequency of adverse events varies by treatment modality and the experience of the treating team. For example, following radical prostatectomy, incontinence rates range from 2 to 47% and impotence rates range from 25 to 89%. Part of the variability relates to how the complication is defined and whether the patient or physician is reporting the event. The time of the assessment is also important. After surgery, impotence is immediate but may reverse over time, while with radiation therapy impotence is not immediate but may develop over time. Of greatest concern to patients are the effects on continence, sexual potency, and bowel function.

Radical Prostatectomy The goal of radical prostatectomy is to excise the cancer completely with a clear margin, to maintain continence by preserving the external sphincter, and to preserve potency by sparing the autonomic nerves in the neurovascular bundle. The procedure is advised for patients with a life expectancy of 10 years or more and is performed via a retropubic or perineal approach, or via a minimally invasive robotic-assisted or hand-held laparoscopic approach. Outcomes can be predicted using postoperative nomograms that consider pretreatment factors and the pathologic findings at surgery. PSA failure is usually defined as a value >0.1 or 0.2 ng/mL. Specific criteria to guide the choice of one approach over another are lacking. Minimally invasive approaches offer the advantage of a shorter hospital stay and reduced blood loss. Rates of cancer control, recovery of continence and recovery of erectile function are comparable. The individual surgeon rather than the surgical approach used is most important in determining outcomes after surgery.

Neoadjuvant hormonal treatment with gonadotropin-releasing hormone (GnRH) agonists/antagonists alone has also been explored in an attempt to improve the outcomes of surgery for high-risk patients using a variety of definitions. The results of several large trials testing 3 or 8 months of androgen depletion before surgery showed that serum PSA levels decreased by 96%, prostate volumes decreased by 34%, and margin positivity rates decreased from 41 to 17%. Unfortunately, these findings have not been shown to improve PSA relapse–free survival.

Factors associated with incontinence following radical prostatectomy include older age and urethral length, which impacts the ability to preserve the urethra beyond the apex and the distal sphincter. The skill and experience of the surgeon are also factors.

The likelihood of recovery of erectile function is associated with younger age, quality of erections before surgery, and the absence of damage to the neurovascular bundles. In general, erectile function begins to return about 6 months after surgery if neurovascular tissue has been preserved. Potency is reduced by half if at least one neurovascular bundle is sacrificed. Overall, with the availability of drugs such as sildenafil, intraurethral inserts of alprostadil, and intracavernosal injections of vasodilators, many patients recover satisfactory sexual function.

Radiation Therapy Radiation therapy is given by external beam, by radioactive sources implanted into the gland, or by a combination of the two techniques.

External beam radiation therapy Contemporary external beam intensity-modulated radiation therapy (IMRT) permits shaping of the dose, and allows the delivery of higher doses to the prostate and a dramatic reduction in normal tissue exposure compared to three-dimensional conformal treatment alone. These advances have enabled the safe administration of doses >80 Gy and resulted in higher local control rates and fewer side effects.

Cancer control after radiation therapy has been defined by various criteria, including a decline in PSA to <0.5 or 1 ng/mL, "nonrising" PSA values, and a negative biopsy of the prostate 2 years after completion of treatment. The current standard definition of biochemical failure (the Phoenix definition) is a rise in PSA by ≥2 ng/mL higher than the lowest PSA achieved. The date of failure is "at call" and not backdated.

Radiation dose is critical to the eradication of prostate cancer. In a representative study, a PSA nadir of <1.0 ng/mL was achieved in 90% of patients receiving 75.6 or 81.0 Gy vs 76 and 56% of those receiving 70.2 and 64.8 Gy, respectively. Positive biopsy rates at 2.5 years were 4% for those treated with 81 Gy vs 27 and 36% for those receiving 75.6 and 70.2 Gy, respectively.

More recently, hypofractionation schedules, utilizing fewer treatments of higher radiation doses, have been evaluated and shown to provide good cancer control rates based on post-treatment

biopsies showing no evidence of cancer, with no apparent increase in treatment-related morbidity. Hypofractionated treatments can range from as few as 5 treatments to upwards of 26 treatments, both regimens representing substantial reductions in treatment length.

Multiple clinical trials have evaluated the use of androgen deprivation therapy (ADT) in combination with radiation. In patients with intermediate-risk prostate cancer, short-course ADT (6 months), when combined with external beam radiotherapy, has demonstrated significant improvements in overall survival. In patients with high-risk disease, longer courses of ADT (18–36 months) have proven superior to shorter courses and represent the current standard of care when combined with radiotherapy.

Neoadjuvant hormone therapy before radiation therapy is used to decrease the size of the prostate and, consequently, to reduce the exposure of normal tissues to full-dose radiation, to increase local control rates, and to decrease the rate of systemic failure. Short-term hormone therapy can reduce toxicities and improve local control rates, but long-term treatment (2–3 years) is needed to prolong the time to PSA failure and lower the risk of metastatic disease in men with high-risk cancers. The impact on survival has been less clear.

The Prostate Testing for Cancer and Treatment (ProtecT) trial investigated the effects of active monitoring, radical prostatectomy, and radical radiotherapy with hormones on patient-reported outcomes in men diagnosed with low- and intermediate-risk prostate cancer (about 75% with Gleason score 6 or Gleason Grade Group 1 cancer). Patient-reported outcomes among 1643 men who completed questionnaires before diagnosis, at 6 and 12 months, and annually thereafter were compared. Of the three treatments, prostatectomy had the greatest negative effect on sexual function and urinary continence, and although there was some recovery, these outcomes remained worse in the prostatectomy group than in the other groups throughout the trial. The negative effect of radiotherapy on sexual function was greatest at 6 months, but sexual function then recovered somewhat and was stable thereafter; radiotherapy had little effect on urinary continence. Sexual and urinary function declined gradually in the active-monitoring group. Bowel function was worse in the radiotherapy group at 6 months than in the other groups but then recovered somewhat, except for the increasing frequency of bloody stools; bowel function was unchanged in the other groups. Urinary voiding and nocturia were worse in the radiotherapy group at 6 months but then mostly recovered and were similar to the other groups after 12 months. Effects on quality of life mirrored the reported changes in function. No significant differences were observed among the groups in measures of anxiety, depression, or general health-related or cancer-related quality of life.

Brachytherapy Brachytherapy is the direct implantation of radioactive sources (seeds) into the prostate. It is based on the principle that the deposition of radiation energy in tissues decreases as a function of the square of the distance from the source **(Chap. 69)**. The goal is to deliver intensive irradiation to the prostate, minimizing the exposure of the surrounding tissues. The current standard technique achieves a more homogeneous dose distribution by placing seeds according to a customized template based on imaging assessment of the cancer and computer-optimized dosimetry. The implantation is performed transperineally as an outpatient procedure with real-time imaging.

Improvements in brachytherapy techniques have resulted in fewer complications and a marked reduction in local failure rates. In a series of 197 patients followed for a median of 3 years, 5-year actuarial PSA relapse–free survival for patients with pretherapy PSA levels of 0–4, 4–10, and >10 ng/mL were 98, 90, and 89%, respectively. In a separate report of 201 patients who underwent posttreatment biopsies, 80% were negative, 17% were indeterminate, and 3% were positive. The results did not change with longer follow-up. Nevertheless, many physicians feel that implantation is best reserved for patients with good or intermediate prognostic features.

Brachytherapy is well tolerated, although most patients experience urinary frequency and urgency that can persist for several months. Incontinence has been seen in 2–4% of cases. Higher complication rates are observed in patients who have undergone a prior transurethral resection of the prostate (TURP), while those with obstructive symptoms at baseline are at a higher risk for retention and persistent voiding symptoms. Proctitis has been reported in <2% of patients.

Active surveillance Although prostate cancer is the most common form of cancer affecting men in the United States, patients are being diagnosed earlier and more frequently present with early-stage disease. Active surveillance, described previously as *watchful waiting* or *deferred therapy*, evolved from (1) studies that evaluated predominantly elderly men with well-differentiated tumors who demonstrated no clinically significant progression for protracted periods, (2) recognition of the contrast between incidence and disease-specific mortality, (3) the high prevalence of autopsy cancers, and (4) an effort to reduce overtreatment and treatment-related side effects. In practice, active surveillance is the treatment recommended to patients with cancers of low aggressiveness that can be safely monitored at fixed intervals with DREs, PSA measurements, imaging (usually prostate MRI), and repeat prostate biopsies as indicated until histopathologic or serologic changes correlative of progression warrant treatment with curative intent.

Case selection is critical, and determining clinical parameters predictive of cancer aggressiveness that can be used to reliably select men most likely to benefit from treatment by active surveillance is an area of intense study. In one prostatectomy series, it was estimated that 10–15% of those treated had "insignificant" disease. One set of criteria includes men with clinical T1c tumors that are biopsy Gleason grade 6 (Grade Group 1) involving 3 or fewer cores, each core having <50% involvement by tumor, and a PSA density of <0.15.

Concerns about active surveillance include the limited ability to predict pathologic findings by needle biopsy even when multiple cores are obtained, the recognized multifocality of the disease, and the possibility of a missed opportunity to cure the disease. Nomograms to help predict which patients can safely be managed by active surveillance continue to be refined, and as their predictive accuracy improves, it can be anticipated that more patients will be candidates.

RISING PSA AFTER DEFINITIVE LOCAL THERAPY

It includes patients in whom the sole manifestation of disease is a rising PSA after surgery and/or radiation therapy. By definition, there is no evidence of disease on imaging studies. For these patients, the central issue is whether the rise in PSA results from persistent disease in the primary site, systemic disease, or both. In theory, disease in the primary site may still be curable by additional local treatment.

The decision to recommend radiation therapy after prostatectomy is guided by the pathologic findings at surgery and an MRI of the prostate or prostate bed, as CT and radionuclide bone scan are typically uninformative. Others recommend that a biopsy of the urethrovesical anastomosis be obtained before considering radiation. New PET tracers such as C-11 choline, F-18 fluciclovine, (both FDA approved) and F-18 or Ga-68 PSMA (prostate-specific membrane antigen) are more sensitive and can detect low-volume disease in the prostate bed or other sites to better inform the decision to recommend additional local therapies. Detection rates, both in and outside the prostate bed, correlate with the absolute level of PSA. Factors that predict for response to salvage radiation therapy are a positive surgical margin, lower Gleason score in the radical prostatectomy specimen, long interval from surgery to PSA failure, slow PSA doubling time, and low (<0.5–1 ng/mL) PSA value at the time of radiation treatment. Radiation therapy is generally not recommended if the PSA was persistently elevated after surgery, which usually indicates that the disease had spread outside of the area of the prostate bed and is unlikely to be controlled with radiation therapy. As is the case for other disease states, nomograms to predict the likelihood of success are available.

For patients with a rising PSA after radiation therapy, salvage local therapy can be considered if the disease was "curable" at the outset, if persistent disease has been documented by a biopsy of the prostate or by PET or other imaging, and if no disease is detectable outside of the prostate bed or regional lymph nodes. Unfortunately, case selection

is poorly defined in most series, and morbidities are significant. Options include salvage radical prostatectomy, salvage cryotherapy, salvage radiation therapy and salvage irreversible electroporation.

The rise in PSA after surgery or radiation therapy may indicate subclinical or micrometastatic disease with or without local recurrence. In these cases, the need for treatment depends, in part, on the estimated probability that the patient will show evidence of metastatic disease on a scan and in what time frame. That immediate therapy is not always required was shown in a series where patients received no systemic therapy until metastatic disease was documented. Overall, the median time to metastatic progression was 8 years, and 63% of the patients with rising PSA values remained free of metastases at 5 years. Factors associated with progression included the Gleason score of the radical prostatectomy specimen, time to recurrence, and PSA doubling time. For those with Gleason grade ≥8, the probability of metastatic progression was 37, 51, and 71% at 3, 5, and 7 years, respectively. If the time to recurrence was <2 years and PSA doubling time was long (>10 months), the proportion with metastatic disease at the same time intervals was 23, 32, and 53%, vs 47, 69, and 79% if the doubling time was short (<10 months). PSA doubling times are also prognostic for survival. In one series, all patients who succumbed to disease had PSA doubling times of ≤3 months. Most physicians advise treatment when PSA doubling times are ≤12 months. A difficulty with predicting the risk of metastatic spread, symptoms, or death from disease in the rising PSA state is that most patients receive some form of therapy before the development of metastases. Nevertheless, predictive models continue to be refined.

METASTATIC DISEASE: NONCASTRATE

The state of *noncastrate metastatic disease* includes men with metastases visible on an imaging study at the time of diagnosis or after local therapy(ies), and noncastrate levels of testosterone (>150 ng/dL). Symptoms of metastatic disease include pain from osseous spread, although many patients are asymptomatic despite extensive spread. Less common are symptoms related to marrow infiltration by tumor (myelophthisis), coagulopathy, or spinal cord compression.

Standard treatment is to deplete/lower androgens by medical or surgical means, the latter being the least acceptable to patients. A less frequently used treatment is to block androgen binding to the AR with antiandrogens. More than 90% of male hormones originate in the testes; <10% are synthesized in the adrenal gland **(Fig. 83-3)**. Survival benefits were shown for the combination of ADT plus docetaxel, and separately for ADT plus abiraterone plus prednisone in large scale randomized phase 3 trials.

Testosterone-Lowering Agents Medical therapies that lower testosterone levels include the GnRH agonists/antagonists, 17,20-lyase inhibitors, CYP-17 inhibitors, and estrogens such as diethylstilbestrol (DES). The last have fallen out of favor due to the risk of vascular complications such as fluid retention, phlebitis, emboli, and stroke. GnRH agonists/antagonists (leuprolide acetate and goserelin acetate) initially produce a rise in luteinizing hormone and follicle-stimulating hormone followed by a downregulation of receptors in the pituitary gland, which effects a chemical castration. They were approved on the basis of randomized comparisons showing an improved safety profile (specifically, reduced cardiovascular toxicities) relative to DES, with equivalent potency. The initial rise in testosterone may result in a clinical flare of the disease and as such are relatively contraindicated in men with significant obstructive symptoms, cancer-related pain, or spinal cord compromise. Pure androgen antagonists such as bicalutamide can be used to prevent flare. GnRH antagonists such as degarelix achieve castrate levels of testosterone within 48 h without the initial rise in serum testosterone and may be associated with a lower risk of cardiovascular complications.

Agents that lower testosterone are associated with an androgen-deprivation syndrome that includes hot flushes, weakness, fatigue, loss of muscle mass, anemia, change in personality, and depression. Changes in lipids, obesity, and insulin resistance, along with an increased risk of diabetes and cardiovascular disease are also seen, along with a decrease in bone density that worsens over time and results in an increased risk of clinical fractures. This is a particular concern in men with preexisting osteopenia that results from hypogonadism or steroid or alcohol use, and which is significantly underappreciated. Baseline fracture risk can be assessed using the FRAX scale, and to minimize fracture risk patients are advised calcium and vitamin D supplementation, along with a bisphosphonate, RANK-ligand inhibitor (denosumab), or torimefene.

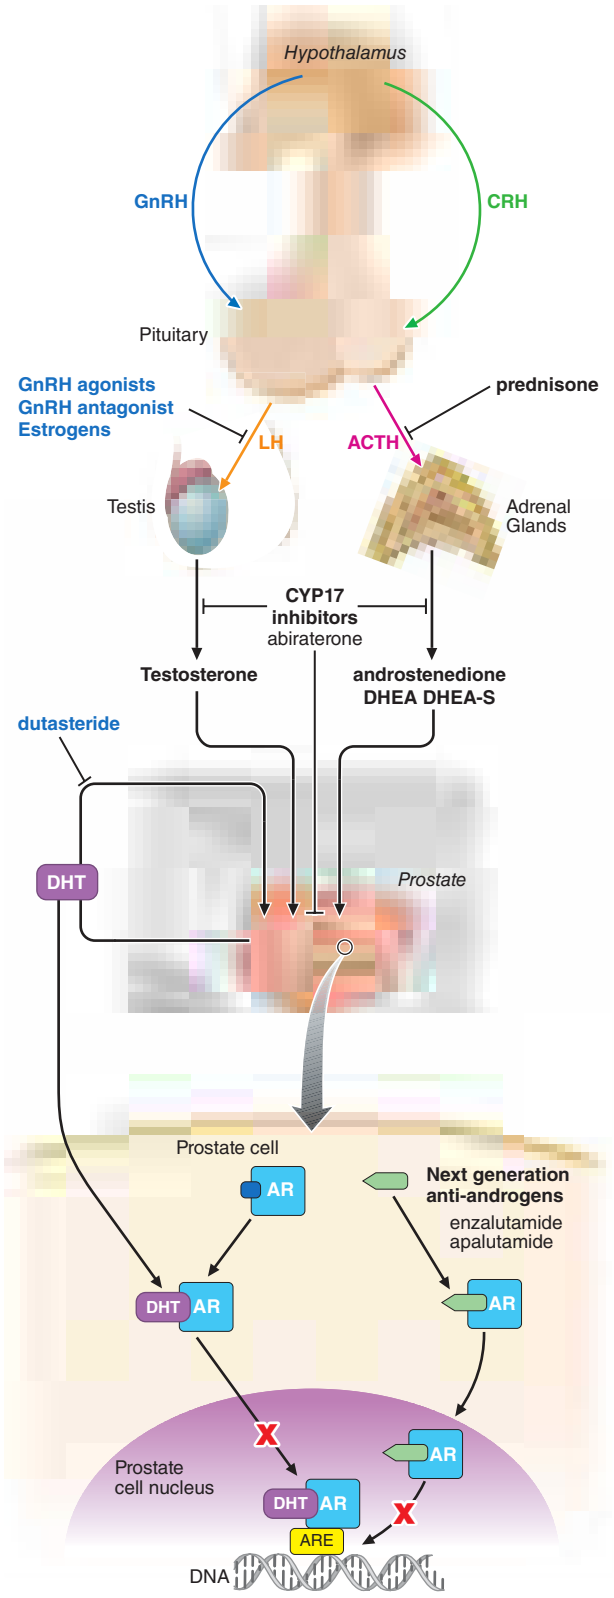

FIGURE 83-3 Sites of action of different hormone therapies.

Antiandrogens Nonsteroidal first-generation antiandrogens such bicalutamide and nilutamide block the ligand binding to the AR and were initially approved to block the flare associated with the rise in serum testosterone associated with GnRH agonist/antagonist therapy. When antiandrogens are given alone, testosterone levels increase, but relative to testosterone-lowering therapies, they cause fewer hot flushes, less of an effect on libido, less muscle wasting, fewer personality changes, and less bone loss. Gynecomastia remains a significant problem but can be prevented in part by tamoxifen or prophylactic breast irradiation.

Most reported randomized trials suggest that the cancer-specific outcomes are inferior when antiandrogens are used alone. Bicalutamide, even at a dose of 150 mg (three times the approved dose for use in combination in GnRH agonists), was associated with a shorter time to progression and inferior survival compared to surgical castration for patients with established metastatic disease.

Improving on the outcomes with ADT alone has been a focus of the field for decades. One approach was to combine a first-generation antiandrogen (flutamide, bicalutamide, or nilutamide) with a GnRH analogue or surgical orchiectomy, which has not been shown to be superior to ADT alone. As a result, use of these first-generation compounds is largely limited to the first 2–4 weeks of treatment, to protect against the flare.

More recently, significant improvements in time to progression and overall survival were reported in large-scale trials for the combination of ADT with docetaxel or with abiraterone acetate plus prednisone, relative to ADT alone. Docetaxel was the first systemic therapy shown to prolong life in metastatic castration-resistant prostate cancer (mCRPC) and was approved in 2004. Abiraterone acetate (a CYP-17 inhibitor shown to reduce androgen levels to the 1–2 ng/dl range) plus prednisone was approved for mCRPC in 2011. With docetaxel, the greatest benefit was seen for patients with "high-volume" disease defined as the presence of ≥4 lesions on radionuclide bone scan or visceral disease. For abiraterone acetate and prednisone, benefit was seen across disease states ranging from high-risk localized to metastatic disease.

Intermittent Androgen Deprivation Therapy (IADT) One way to reduce the side effects of androgen depletion is to administer antiandrogens on an intermittent basis. This was proposed as a way to prevent the selection of cells that are resistant to androgen depletion. The hypothesis is that by allowing endogenous testosterone levels to rise, the cells that survive androgen depletion will induce a normal differentiation pathway. In this way, the surviving cells that are allowed to proliferate in the presence of androgen will retain sensitivity to subsequent androgen depletion. Applied in the clinic, androgen depletion is continued for 2–6 months beyond the point of maximal response. Once treatment is stopped, endogenous testosterone levels increase, and the symptoms associated with hormone treatment abate. PSA levels also begin to rise, and at some level treatment is restarted. With this approach, multiple cycles of regression and proliferation have been documented in individual patients. Unknown is whether the intermittent approach increases, decreases, or does not change the overall duration of sensitivity to androgen depletion. The approach is safe, but long-term data are needed to assess the course in men with low PSA levels. A trial to address this question is ongoing.

Outcomes of Androgen Deprivation The anti–prostate cancer effects of the various androgen depletion strategies are similar, and the clinical course is predictable: an initial response, then a period of stability in which tumor cells are dormant and nonproliferative, followed after a variable period of time by a rise in PSA and regrowth that is visible on a scan as a castration-resistant lesion. Androgen depletion is not curative because cells that survive castration are present when the disease is first diagnosed. Considered by disease manifestation, PSA levels return to normal in 60–70% of patients, and measurable disease regression occurs in 50%; improvements in bone scan occur in 25% of cases, but the majority remain stable. Duration of survival is inversely proportional to disease extent at the time androgen depletion is first started and the nadir level of PSA at 6 months. Patients with nadir values above a certain threshold have markedly inferior survival times and should be considered for alternative approaches.

An unresolved question remains on how early systemic therapies should be offered to patients: in the adjuvant setting after surgery or radiation treatment of the primary tumor; at the time that a PSA recurrence is documented; or wait until metastatic disease or symptoms of disease are manifest? Trials in support of early therapy have been largely underpowered relative to the reported benefit or have been criticized on methodologic grounds. One trial which showed a survival benefit for patients treated with radiation therapy and 3 years of ADT, relative to radiation alone, was criticized for the poor outcomes of the control group. Another trial showing a survival benefit for patients with positive lymph nodes who were randomized to immediate medical or surgical castration compared to observation (p = .02) was criticized because the confidence intervals around the 5- and 8-year survival distributions for the two groups overlapped.

METASTATIC DISEASE: CASTRATE

Castration-resistant prostate cancer (CRPC), disease that progresses while the measured levels of testosterone in the blood are 50 ng/mL or lower, can produce some of the most feared complications of the disease and is lethal for most men. The most common manifestation is a rising PSA, frequently co-occurring with progression in bone. Nodal and/or visceral spread is less frequent and symptoms may or may not be present. The bone- and PSA-dominant pattern limits the ability to assess treatment effects reliably because traditional bone imaging is inaccurate and no PSA-based outcome has been shown to be a true surrogate for survival. It is essential to define therapeutic objectives based on the manifestations of the disease in the individual. As such, for the patient with symptomatic bone disease, relief of pain can be more clinically relevant than lowering the PSA. Naturally, for all patients the central focus is delaying or preventing disease progression, symptom development, and death from cancer.

Through 2010, docetaxel was the only FDA-approved life-prolonging therapy for CRPC. Since then, our understanding of the biology of the disease has increased significantly, which in turn has led to improved therapies. In particular, it is now recognized that the majority of mCRPCs continue to express the AR, which in upwards of 50% of cases harbors a series of oncogenic changes including overexpression of the receptor itself and the enzymes in the androgen biosynthesis pathways. These oncogenic changes have been successfully targeted with the next-generation antiandrogen enzalutamide and the CYP-17 inhibitor abiraterone acetate (given in combination with prednisone), both of which have been proven to prolong life and are FDA-approved for use in CRPC in both the pre- and post-chemotherapy setting. More recently, the results of large-scale molecular profiling efforts have led to biologically based pathway-focused classification that showed a markedly higher than expected frequency of germline and somatic BRCA2 alterations, along with other genes in the DNA damage repair pathway, that has been successfully treated with poly ADP ribose polymerase (PARP) inhibitors. Other classes of therapy that have been approved based on a demonstrated survival benefit include the biologic agent sipuleucel-T, the second-generation taxane cabazitaxel, and the alpha-emitting bone targeting radiopharmaceutical radium-223. An intense of focus of current CRPC research is to understand the optimal sequence in which to utilize these agents to maximize benefit for the individual patient.

Pain Management Pain secondary to osseous metastases is one of the most feared complications of the disease and a major cause of morbidity, worsened by the narcotics needed to control symptoms. Management requires accurate diagnoses because non-cancer etiologies including degenerative disease, spinal stenosis, and vertebral collapse secondary to bone loss are common. Neurologic symptoms, including those suggestive of base of skull disease or spinal cord compromise, require emergency evaluation because loss of function may be permanent if not addressed quickly. Neurologic symptoms

or loss of function are best treated with external beam radiation, as are single sites of pain. Diffuse symptoms in the absence of neurologic deficits can be treated with bone-seeking radioisotopes such as radium-223 or the beta emitter ^{153}Sm-EDTMP, or mitoxantrone, or other systemic therapies such as abiraterone acetate, enzalutamide, and docetaxel. Radium-223 is indicated for patients with symptoms while ^{153}Sm-EDTMP and mitoxantrone are approved for the palliation of pain but not shown to prolong life. Abiraterone, enzalutamide, and docetaxel do not have a formal indication for pain, but were shown to palliate pain in the registration trials that led to their approval by showing a survival benefit.

Other bone-targeting agents, including bisphosphonates such as zoledronic acid and the RANK-ligand inhibitor denosumab, have been shown to reduce the frequency and development of skeletal complications including pain requiring analgesia, neurologic compromise from epidural extension of tumor, and/or the need for surgery or radiation therapy to treat symptomatic osseous disease. It is important to note that for all of these agents, the direct effect on the tumor is modest and benefits are seen without declines in PSA or improvements on imaging.

BENIGN DISEASE

BENIGN PROSTATIC HYPERPLASIA

BPH is a pathologic process that contributes to the development of lower urinary tract symptoms (LUTS) in men. LUTS, arising from lower urinary tract dysfunction, are further subdivided into obstructive symptoms (urinary hesitancy, straining, weak stream, terminal dribbling, prolonged voiding, incomplete emptying) and irritative symptoms (urinary frequency, urgency, nocturia, urge incontinence, small voided volumes). LUTS and other sequelae of BPH are not just due to a mass effect, but also likely due to a combination of the prostatic enlargement and age-related detrusor dysfunction.

Diagnostic Procedures and Treatment LUTS symptoms are generally measured using a validated, reproducible index that is designed to determine disease severity and response to therapy—the American Urological Association's Symptom Index (AUASI), also adopted as the International Prostate Symptom Score (IPSS) (Table 83-2). Serial AUASI is particularly useful in following patients as they are treated with various forms of therapy. Asymptomatic patients do not require treatment regardless of the size of the gland, while those with an inability to urinate, gross hematuria, recurrent infection, or bladder stones may require surgery. In patients with symptoms, uroflowmetry can identify those with normal flow rates who are unlikely to benefit from treatment, and bladder ultrasound can identify those with high postvoid residuals who may need intervention. Pressure-flow (urodynamic) studies detect primary bladder dysfunction. Cystoscopy is recommended if hematuria is documented and to assess the urinary outflow tract before surgery. Imaging of the upper tracts is advised for patients with hematuria, a history of calculi, or prior urinary tract problems.

Symptomatic relief is the most common reason men seek treatment for BPH, and therefore symptomatic relief is usually the goal of therapy for BPH. Alpha-adrenergic receptor antagonists are thought to treat the dynamic aspect of BPH by reducing sympathetic tone of the bladder outlet, thereby decreasing resistance and improving urinary flow. 5ARIs are thought to treat the static aspect of BPH by reducing prostate volume and having a similar, albeit delayed effect. They have also proven to be beneficial in the prevention of BPH progression, as measured by prostate volume, the risk of developing acute urinary retention, and the risk of having BPH-related surgery. The use of an alpha-adrenergic receptor antagonist and a 5ARI as combination therapy seeks to provide symptomatic relief while preventing progression of BPH.

Another class of medications that has shown improvement in LUTS secondary to BPH is phosphodiesterase-5 (PDE5) inhibitors, used currently in the treatment of erectile dysfunction. All four of the PDE5 inhibitors available in the United States, sildenafil, vardenafil, tadalafil, and avanafil, appear to be effective in the treatment of LUTS secondary to BPH. The use of PDE5 inhibitors is not without controversy, however, given the fact that short-active phosphodiesterase inhibitors such as sildenafil need to be dosed separately from alpha blockers such as tamsulosin because of potential hypotensive effects.

Symptoms due to BPH often coexist with symptoms due to overactive bladder, and the most common pharmacologic agents for the treatment of overactive bladder symptoms are anticholinergics. This has led to multiple studies evaluating the efficacy of anticholinergics for the treatment of LUTS secondary to BPH.

Surgical therapy is now considered second-line therapy and is usually reserved for patients after a trial of medical therapy. The goal of surgical therapy is to reduce the size of the prostate, effectively reducing resistance to urine flow. Surgical approaches include TURP, transurethral incision, or removal of the gland via a retropubic, suprapubic, or

TABLE 83-2 AUA Symptom Index

QUESTIONS TO BE ANSWERED	AUA SYMPTOM SCORE (CIRCLE 1 NUMBER ON EACH LINE)					
	NOT AT ALL	LESS THAN 1 TIME IN 5	LESS THAN HALF THE TIME	ABOUT HALF THE TIME	MORE THAN HALF THE TIME	ALMOST ALWAYS
Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0+	1	2	3	4	5
Over the past month, how often have you had to urinate again less than 2 h after you finished urinating?	0	1	2	3	4	5
Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	(None)	(1 time)	(2 times)	(3 times)	(4 times)	(5 times)

84 Testicular Cancer

David J. Vaughn

Testicular germ cell tumors (GCTs) represent 95% of all testicular neoplasms. Non-germ cell tumors of the testis are much less common. Approximately 5% of GCTs arise in extragonadal locations including the mediastinum, retroperitoneum, and pineal gland. Treatment for testicular GCTs is determined by pathology and stage. The development of effective chemotherapy for this disease represents a landmark achievement in oncology. About 95% of newly diagnosed patients with testicular GCTs will be cured. For this reason, testicular cancer has been called "a model for a curable neoplasm."

INCIDENCE

In 2016, ~8700 cases of testicular GCTs will be diagnosed in the United States, with <400 deaths. These tumors are diagnosed most commonly in men between 20 and 40 years. It has recently been reported that the incidence of GCTs is increasing in men 50 years and older.

GLOBAL CONSIDERATIONS

The incidence of testicular GCTs appears to be increasing worldwide. The disease has the highest incidence in Scandinavia, Western Europe, and Australia/New Zealand. Africa and Asia have the lowest incidence. The incidence in the United States and the United Kingdom is intermediate. While there does not appear to be a distinct biology related to geography, several countries have reported a migration to earlier stage disease in part related to public awareness and earlier diagnosis.

EPIDEMIOLOGY

GCTs are predominantly seen in young Caucasian men. The disease is much less commonly seen in African Americans. Although most patients with GCTs do not have a family history of this disease, there are rare familial cases. Interestingly, the risk of GCT is higher in male siblings and cousins than in offspring of the patient. Although epidemiological studies have been performed attempting to identify a relationship with environmental exposures, no conclusive causal links have been established.

Risk Factors The strongest risk factors for testicular GCT include a prior history of the disease, cryptorchidism, and a history of testicular intratubular germ cell neoplasia (ITGCN). Patients with a prior history of testicular GCT have a 2% risk of developing a contralateral GCT. These are more commonly metachronous than synchronous. Men with cryptorchidism have approximately a four- to sixfold increased risk of developing testicular GCT. Orchidopexy before puberty decreases but does not eliminate this risk. Interestingly, the contralateral descended testis is also at risk for this disease. Men undergoing infertility evaluation in which a testicular biopsy demonstrates ITGCN have a 50% risk of developing GCT. Although scrotal ultrasound of patients with testicular GCT may demonstrate testicular microcalcifications that may be related to ITGCN, the significance of testicular microcalcifications in the general population is unclear.

BIOLOGY

The primordial germ cell is the cell of origin for GCTs. All malignant GCTs arise from ITGCN. The molecular events that result in the development of ITGCN and subsequent malignant GCT have not been fully determined. However, genetic analysis of GCTs have demonstrated an excess copy number of isochromosome 12p (i[12p]) in most cases. Several genome-wide association studies have identified independent loci associated with testicular GCT risk. The strongest of these is the *KITLG* (KIT ligand) locus on chromosome 12.

PATHOLOGY

GCTs are either seminomas or nonseminomas. For a tumor to be considered a seminoma, it must be 100% seminoma. Any mixed GCT is best approached as a nonseminomatous GCT (NSGCT). Seminomas represent ~50% of cases. Seminomas arise most commonly in patients in the fourth decade of life. Seminomas may contain syncytiotrophoblastic cells which may secrete β human chorionic gonadotropin (HCG). Seminomas do not secrete α fetoprotein (AFP). Seminomas are exquisitely sensitive to both chemotherapy and radiation therapy. Seminomas are believed to be a common precursor that subsequently differentiates into the NSGCT subtypes. NSGCTs are most commonly diagnosed in the third decade of life. The histologic subtypes include embryonal carcinoma, yolk sac tumor, choriocarcinoma, and teratoma. Embryonal carcinoma is the most undifferentiated NSGCT subtype with the potential to differentiate into the other subtypes. Embryonal carcinoma may secrete AFP, HCG, both, or neither. Yolk sac tumor (also referred to as endodermal sinus tumor) often secretes AFP. Choriocarcinoma is an aggressive subtype, often secreting HCG at very high levels. These NSGCT subtypes are all considered chemotherapy sensitive. Teratoma is composed of somatic cell types that are derived from two or more germinal layers (endoderm, mesoderm, and ectoderm). Teratomas are classified as mature, in which cell types resemble normal adult somatic tissue; immature, in which cell types resemble fetal somatic tissue; and malignant, in which the cell types have undergone malignant transformation into the malignant counterpart of the somatic tissue. Teratomas are chemotherapy resistant and must be approached surgically.

INITIAL PRESENTATION

Signs and Symptoms Although a painless testicular mass is pathognomonic of a GCT, most patients present with testicular swelling, firmness, discomfort, or a combination of these. The differential diagnosis may include epididymitis or orchitis and a trial of antibacterials may be considered. Patients with retroperitoneal metastases may complain of back or flank pain. Patients may have cough, shortness of breath, or hemoptysis as a result of lung metastases. In patients with elevation of serum HCG, gynecomastia may be present. Diagnostic delay is not uncommon, and may be associated with a more advanced stage at diagnosis.

Physical Examination Careful examination of the affected testis and the contralateral normal testis should be performed. Many tumors

will have a hard consistency to palpation. Some patients may show testicular atrophy. Evaluation for supraclavicular lymphadenopathy, gynecomastia, and abdominal mass should be performed. Inguinal lymphadenopathy is rare. Most patients with lung metastases will have normal auscultation of the lungs.

Diagnostic Testing If a firm testicular mass is identified, a scrotal ultrasound should be performed. Patients with suspected epididymitis or orchitis who do not respond to antibiotics should also undergo scrotal ultrasound. Scrotal ultrasound should include both testicles. On ultrasound, a testicular GCT is hypoechoic and may be multifocal. A solid mass identified on ultrasound should be considered malignant until otherwise proven. Transscrotal aspiration or biopsy of a testicular mass should never be performed. Such scrotal violation may result in tumor seeding of the scrotum or inguinal lymph nodes.

Serum Tumor Markers Serum AFP, HCG, and lactate dehydrogenase (LDH) should be measured in patients suspected of testicular GCT. AFP is elevated in ~60–70% of patients who present with NSGCTs. Seminomas never secrete AFP. A patient with a seminoma with elevation of AFP should be approached as having a NSGCT. The half-life of AFP is 5–7 days. A falsely elevated AFP may be seen in patients with hepatic disease or a condition called hereditary persistence of AFP in which patients may have baseline AFP levels that are mildly elevated. HCG may be elevated in both NSGCTs as well as seminomas. Patients with choriocarcinoma may have markedly elevated levels of HCG. The half-life for HCG is 24–36 h. False-positive elevation of HCG may be seen secondary to hypogonadism, marijuana use, or as a result of interfering substances measured by the assay. LDH is a nonspecific marker for GCT. Its principal use is to help in the assessment of the risk classification of a patient with metastatic disease. Although elevation of serum tumor markers support the diagnosis of a testicular GCT, it should be remembered that most patients with a seminoma and up to a third of patients with NSGCTs do not have elevated levels.

INITIAL MANAGEMENT

Inguinal Orchiectomy Prompt referral to urology should be performed if a testicular GCT is suspected. The initial treatment for most patients suspected of having a testicular GCT is radical inguinal orchiectomy with removal of the testicle and spermatic cord to the level of the internal inguinal ring. In patients who present with metastatic disease and the diagnosis of GCT is certain, orchiectomy may be deferred until completion of chemotherapy. Pathologic examination of the entire testicle is important, since testicular GCTs may be multifocal. Given the rarity of this cancer, review by an experienced pathologist is essential for accurate tumor classification. Serum tumor markers should be obtained before and after orchiectomy.

Staging The staging of testicular GCT is based upon an understanding of the pattern of spread. The initial spread is by the lymphatic route to the retroperitoneal lymph nodes. A left-sided testicular GCT spreads first to the primary landing zone of left paraaortic lymph nodes inferior to the left renal vessels. A right-sided testicular GCT spreads first to the primary landing zone of the aortocaval nodes inferior to the right renal vessels. Nodal metastases may extend into the iliac regions. If scrotal violation occurred, inguinal lymph node metastases may be seen. Subsequent lymphatic spread is to the retrocrural, mediastinal, and supraclavicular lymph nodes. Hematogenous spread to the lung is the next most common site of metastasis. Metastases to the liver, bone, and brain are less commonly seen. Patients with newly diagnosed testicular GCTs should undergo computed tomography (CT) scan of the abdomen and pelvis. Chest x-ray should be performed. CT scan of the chest is performed if retroperitoneal metastases are present or if lung nodules are identified on chest x-ray. Bone scan and magnetic resonance imaging (MRI) of the brain are not routinely performed unless clinically indicated. Positron emission tomography (PET) has little role in the initial staging of testicular GCTs.

The American Joint Committee on Cancer tumor/node/metastasis (TNM) staging classification is used. There are three main stages of testicular GCT. Stage I is limited to the testis; stage II involves the retroperitoneal lymph nodes; stage III includes lymph node involvement beyond the retroperitoneum and/or distant metastatic disease.

STAGE-BASED MANAGEMENT

Treatment of testicular GCT is based upon two factors: (1) whether the tumor is seminoma or NSGCT, and (2) the stage of the patient. This is summarized in Fig. 84-1.

Stage I • **SEMINOMA** About 70% of newly diagnosed patients with seminoma present with stage I disease. This is defined as no evidence of metastatic disease on imaging of the chest, abdomen, and pelvis. If pre-orchiectomy serum HCG is elevated, this must normalize post-orchiectomy to be considered stage I. Approximately 15% of patients with stage I seminoma have metastatic disease at the microscopic level, usually in the retroperitoneum. Historically, patients with stage I seminoma were treated with a course of adjuvant radiation therapy to the paraaortic lymph nodes. While still an option, this is not usually performed because of concerns for late radiation-induced secondary malignancies. Active surveillance is the most common approach elected by these patients following orchiectomy. With active surveillance, interval physical examination and CT scan of the abdomen are performed. For the 15% of patients that develop metastatic disease during active surveillance, treatment with definitive radiation therapy or chemotherapy is curative in nearly all. A third option for clinical stage I seminoma is adjuvant chemotherapy with carboplatin monotherapy for one cycle. While effective in decreasing the risk of recurrence, it should be remembered that most patients are cured by orchiectomy alone, and therefore the additional treatment is unnecessary. In addition, long-term data on toxicity and efficacy are not available.

NSGCTs About 40% of newly diagnosed patients with NSGCTs present with stage I disease. Because NSGCTs have an increased potential for invasion and metastasis, spread to the retroperitoneum and beyond is more common than with seminoma. If pre-orchiectomy serum tumor markers are elevated, these must normalize post-orchiectomy to be considered stage I. Patients with persistently elevated or rising serum tumor markers after orchiectomy have stage IS disease and should be treated with cisplatin-based chemotherapy. If the tumor is pT1, defined as limited to testis and epididymis with no vascular or lymphatic invasion and no invasion into tunica vaginalis, the risk of recurrence is approximately 20%. However, if the tumor is pT2, defined as limited to testis and epididymis with vascular or lymphatic invasion, or tumor extension into tunica vaginalis, the risk of recurrence is ~50%. Historically, a prophylactic retroperitoneal lymph node dissection (RPLND) was performed. This surgery is not only diagnostic, but also therapeutic. In fact, most patients who undergo prophylactic RPLND will never require chemotherapy. While still an option, this approach subjects many patients to unnecessary major abdominal surgery. RPLND is also associated with a small risk of retrograde ejaculation due to nerve injury, and nerve sparing techniques have been developed. Active surveillance is frequently performed especially for patients with pT1 disease. Most patients who relapse will be treated with cisplatin-based chemotherapy and achieve cure rates approaching 100%. Active surveillance can also be employed for patients with pT2 disease, although the risk of progression is significantly higher. For this reason, some advocate adjuvant cisplatin-based chemotherapy such as BEP for one cycle for patients with pT2 disease. Other centers favor a prophylactic RPLND. Almost all patients who present with stage I NSGCTs will achieve cure.

Stage II • **SEMINOMA** Approximately 15–20% of newly diagnosed patients with seminoma present with stage II disease. Patients are subgrouped into IIA, IIB, or IIC based upon the size of the retroperitoneal nodes (2 cm or less, more than 2 to 5 cm, or >5 cm, respectively). Patients with stage IIA disease are usually treated with "dogleg" radiation therapy which includes the paraaortic and ipsilateral iliac nodes. Cisplatin-based chemotherapy may also be considered. Stage IIB disease is treated with cisplatin-based chemotherapy or, in select patients, radiation therapy. Most patients treated with radiation therapy that relapse will subsequently be cured with cisplatin-based chemotherapy.

	Seminoma	NSGCT
Stage IA pT1: Testis only, no vascular/lymphatic invasion	Active surveillance; or, Adjuvant carboplatin x 1 cycle; or, Adjuvant para-aortic RT	Active surveillance; or, Nerve sparing RPLND
Stage IB pT2: Testis only, with vascular/lymphatic invasion or extension through tunica albuginea into tunica vaginalis	Active surveillance; or, Adjuvant carboplatin x 1 cycle; or, Adjuvant para-aortic RT	Adjuvant BEP x 1 cycle; or, Active surveillance; or, Nerve sparing RPLND
Stage IS Elevated serum tumor markers post-orchiectomy	BEP x 3 cycles; or, EP x 4 cycles	BEP x 3 cycles; or, EP x 4 cycles

A

	Seminoma	NSGCT
Stage IIA N1: nodes ≤ 2 cm	Para-aortic and ipsilateral iliac RT; or, BEP x 3 cycles or EP x 4 cycles	Nerve-sparing RPLND; or, BEP x 3 cycles or EP x 4 cycles
Stage IIB N2: nodes > 2 to 5 cm	BEP x 3 cycles or EP x 4 cycles; or, Para-aortic and ipsilateral iliac RT	BEP x 3 cycles or EP x 4 cycles +/– post-chemotherapy RPLND
Stage IIC N3: nodes > 5 cm	BEP x 3 cycles or EP x 4 cycles	BEP x 3 cycles or EP x 4 cycles +/– post-chemotherapy RPLND

FIGURE 84-1 Stage-based management of testicular GCT.

	Seminoma	NSGCT
Stage IIIA (good-risk)	BEP x 3 cycles; or, EP x 4 cycles	BEP x 3 cycles; or, EP x 4 cycles; +/– Post-chemotherapy surgery
Stage IIIB (intermediate-risk)	BEP x 4 cycles; or, VIP x 4 cycles	BEP x 4 cycles; or, VIP x 4 cycles +/– Post-chemotherapy surgery
Stage IIIC (poor-risk)	N/A	BEP x 4 cycles; or, VIP x 4 cycles +/– Post-chemotherapy surgery

Abbreviations: BEP, bleomycin, etoposide, cisplatin; EP, etoposide, cisplatin; NSGCT, non-seminomatous germ cell tumor; RPLND, retroperitoneal lymph node dissection; RT, radiation therapy; VIP, etoposide, ifosfamide, cisplatin.

C

FIGURE 84-1 (Continued)

For patients with stage IIC disease, cisplatin-based chemotherapy should be used.

NSGCTs Approximately 15% of newly diagnosed patients with NSGCTs present with clinical stage II disease. Patients with stage IIA disease may be treated with primary RPLND. Alternatively, these patients may be treated with cisplatin-based chemotherapy. Patients with stage IIB and IIC disease are best initially managed with cisplatin-based chemotherapy.

Stage III Patients who present with stage III GCT (seminoma or NSGCT) are treated with cisplatin-based chemotherapy. These patients are classified into good-, intermediate-, or poor-risk categories using the International Germ Cell Consensus Classification system, which is based upon clinical factors including histology, site of primary, the presence of non-pulmonary visceral metastatic disease, and the level of post-orchiectomy serum tumor markers **(Table 84-1)**. Most patients with stage III GCT present with good-risk disease; >90% will be cured. The remainder present with intermediate-risk or poor-risk disease, associated with 5-year survival rates of ~80% and 50%, respectively. Select patients with rapidly progressive metastatic disease and life-threatening symptoms such as hemoptysis in whom there is a high clinical suspicion of GCT should emergently initiate cisplatin-based chemotherapy, even without a tissue diagnosis.

Chemotherapy The development of cisplatin-based chemotherapy represents an important advance in cancer medicine. Through a series of carefully performed clinical trials with the aim of maximizing cure while minimizing the extent of treatment, the chemotherapy approach to the treatment of these patients has been standardized.

TABLE 84-1 International Germ Cell Consensus Classification System

RISK GROUP	SEMINOMA	NSGCT
Good	Any primary site; and normal AFP, any HCG, any LDH; and nonpulmonary visceral metastases absent	Gonadal or retroperitoneal primary; and nonpulmonary visceral metastases absent; and AFP <1000 ng/mL; and HCG <5000 mIU/mL; and LDH <1.5 × ULN
Intermediate	Any primary site; and normal AFP, any HCG, any LDH; and nonpulmonary visceral metastases present	Gonadal or retroperitoneal primary; and nonpulmonary visceral metastases absent; and one of the following: AFP 1000–10,000 ng/mL HCG 5000–50,000 mIU/mL LDH 1.5–10 × ULN
Poor	N/A	Mediastinal primary; or nonpulmonary visceral metastases present; or one of the following: AFP >10,000 ng/mL HCG >50,000 mIU/mL LDH >10 × ULN

Abbreviations: AFP, α fetoprotein; HCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; N/A, not applicable; NSGCT, nonseminomatous germ cell tumor; ULN, upper limit normal. Nonpulmonary visceral metastases include liver, bone, and brain.

Source: International Germ Cell Cancer Collaborative Group: International Germ-Cell Consensus Classification: A prognostic factor based staging system for metastatic germ cell tumors. J Clin Oncol 15:594, 1997.

Patients with good-risk metastatic GCT are treated with either three cycles of bleomycin, etoposide, cisplatin (BEP) or four cycles of etoposide, cisplatin (EP). Patients with intermediate- and poor-risk metastatic disease are treated with either four cycles of BEP or four cycles of etoposide, ifosfamide, cisplatin (VIP). Maintaining dose and schedule is important, as dose modifications and delays have been associated with inferior outcomes. Serum tumor markers should be monitored throughout treatment and should normalize during or after treatment. Cisplatin-based chemotherapy is associated with myelosuppression, nausea and vomiting, and alopecia. Cisplatin may result in nephrotoxicity, ototoxicity, and peripheral neuropathy. Bleomycin may result in pulmonary toxicity and risk factors for this include age greater than 40, renal failure, tobacco use, and the cumulative dose of bleomycin received. For patients at increased risk of bleomycin-induced pneumonitis, non-bleomycin-containing regimens as noted above may be given. Cisplatin-based chemotherapy is also associated with sterility. Approximately 30% of newly diagnosed testicular GCT patients have severe oligospermia or azospermia. For the remainder with normal baseline spermatogenesis who receive cisplatin-based chemotherapy, all will be azospermic at the completion of therapy. Approximately 80% of these patients will recover spermatogenesis over a period of several years. For this reason, pre-chemotherapy sperm banking should be offered to all patients treated with chemotherapy.

Post-Chemotherapy Surgery Upon completion of cisplatin-based chemotherapy, many patients with normalized serum tumor markers will have radiographic evidence of residual masses. In approximately half of patients with NSGCT, the residual mass is composed of necrosis and/or fibrosis. About 40% will have residual teratoma and only 10% will have residual viable non-teratomatous GCT. Unfortunately, radiographic imaging cannot accurately differentiate between these entities. For this reason NSGCT patients with residual masses after chemotherapy undergo resection of all sites of disease. This most commonly includes a post-chemotherapy RPLND. However, thoracotomy and neck dissection are required in some patients. If the patients are found to have residual necrosis or teratoma, no additional therapy is required. However, for patients with residual viable non-teratomatous GCT, two additional cycles of chemotherapy are frequently administered. It should be noted that in most centers patients with minimal residual tumors defined as retroperitoneal lymph nodes of <10 mm in short axis will forego post-chemotherapy RPLND. Patients who experience normalization of serum tumor markers with first-line chemotherapy but have enlarging tumors, most often cystic masses in the retroperitoneum, may have "growing teratoma syndrome." These patients are best approached with surgery.

For patients with metastatic seminoma, ~20% of residual masses harbor viable tumor; the remainder have only necrosis. Patients with residual masses 3 cm or less may be observed without surgery. For patients with residual masses >3 cm, FDG-PET may be used to distinguish necrosis from viable seminoma and identify patients who should be considered for post-chemotherapy surgery.

RELAPSED DISEASE

Approximately 20–30% of patients with metastatic GCTs treated with cisplatin-based chemotherapy will not achieve durable disease control. Most of these patients will experience disease progression within 2 years following completion of chemotherapy. The International Prognostic Factors Study Group developed a risk stratification classification system for patients in first relapse. Contributors to a worsened prognosis include NSGCT histology, extragonadal primary, incomplete response to first-line chemotherapy, time to relapse of 3 months or less, level of serum tumor markers at relapse, and the presence of non-pulmonary visceral metastatic disease.

Patients in first relapse may be treated with either conventional-dose salvage chemotherapy or high-dose salvage chemotherapy with autologous stem cell rescue. There is controversy concerning which approach is optimal. Some institutions advocate for risk stratification, with more favorable prognosis patients receiving conventional-dose chemotherapy and worse prognosis patients receiving high-dose chemotherapy. The most commonly utilized conventional-dose regimen includes paclitaxel, ifosfamide, and cisplatin (TIP). In one study of TIP in patients with more favorable risk disease, approximately two-thirds experienced 2-year progression-free survival. High-dose chemotherapy consists of initial salvage therapy followed by stem cell harvest and then two or three cycles of high-dose carboplatin and etoposide (CE) with stem cell rescue. The largest series of patients treated with high-dose chemotherapy was reported by researchers at Indiana University where this approach is considered standard for most patients in first relapse regardless of risk classification. In their study, ~70% of patients in first relapse achieved durable progression-free survival. A large retrospective analysis has compared conventional-dose salvage chemotherapy to high-dose salvage chemotherapy in patients in first relapse. This study reports a more favorable outcome with high-dose salvage chemotherapy across nearly all risk groups. However given the retrospective nature of this study and the controversy concerning optimal approaches, an international randomized trial comparing conventional dose chemotherapy (TIP) to high-dose chemotherapy with autologous stem cell rescue (TI-CE) has been initiated.

Some patients who experience disease progression after conventional-dose salvage chemotherapy may successfully be treated with high-dose salvage chemotherapy with autologous stem cell rescue. Patients with disease progression after high-dose salvage chemotherapy may be treated with subsequent chemotherapy regimens that include gemcitabine/oxaliplatin, gemcitabine/paclitaxel, epirubicin/cisplatin, and oral etoposide. While these patients may benefit from third-line chemotherapy, few will achieve durable disease control. Select patients with relapsed but resectable disease may be candidates for salvage or so-called "desperation" surgery.

Patients who experience disease progression >2 years after chemotherapy are considered to have "late relapse." Late relapse appears to have a different biology than early relapse. These patients tend to have more chemotherapy-resistant disease. Patients with late relapse usually have NSGCT with elevation of serum AFP. Many of these patients recur in the retroperitoneum many years after first-line chemotherapy, and this likely represents residual retroperitoneal disease that was not controlled after first-line therapy. These patients are best approached with salvage surgery.

EXTRAGONADAL GCTs

Approximately 5% of patients who present with GCTs have extragonadal primaries. These mainly originate in the mediastinum or retroperitoneum. Patients suspected of extragonadal GCT should undergo scrotal ultrasound to exclude a gonadal primary. Extragonadal seminomas have a similar excellent prognosis as their gonadal counterparts and are approached the same. Mediastinal NSGCTs are classified as poor-risk and are treated with either four cycles of BEP or four cycles of VIP. These patients frequently require post-chemotherapy thoracic surgery for residual disease. For this reason, some advocate avoiding bleomycin in this patient population. Klinefelter's syndrome is associated with an increased risk of mediastinal NSGCTs. Rarely, mediastinal NSGCTs are associated with hematologic disorders including acute myelogenous leukemia. NSGCTs arising in the retroperitoneum do not have a worse prognosis than their gonadal counterparts. Many patients who present with extragonadal GCTs will undergo core needle biopsy for diagnosis. However, select patients with extragonadal tumors and definitive elevation of serum tumor markers may initiate chemotherapy without a tissue diagnosis.

Cancers of unknown primary are defined as histologically proven metastatic malignancy in which the primary site is not obvious. A subgroup of patients with cancer of unknown primary have occult GCTs. Male gender, age <65 years, midline tumors, and nonsmoking status increase the likelihood of this presentation. Pathology may demonstrate a poorly differentiated malignant neoplasm. Immunohistochemical staining is used to exclude lymphoma. Tumor may be analyzed by FISH for i(12p) which confirms the diagnosis. Even if the diagnosis is not certain, patients should be treated with cisplatin-based chemotherapy, which will cure up to 20% of this patient group.

TESTICULAR NON-GERM CELL TUMORS

Rarely, patients may develop testicular non-GCTs. These include lymphoma, most commonly occurring in men over the age of 50; sex cord stromal tumors including Leydig cell tumors and Sertoli cell tumors; mesothelioma of the tunica vaginalis; and, paratesticular sarcoma. Metastasis to the testis is rare, most commonly occurring in patients with advanced prostate cancer and melanoma.

SURVIVORSHIP AND LATE EFFECTS

Because most patients with testicular GCT will experience long-term survival, survivorship care is important. Since many of these patients will be followed by primary care physicians, an understanding of the physical, psychological, and social late effects is important. Late effects are defined as health problems that occur months or years after a disease is diagnosed or after treatment has ended. Late effects may be related to the underlying cancer or to the treatment the patient received. In long-term survivors of testicular GCT, increased cardiovascular risk and increased secondary malignancies have been reported. Patients treated with cisplatin-based chemotherapy have an increased risk of hypertension, hyperlipidemia, metabolic syndrome, and cardiovascular events. Patients treated with high cumulative doses of etoposide (such as patients who receive standard chemotherapy, relapse, and then receive salvage high dose chemotherapy) may experience up to a 1–2% risk of developing acute myelogenous leukemia, typically 2–3 years after completing therapy and associated with an 11q23 translocation. Patients treated with radiation therapy, cisplatin-based chemotherapy, or both have an increased risk of developing secondary solid malignancies.

85 Gynecologic Malignancies

David Spriggs

OVARIAN CANCER

INCIDENCE AND PATHOLOGY

Ovarian cancer remains a leading cause of cancer deaths in American women, ranking behind lung, breast, colon, and pancreatic cancers. The ovary is responsible for the hormone and egg production. Between menarche (11–13 years) and menopause (45–55 years), the ovary is responsible for follicle maturation associated with egg maturation, ovulation, and cyclical sex steroid hormone production. These complex biologic functions are linked to stromal and germ cells within the ovary. These cells can be broadly grouped into stromal cells and ovarian germ cells and the enveloping epithelial cells. Malignancies arising in each group include multiple histological variants with unique neoplastic behaviors. Epithelial tumors are the most common histological variant of ovarian neoplasms; they may be benign (50%), frankly malignant (33%), or of borderline malignancy of low malignant potential (16%). In adnexal masses detected by imaging or physical examination, age influences risk of malignancy; tumors in younger women are more likely benign. In the malignant group, the most common tumors are epithelial. In the group of the ovarian epithelial, malignancies are the serous tumors (60–70%); mucinous tumors (10%), endometrioid (10–15%), and clear cell (10–15%), tumors. The distribution of histologic types varies in different parts of the world. Less common stromal tumors arise from the ancillary, supportive cells such as steroid hormone-producing cells and likewise have different phenotypes and clinical presentations. Most stromal tumors do not produce estrogen, but ectopic hormone production can be seen in certain subtypes. Tumors arising in the ovarian germ cell lineage are generally similar in biology and behavior to testicular tumors in males, although their intraperitoneal location alters some metastatic behaviors (Chap. 84). Ovarian tissue may also host metastatic tumors arising from breast, colon, gastric, and pancreatic primaries. Bilateral ovarian masses from metastatic mucin-secreting gastrointestinal cancers are termed *Krukenberg tumors*. A survey of other potential primaries is commonly required during the diagnostic workup of ovarian masses.

OVARIAN CANCER OF EPITHELIAL ORIGIN

Epidemiology An American woman has ~1 in 72 lifetime risk (1.6%) of developing ovarian cancer, with the majority of affected women developing epithelial tumors. In 2017, 22,440 cases of ovarian cancer with 14,195 deaths are expected in the United States. Sporadic (not familial) epithelial tumors of the ovary have a peak incidence in women in their fifties and sixties, although age at presentation ranges from the third decade to the eighties and nineties. Ovarian cancer risk has been linked to an interactive mixture of epidemiologic, environmental, and genetic factors. Nulliparity, obesity, diet, infertility treatments, and possibly hormone replacement therapy have all been linked to an increase in risk. Protective factors include the use of oral contraceptives, multiparity, tubal ligation, aspirin use, and breast-feeding. Other epidemiologic factors such as the use of perineal talcum agents remain controversial. The mechanisms underlying the various protective factors are largely unknown, but theories include suppression of ovulation, modulation of gonadotropins and progestins, and perhaps reduction of ovarian inflammation and damage associated with the repair of the ovarian cortex associated with ovulation.

GENETICS AND PATHOGENESIS

Ovarian cancers are divided into type 1 cancers and a more aggressive type 2 variant. The type 1 cancers are characterized by low-grade histology and more indolent behavior. These tumors include the low malignant potential tumors, low-grade endometrial and mucinous histologies, and clear cell cancers. Genetic alterations commonly include mutations in *KRAS, BRAF, PTEN*, and *PIK3CA*. In contrast, studies have implicated serial genetic changes in the fallopian tube as the actual site of origin for most type 2 serous epithelial ovarian cancers. These aggressive tumors are more common and linked to losses in *TP53* and DNA repair capacity. Carcinoma in situ has been identified in the tubal epithelium with early losses in *TP53* and the *BRCA1/BRCA2* genes characterizing early tubal intraepithelial cancers. Following these two early genetic events, additional mutations in these transformed cells lead to tumor cell shedding, metastasis, and invasion. These type 2, poorly differentiated "ovarian" cancer cells can then spread to the ovaries, and the peritoneal cavity, aided by the ovarian cancer cell's affinity for mesothelial lining cells.

TABLE 85-1 Staging and Survival in Gynecologic Malignancies

STAGE	OVARIAN	5-YEAR SURVIVAL, %	ENDOMETRIAL	5-YEAR SURVIVAL, %	CERVIX	5-YEAR SURVIVAL, %
0	—		—		Carcinoma in situ	100
I	Confined to ovary	88–95	Confined to corpus	>90	Confined to uterus	85
II	Confined to pelvic organs	70–80	Involves corpus and cervix	~75	Invades beyond uterus but not to pelvic wall	65
III	Intraabdominal spread to omentum, diaphragm or lymph nodes	20–40	Extends outside the uterus but not outside the true pelvis	45–60	Extends to pelvic wall and/or lower third of vagina, or hydronephrosis	35
IV	Spread outside abdominal cavity, parenchymal spread + pleural effusion cytology or extra-abdominal lymph nodes (inguinal, thoracic or supraclavicular)	17	Extends outside the true pelvis or involves the bladder or rectum	~20	Invades mucosa of bladder or rectum or extends beyond the true pelvis	7

In work done as part of the Tumor Genome Atlas, type 2, serous ovarian cancer is principally a disease characterized by amplifications and deletions rather than point mutations. Damage to the tumor suppressor gene *TP53* occurs in >95% of serous ovarian cancers. Damage to homologous DNA repair genes including *BRCA1 and BRCA2* was also common in these tumors. Low prevalence but statistically recurrent somatic mutations in seven other genes including *NF1, RB1*, and *CDK12* were also seen. The most common heritable abnormality linked to ovarian cancer is a germ-line mutation in either *BRCA1* (chromosome 17q12-21) or *BRCA2* (chromosome 13q12-13). These genes are important parts of the homologous DNA repair machinery for double-stranded DNA break repair. Individuals inheriting a single copy of a mutant allele (these act as autosomal dominant genes) have an increased lifetime risk of breast (46–87% for *BRCA1*; 38–84% for *BRCA2*) and ovarian cancer (39–63% for *BRCA1*; 16.5–27% for *BRCA2*). Many of these women have a family history that includes multiple cases of breast and/or ovarian cancer of at an early age. Male breast cancer, pancreatic cancer, and prostate cancer are also linked to familial *BRCA2* mutations. The most common malignancy in these women is breast carcinoma, although women harboring germ-line *BRCA1* mutations have a marked increased risk of developing ovarian malignancies in their forties and fifties. Women harboring a mutation in *BRCA2* have a lower penetrance of ovarian cancer with onset typically in their fifties or sixties. Other uncommon germ-line mutation of other genes encoding proteins linked to homologous DNA repair (e.g., *PALB2*) can also contribute to cancer risk although the frequency mutation and magnitude of risk increment is much lower and not well defined. Screening studies, even in the *mBRCA1/mBRCA2* families, suggest that any of the available screening techniques, including serial evaluation of the CA-125 tumor marker and transvaginal ultrasound, are insufficient to reliably detect early-stage ovarian cancer. Uniform germ-line *BRCA1/BRAC2* testing is recommended for all incident epithelial ovarian cancers to detect probands and identify relatives at risk. Women with these high-risk germ-line mutations are advised to undergo prophylactic removal of fallopian tubes and ovaries after completing childbearing and ideally before age 40. Early prophylactic salpingo-oophorectomy is highly protective. Salpingo-oophorectomy also appears to protect these women from subsequent breast cancer (risk reduction 50%). Prophylactic salpingectomy is almost certainly a key part of any surgical prophylaxis strategy for ovarian cancer, but the benefits of oophorectomy on either ovarian or breast cancer risk have not yet been clearly defined. Although less common, ovarian cancer is also another form of cancer (along with colorectal and endometrial cancer) that may develop in women with Lynch syndrome, type II, caused by mutations in one of the DNA mismatch repair genes (*MSH2, MLH1, MLH6, PMS1, PMS2*). Ovarian cancer may appear in women <50 years of age in this syndrome.

Presentation Neoplasms of the ovary tend to be painless unless they undergo torsion. Symptoms are therefore typically related to compression of local organs or due to symptoms from metastatic disease. Women with tumors localized to the ovary sometimes do have an increased incidence of symptoms including pelvic discomfort, bloating, and perhaps changes in a woman's typical urinary or bowel pattern. Unfortunately, these symptoms are common in primary care and are frequently dismissed by either the woman or her health care team until later stages of disease. The pathogenic factors and timing of spread beyond the ovary are still not well understood. The most common symptoms at presentation include a period of progressive complaints that typically include some combination of nausea, early satiety, bloating, indigestion, constipation, and abdominal pain. Signs include the rapid increase in abdominal girth due to the accumulation of ascites that typically alerts the patient and her physician that the concurrent gastrointestinal symptoms are likely associated with malignant pathology. Radiologic evaluation typically demonstrates a complex adnexal mass with ascites, carcinomatosis, with pelvic, para-aortic and mesenteric adenopathy in advanced disease. Positron emission tomography (PET) scans are generally not required. Laboratory evaluation demonstrates a markedly elevated CA-125, a shed mucin (MUC16) associated with, but not specific for, ovarian cancer. Ovarian cancers are divided into four stages, with stage I tumors confined to the ovary, stage II malignancies confined to the pelvis, and stage III confined to the peritoneal cavity and retroperitoneal nodes **(Table 85-1)**. These three stages are subdivided, with the most common presentation, stage IIIc, defined as tumors with bulky intraperitoneal disease or positive lymph node involvement. About 70% of women present with stage III disease. Stage IV disease includes women with parenchymal metastases (liver, lung, spleen) or, alternatively, abdominal wall or pleural disease. The 30% not presenting with stage III disease are roughly evenly distributed among the other stages.

Screening Ovarian cancer is a highly lethal condition, curable in early stages, and seldom curable in advanced stages; hence, screening is of considerable interest. Early-stage tumors often secrete excessive amounts of normal proteins that can be measured in the serum such as CA-125, mesothelin, and HE-4. Nevertheless, the incidence of ovarian cancer in the middle-aged female population is very low, with only ~1 in 2000 women between the ages of 50 and 60 carrying an asymptomatic and undetected tumor. Thus, effective screening techniques must be both sensitive and highly specific so to minimize the number of false positives. Panels of serum markers have not improved on CA-125 alone, although risk assessment by algorithms with multiple CA-125 is in advanced testing. No other screening strategies have been successful to date. Some large studies have suggested that low specificity screening might even worsen mortality in the screened population. Screening for ovarian cancer is currently not recommended outside of a clinical trial.

TREATMENT

Ovarian Cancer

TREATMENT

Epithelial ovarian cancer can be divided into distinct "disease states" for the purpose of treatment selection as shown in **Fig. 85-1**. Surgery by a skilled gynecologic oncologist remains the mainstay of initial therapy for ovarian cancer. The amount of residual visible

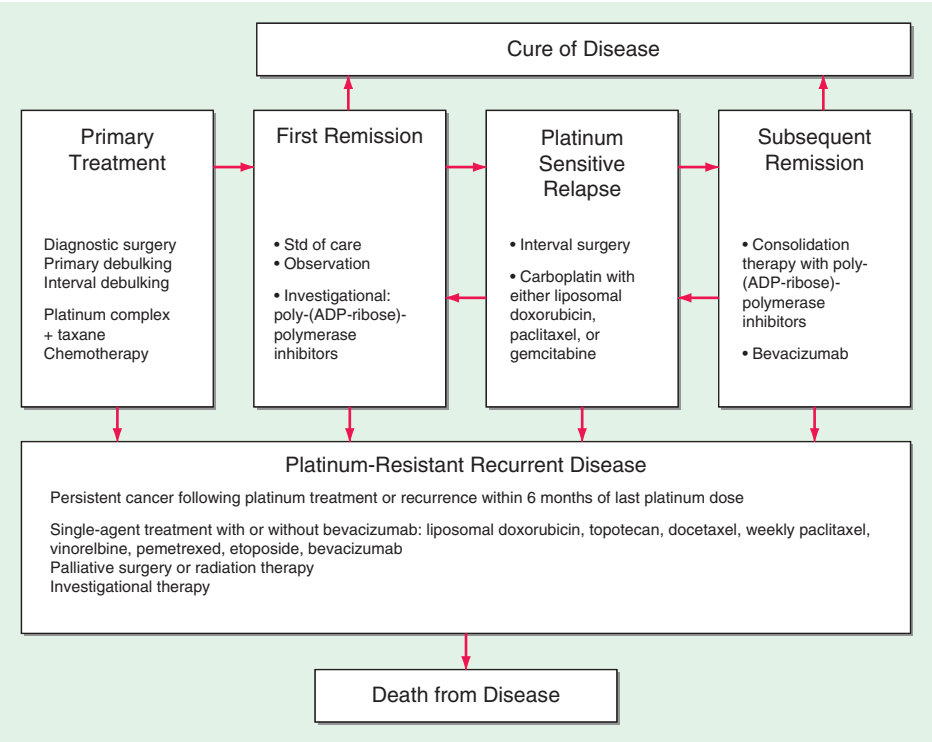

FIGURE 85-1 Disease states model of epithelial ovarian cancer and its treatment. Each box represents a relatively homogeneous group of patients that share a palette of potential treatment choices and have a similar prognosis. The arrows indicate that a single patient may move from one state to another during the course of her illness and the choice of treatments will become different in her new disease state.

cancer at the end of a primary operation is strongly predictive of outcome, and is paired with histology, grade, and stage to determine prognosis and treatment. In women presenting with a localized ovarian mass, the principal diagnostic and therapeutic maneuver is abdominal surgery to determine if the tumor is benign or malignant. In the event that the tumor is malignant, the surgical specimen will determine if the tumor arises in the ovary or is a site of metastatic disease. Metastatic disease to the ovary can be seen from primary tumors of the colon, appendix, stomach (Krukenberg tumors), and breast. Needle biopsy is contraindicated to avoid malignant contamination of the peritoneal cavity with malignant cells. Typically, women undergo laparoscopic evaluation and unilateral salpingo-oophorectomy for diagnostic purposes. If pathology reveals a primary ovarian malignancy or disseminated disease is present, then the procedure should be followed by a total hysterectomy, removal of the remaining tube and ovary, omentectomy, and pelvic node sampling along with biopsies of the peritoneal cavity and diaphragms. This extensive surgical procedure is performed because ~30% of tumors that by visual inspection appear to be confined to the ovary have already disseminated to the peritoneal cavity and/or surrounding lymph nodes. As with axillary dissections in breast cancer, node sampling is diagnostic but full lymphadenectomy appears to provide little or no additional therapeutic advantage over nodal sampling. The desired outcome of an ovarian cancer surgery is always an "R0" resection, with no visible residual cancer. The less favorable "optimal resection" (no disease greater than 1 cm in size) is still clinically useful and the prognosis of those patients is much better than the patients who are left with >1 cm disease at the end of surgery. These "suboptimally debulked" patients derive very little benefit from their surgery. Patients without gross residual disease after resection have a median survival in excess of 60 months, compared to 28–42 months for those left with macroscopic tumor.

After appropriate surgical treatment, primary chemotherapy will consist of combination treatment with paclitaxel and carboplatin. Primary chemotherapy can be delivered intravenously or alternatively, some therapy can be directly administered into the peritoneal cavity via an indwelling catheter. Several randomized studies have demonstrated improved survival with intraperitoneal therapy, but this approach is technically difficult and is increasingly replaced by carboplatin and dose dense (weekly) paclitaxel, which appears to offer similar results in some studies.

With optimal debulking surgery and platinum-based chemotherapy (usually carboplatin dosed to an area under the curve [AUC] of 6.0 plus paclitaxel 175 mg/m^2 by 3-h infusion in monthly cycles), 70% of women who present with advanced-stage tumors respond, and 40–50% experience a complete remission with normalization of their CA-125, CT scans, and physical examination. These patients are sometimes enrolled in consolidation trials to extend remission and increase likelihood of cure. New immunotherapies and poly–ADP ribose polymerase inhibitors (PARPi) such as olaparib are in active testing in these patients because less than half of the complete responders are cured. Disease recurs within 1–4 years from the completion of their primary therapy. CA-125 levels often increase as a first sign of relapse and CT scan findings are confirmatory. Recurrent disease is managed, but rarely cured, with additional surgery and variety of chemotherapeutic agents. Eventually all of these women develop chemotherapy-refractory disease and refractory ascites, poor bowel motility, and obstruction or tumor-infiltrated aperistaltic bowel are all common premorbid events. Limited surgery to relieve intestinal obstruction, localized radiation therapy to relieve pressure or pain from masses, or palliative chemotherapy may be helpful. Agents with >15% response rates include gemcitabine, topotecan, liposomal doxorubicin, and bevacizumab.

Five-year survival correlates with the stage of disease: stage I, 90–95%; stage II, 70–80%; stage III, 25–40%; stage IV, 10–15% (Table 85-1). Prognosis is also influenced by histologic grade: 5-year survival is 88% for well-differentiated tumors, 58% for moderately differentiated tumors, and 27% for poorly differentiated tumors. Histologic type has less influence on outcome.

UNCOMMON OVARIAN TUMORS

Low Malignant Potential Tumors (Borderline Tumors)

These type 1 tumors are found in younger women (ages 40–50), indolent in behavior and few of these patients will succumb to their tumors (10 years survival may approach 98%) although recurrence is not uncommon.

Certain features like micropapillary histology and microinvasion are linked to a more aggressive behavior. Patients with tumors of low malignant potential are managed primarily by surgery; chemotherapy and radiation therapy do not substantially alter survival.

Stromal Tumors Approximately 7% of ovarian neoplasms are stromal tumors, with ~1800 cases expected each year in the United States. Ovarian stromal tumors or sex cord tumors are most common in women in their fifties or sixties, but tumors can present at any age. These tumors arise from the mesenchymal components of the ovary, including both steroid-producing cells and fibroblasts. Most of these tumors are indolent tumors with limited metastatic potential and present as unilateral solid masses. These tumors primarily are discovered by the detection of an abdominal mass sometimes with abdominal pain due to ovarian torsion, intratumoral hemorrhage, or rupture. Rarely, stromal tumors can produce estrogen and present with breast tenderness as well as precocious puberty in children, menstrual disturbances in reproductively active women, or postmenopausal bleeding. In some women, estrogen-associated secondary malignancies, such as endometrial or breast cancer, may present as synchronous malignancies. Sertoli-Leydig tumors often present with hirsutism, virilization due to increased production androgens. Hormonally inert tumors include fibroma that presents as a solitary mass often in association with ascites and occasionally hydrothorax also known as Meigs' syndrome. A subset of these tumors present in individuals with a variety of inherited disorders that predispose them to mesenchymal neoplasia including Ollier's disease (juvenile granulosa cell tumors) and Peutz-Jeghers syndrome (ovarian sex cord tumors). The treatment of these tumors is almost exclusively by surgical resection. Chemotherapy with carboplatin and paclitaxel is generally reserved for either unresectable or multiply recurrent tumors.

Germ Cell Tumors of the Ovary Germ cell tumors, like their counterparts in the testis, are cancers of germ cells. These totipotent cells contain the programming for differentiation to essentially all tissue types, and hence the germ cell tumors include a histologic menagerie of bizarre tumors, including benign teratomas (dermoid cysts) and a variety of malignant tumors, such as dysgerminoma, immature teratomas, yolk sac malignancies, and choriocarcinomas. Benign teratoma (or dermoid cyst) is the most common germ cell neoplasm of the ovary and often presents in young woman. These tumors include a complex mixture of differentiated tissue including tissues from all three germ layers. In older women these differentiated tumors can develop malignant transformation, most commonly squamous cell carcinomas. Malignant germ cell tumors include dysgerminomas, yolk sac tumors, immature teratomas, as well as embryonal and choriocarcinomas. Germ cell tumors can present at all ages, but the peak age of presentation tends to be in adolescents. Typically these tumors will become large ovarian masses, which eventually present as palpable low abdominal or pelvic masses. Like sex cord tumors, torsion or hemorrhage may present urgently or emergently as acute abdominal pain. Some of germ cell tumors produce elevated levels of human chorionic gonadotropin (hCG) or α fetoprotein (AFP). Unlike epithelial ovarian cancer, these tumors have a higher proclivity for nodal or hematogenous metastases. Germ cell tumors typically present in women who are of childbearing age, and because bilateral tumors are uncommon (except in dysgerminoma, 10–15%), the typical treatment is unilateral oophorectomy or salpingo-oophorectomy with lymph node sampling. Most commonly, women with advanced malignant germ cell tumors typically receive bleomycin, etoposide, and cisplatin (BEP) chemotherapy, in an analogous fashion to the treatment of testicular cancers. In the majority of these women, even those with advanced-stage disease, cure is expected. Dysgerminoma is the ovarian counterpart of testicular seminoma and is highly curable. Although the tumor is highly radiation-sensitive, radiation produces infertility in many patients. BEP chemotherapy is as effective or more so without causing infertility.

FALLOPIAN TUBE CANCER

Transport of the egg to the uterus occurs through the fallopian tube, with the distal ends of these tubes composed of fimbriae that drape about the ovarian surface and capture the egg as it erupts from the ovarian cortex. As described previously, the majority of type 2 ovarian cancers are now thought to arise from the tubal epithelium. As might be expected, fallopian tube malignancies are typically serous histology and share the biology and recommended treatment as serous ovarian cancer. These tumors often present as clinically isolated adnexal masses, but like ovarian cancer, these tumors spread relatively early throughout the peritoneal cavity. Fallopian tubal cancers have a natural history and treatment that is essentially identical to ovarian cancer (Table 85-1).

CERVICAL CANCER

ETIOLOGY AND GENETICS

Cervical cancer is the second most common and the most lethal malignancy in women worldwide. Infection with high-risk strains of human papillomavirus (HPV) is the primary neoplastic-initiating event in the vast majority of women with invasive cervical cancer. This double-strand DNA virus infects epithelium near the transformation zone of the cervix where underlying columnar epithelium becomes squamous epithelium. More than 60 types of HPV are known, with ~20 types having the ability to generate high-grade dysplasia and malignancy. HPV16 and 18 are the types most frequently associated with high-grade dysplasia, but types 31, 33, 35, 52, and 58 are also considered to be high-risk variants. The large majority of sexually active adults are exposed to HPV, and most women clear the infection without specific intervention. The 8-kilobase HPV genome encodes seven early genes, most notably *E6* and *E7*, which can bind to *RB* and *p53*, respectively. High-risk types of HPV encode *E6* and *E7* molecules that are particularly effective at inhibiting the normal cell cycle checkpoint functions of these regulatory proteins, leading to immortalization but not full transformation of cervical epithelium. A minority of women will fail to clear the infection with subsequent HPV integration into the host genome. Over as little as a few months to several years, some of these persistently infected women develop worsening dysplasia, a premalignant condition that, untreated, can progress to cervical carcinoma. Complete transformation to cancer occurs over a period years and almost certainly requires the acquisition of other poorly defined genetic mutations within the infected and immortalized epithelium.

Approximately 528,000 new cases of cervical cancer were reported in 2012 worldwide with approximately an estimated 266,000 deaths. Cancer incidence is particularly high in women residing in central and South America, the Caribbean, and southern and eastern Africa. Mortality rate is disproportionately high in Africa. In the United States, an estimated 12,800 women will be diagnosed with cervical cancer this year, and 4210 women will die of the disease. Efforts in developed countries have looked at high-technology screening techniques for HPV involving polymerase chain reaction (PCR) and other molecular technologies.

In the integrated genomic characterization of cervical cancer by the Cancer Genome Atlas (TCGA), integration of HPV sequences was found in all of the HPV18 linked cancers and over 3 quarters of the HPV16 cancers. The cervical tumors also showed a characteristic APOBEC (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like; a family of cytidine deaminases that edit DNA and are endogenous mutagenic enzymes) pattern of mutagenesis with *ERBB3*, *CASP8*, and *TGFRB2* identified as significantly mutated genes presumably linked to progression from dysplasia to carcinoma. Amplification of immune targets PD-L1 and PD-L2 was also seen, which may suggest vulnerability to immunotherapy. In the much smaller number of HPV negative cancers, mutations in the common oncogenes *KRAS*, *ARID1A*, and *PTEN* were commonly seen. The clinical behavior of these cancers is likely to be different.

HPV INFECTION AND PREVENTION

The Pap smear is the primary detection method for asymptomatic preinvasive cervical dysplasia of squamous epithelial lining during a gynecologic examination. Because of the delay between dysplasia and frank cervical cancer is years long; annual (or longer) screening and prevention strategies that detect precancerous dysplasia and carcinoma

in situ can be implemented successfully. Annual or biannual cervical scraping for cytology (Pap Smear) is highly effective in reducing the incidence of cervical cancer by early detection and subsequent surgical treatment. Although no randomized trial data demonstrate the utility of Pap smears, the dramatic drop in cervical cancer incidence and death in developed countries employing wide-scale screening provides strong evidence for its effectiveness. The incorporation of HPV testing by PCR or other molecular techniques increases the sensitivity of detecting cervical pathology but at the cost of lower sensitivity in that it identifies many women with transient infections who require no specific medical intervention. Unfortunately, both the collection of a Pap smear and its cytological evaluation require infrastructure beyond the means of many middle- and low-income countries. High-throughput, low-technology prevention strategies are needed to identify and treat women bearing high-risk but treatable cervical dysplasia.

A primary prevention strategy relies on HPV vaccines. Currently approved vaccines include the recombinant proteins to the late proteins, L1 and L2 of HPV-16 and -18 as well as other, less common cancer causing isotypes 11, 31, 33, 45, 52, and 58. Vaccination of girls aged 11–13 years with two injections (one year apart) before the initiation of sexual activity dramatically reduces the rate of high-risk HPV infection and subsequent dysplasia. There is also partial protection against other HPV types, although vaccinated women are still at risk for HPV infection and still benefit from standard Pap smear screening.

CLINICAL PRESENTATIONS

Risk Factors Clinical risk factors include many HPV infection–linked features: a high number of sexual partners, early age of first intercourse, and history of venereal disease. Smoking is a cofactor; heavy smokers have a higher risk of dysplasia with HPV infection. HIV infection, especially when associated with low CD4+ T-cell counts, is associated with a higher rate of high-grade dysplasia and likely a shorter latency period between infection and invasive disease. Histologically, the majority of cervical malignancies are squamous cell carcinomas associated with HPV, but adenocarcinomas are also HPV-related, and both arise in transitional zone of the endocervical canal; the lesions in the canal or cervical glands may not be seen by visual inspection of the cervix and can be missed by Pap smear screening. Uncommon malignancies including carcinoids, small cell carcinomas, sarcomas, and lymphomas are also found but are linked to HPV infection.

Diagnosis of Cervical Cancer Early cancer of the cervix is asymptomatic and this underlies the recommendations for routine gynecologic care. Larger, invasive carcinomas often have symptoms or signs including postcoital spotting or intermenstrual cycle bleeding or menometrorrhagia. Foul-smelling or persistent yellow discharge may also be seen. Presentations that include pelvic or sacral pain suggest lateral extension of the tumor into pelvic nerve plexus by either the primary tumor or a pelvic node and are signs of advanced-stage disease. Likewise, flank pain from hydronephrosis from ureteral compression or deep venous thrombosis from iliac vessel compression suggests either extensive nodal disease or direct extension of the primary tumor to the pelvic sidewall. The most common finding upon physical examination is a visible tumor on the cervix. Larger tumors may be identified by inspection and biopsied directly. Staging of cervical cancer is performed by clinical examination. Stage I cervical tumors are confined to the cervix, whereas stage II tumors extend into the upper vagina or paracervical soft tissue (Fig. 85-2). Stage III tumors extend to the lower vagina or the pelvic sidewalls, whereas stage IV tumors invade the bladder or rectum or have spread to distant sites. While radiographic studies are not part of the formal clinical staging of cervical cancer, treatment planning requires them for appropriate therapy. CT can detect hydronephrosis indicative of pelvic sidewall disease but is not accurate at evaluating other pelvic structures. MRI is more accurate at estimating uterine extension and paracervical extension of disease into soft tissues typically bordered by broad and cardinal ligaments that support the uterus in the central pelvis. Very small stage I cervical tumors can be treated with a variety of surgical procedures. In young women desiring to maintain fertility, radical trachelectomy removes the cervix with subsequent anastomosis of the upper vagina to the uterine corpus; however, subsequent pregnancies may be more problematic. Large stage I cervical tumors (4 cm) confined to the cervix and all stage II–IV patients are treated with radiation therapy in combination with cisplatin-based chemotherapy. This multimodality treatment can offer the patient with advanced stage disease, a 40–80% of cure depending on the clinical circumstances. Platinum agents (cisplatin or carboplatin) combined with paclitaxel and bevacizumab are generally considered as the best palliative choice for metastatic cervical cancer patients. Secondary chemotherapy confers minimal improvement in most patients.

UTERINE CANCER

EPIDEMIOLOGY

Several different tumor types arise in uterine corpus. Most tumors arise in the glandular lining and are endometrial adenocarcinomas. Benign (leiomyomas) and malignant tumors (leiomyosarcomas) can also arise in the uterine smooth muscle and have very different clinical features. The endometrioid histologic subtype of endometrial cancer is the most common gynecologic malignancy in the United States. In 2017, over 60,000 new corpus cancers of uterus are projected for American women, but the surgical cure rate is high, and about 10,920 deaths from uterine cancers are predicted. Development of these tumors is a multistep process with estrogen playing an important early role in driving endometrial gland proliferation. Relative overexposure to this class of hormones is the principal risk factor for the subsequent development of endometrioid tumors. In contrast, progestins drive glandular maturation and are protective. Hence, women with high endogenous or pharmacologic exposure to estrogens, especially if unopposed by progesterone, are at higher risk for endometrial cancer. Obese women, women treated with postmenopausal estrogens or

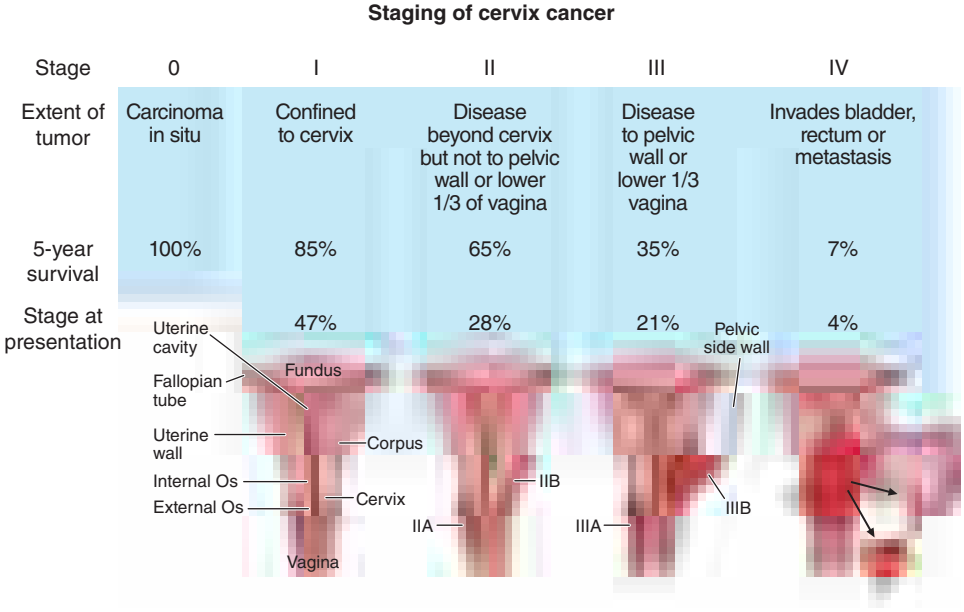

FIGURE 85-2 Anatomic display of the stages of cervix cancer defined by location, extent of tumor, frequency of presentation, and 5-year survival. *(From MV Seiden: Gynecologic malignancies, in Harrison's Principles of Internal Medicine, 19th ed. New York, McGraw-Hill.)*

women with estrogen-producing tumors are at higher risk for endometrial cancer. In addition, long-term treatment with tamoxifen, which has antiestrogenic effects in breast tissue but can show weak estrogenic effects in uterine epithelium, is associated with an increased risk of endometrial cancer.

Genetics Women with a germ-line mutation in one of the series of DNA mismatch repair genes associated with the Lynch syndrome, also known as hereditary nonpolyposis colon cancer (HNPCC) syndrome, are at increased risk for endometrioid endometrial carcinoma. These individuals have germ-line mutations in *MSH2*, *MLH1*, and in rare cases *PMS1* and *PMS2*. Individuals who carry these mutations typically have a family history of cancer and are at markedly increased risk for colon cancer and modestly increased risk for ovarian cancer and a variety of other tumors. Middle-aged women with HNPCC carry a 4% annual risk of endometrial cancer and a relative overall risk of approximately 200-fold as compared to age-matched women without HNPCC. In sporadic cancers, secondary events such as mutation of the *PI3K* gene or the loss of the *PTEN* tumor suppressor gene likely serve as secondary "hits" in the carcinogenesis of estrogenic excess. The molecular events that underlie less common endometrial cancers such as clear cell and papillary serous tumors of the uterine corpus are less well understood.

PATHOLOGY

Approximately 75–80% of endometrial cancers are adenocarcinomas and have been characterized as type 1 (estrogen-linked) endometrial cancers and type 2 cancers that have less clear associations with estrogens (clear cell cancers, serous cancers, and mucinous cancers). Endometrial serous cancers show TP53 functional loss and behave clinically like ovarian cancers. Serous endometrial cancers are marked by a much higher risk of distant recurrence and a lower risk for locoregional spread. Prognosis depends on stage, histologic grade, and depth of myometrial invasion.

CLINICAL PRESENTATION

The majority of women with tumors of the uterine corpus present with postmenopausal vaginal bleeding due to shedding of the malignant endometrial lining. Premenopausal women often will present with atypical bleeding between typical menstrual cycles. These signs typically bring a woman to the attention of a health care professional, and the majority of women present with early-stage disease in which the tumor is confined to the uterine corpus and the consequent high cure rate. Diagnosis is typically established by endometrial biopsy. Epithelial tumors may spread to pelvic or para-aortic lymph nodes. Serous tumors tend to have patterns of spread much more reminiscent of ovarian cancer, and patients may present with omental/peritoneal disease and sometimes ascites. Some women with endometrial cancer have a history of endometriosis. Some women presenting with uterine sarcomas will present with pelvic pain. Sarcomas commonly are found by detection of symptomatic large pelvic masses that may or may not be associated with dysfunctional bleeding.

TREATMENT

Uterine Cancer

Most women with endometrial cancer have disease that is localized to the uterus (75% are stage I, Table 85-1), and definitive treatment typically involves a hysterectomy with removal of the ovaries and fallopian tubes. The resection of lymph nodes does not improve outcome, but sentinel node resection does provide staging and prognostic information. Node involvement defines stage IIIC disease. Tumor grade and depth of invasion are the two key prognostic variables in early-stage tumors, and women with low-grade and/or minimally invasive tumors (<50% myometrial penetration) are typically observed after definitive surgical therapy. Patients with high-grade tumors or tumors that are deeply invasive (stage IB) are at higher risk for pelvic recurrence or recurrence at the vaginal cuff, which is typically prevented by intravaginal brachytherapy.

Women with regional metastases or metastatic disease (3% of patients) with low-grade tumors can be treated with progesterone or tamoxifen. Poorly differentiated tumors lack hormone receptors and are typically resistant to hormonal manipulation. The role of adjuvant chemotherapy in stage I–II disease is currently under investigation but is usually employed for advanced stage (III–IV) cancer and most tumors with serous histology. Carboplatin and paclitaxel combinations are the current standard of care. Chemotherapy for metastatic disease is delivered with palliative intent. Potentially active drugs include bevacizumab, mTOR inhibitors (e.g., temsirolimus). Patients with advanced cancer and known mismatch repair deficits may respond particularly well to immunotherapy with antagonists of the PD1/PDL1 axis.

Chemotherapy of leiomyosarcomas of the uterus with docetaxel/gemcitabine, ifosfamide/doxorubicin, and trabectedin can have substantial benefit. Carcinosarcomas of the uterus contain both mesenchymal and epithelial components but will often respond to paclitaxel and platinum complex therapy.

GESTATIONAL TROPHOBLASTIC TUMORS

Gestational trophoblastic diseases represent a spectrum of neoplasia from benign hydatidiform mole to choriocarcinoma due to persistent trophoblastic disease associated most commonly with molar pregnancy but occasionally seen after normal gestation. The most common presentations of trophoblastic tumors are partial and complete molar pregnancies. These represent ~1 in 1500 conceptions in developed Western countries. The incidence widely varies globally, with areas in Southeast Asia having a much higher incidence of molar pregnancy. Regions with high molar pregnancy rates are often associated with diets low in carotene and animal fats.

RISK FACTORS

Trophoblastic tumors result from the outgrowth or persistence of placental tissue. They arise most commonly in the uterus but can also arise in other sites such as the fallopian tubes due to ectopic pregnancy. Risk factors include poorly defined dietary and environmental factors as well as conceptions at the extremes of reproductive age, with the incidence particularly high in females conceiving younger than age 16 or older than age 50. In older women, the incidence of molar pregnancy might be as high as one in three, likely due to increased risk of abnormal fertilization of the aged ova. Most trophoblastic neoplasms are associated with complete moles, diploid tumors with all genetic material from the paternal donor (known as uniparental disomy). This is thought to occur when a single sperm fertilizes an enucleate egg that subsequently duplicates the paternal DNA. Trophoblastic proliferation occurs with exuberant villous stroma. If pseudopregnancy extends out past the 12th week, fluid progressively accumulates within the stroma leading to "hydropic changes." There is no fetal development in complete moles.

Partial moles arise from the fertilization of an egg with two sperm; hence two-thirds of genetic material is paternal in these triploid tumors. Hydropic changes are less dramatic, and fetal development can often occur through late first trimester or early second trimester at which point spontaneous abortion is common. Laboratory findings will include excessively high hCG and high AFP. The risk of persistent gestational trophoblastic disease after partial mole is ~5%. Complete and partial moles can be noninvasive or invasive. Myometrial invasion occurs in no more than one in six complete moles and a lower portion of partial moles.

PRESENTATION OF INVASIVE TROPHOBLASTIC DISEASE

The clinical presentation of molar pregnancy is changing in developed countries due to the early detection of pregnancy with home pregnancy kits and the very early use of Doppler and ultrasound to evaluate the early fetus and uterine cavity for evidence of a viable fetus. Thus, in these countries, the majority of women presenting with trophoblastic disease have their moles detected early and have typical symptoms of early pregnancy including nausea, amenorrhea, and breast tenderness.

With uterine evacuation of early complete and partial moles, most women experience spontaneous remission of their disease as monitored by serial hCG levels. These women require no chemotherapy. Patients with persistent elevation of hCG or rising hCG postevacuation have persistent or actively growing gestational trophoblastic disease and require therapy. Most series suggest that between 15 and 25% of women will have evidence of persistent gestational trophoblastic disease after molar evacuation.

In women who lack access to prenatal care, presenting symptoms can be life threatening including the development of preeclampsia or even eclampsia. Hyperthyroidism can also be seen. Evacuation of large moles can be associated with life-threatening complications including uterine perforation, volume loss, high-output cardiac failure, and adult respiratory distress syndrome (ARDS).

For women with evidence of rising hCG or radiologic confirmation of metastatic or persistent regional disease, prognosis can be estimated through a variety of scoring algorithms that identify those women at low, intermediate, and high risk for requiring multiagent chemotherapy. In general, women with widely metastatic nonpulmonary disease, very elevated hCG, and prior normal antecedent term pregnancy are considered at high risk and typically require multiagent chemotherapy at an expert center for cure. Even very advanced gestational trophoblastic disease is almost uniformly curable when managed by an expert in this rare malignancy.

TREATMENT

Invasive Trophoblastic Disease

Management of invasive trophoblastic disease should be 100% curative and complex patients should be managed by clinicians experienced in this disease. The management for a persistent and rising hCG postevacuation of a molar conception is typically chemotherapy, although surgery can play an important role for chemotherapy-resistant disease that is isolated in the uterus (especially if childbearing is complete) or to control hemorrhage. For women wishing to maintain fertility or with metastatic disease, the preferred treatment is chemotherapy. Trophoblastic disease is exquisitely sensitive to chemotherapy and guided by serial serum hCG testing, successful, curative treatment is the rule. Single-agent treatment with methotrexate or actinomycin D cures 90% of women with low-risk disease. Patients with high-risk disease (very high hCG levels, presentation 4 or more months after pregnancy, brain or liver metastases, failure of methotrexate therapy) are typically treated with multiagent chemotherapy (etoposide, methotrexate, and actinomycin D alternating with cyclophosphamide and vincristine [EMA-CO]), which is typically curative even in those women with extensive metastatic disease. Cisplatin and etoposide alternating with etoposide / methotrexate/ actinomycin D is used for the highest risk patients. In the highest-risk patients with liver lung and brain metastases, hemorrhage from the rich tumor vasculature is a major risk during chemotherapy initiation. Cured women may get pregnant again without evidence of increased fetal or maternal complications.

86 Primary and Metastatic Tumors of the Nervous System

Lisa M. DeAngelis, Patrick Y. Wen

Primary brain tumors are diagnosed in ~78,000 people each year in the United States. At least 25,000 are malignant, and most of these are gliomas. Meningiomas account for 35%, vestibular schwannomas 10%, and central nervous system (CNS) lymphomas ~2%. Brain metastases are three times more common than all primary brain tumors combined and are diagnosed in ~150,000 people each year. Metastases to the leptomeninges and epidural space of the spinal cord each occur in ~3–5% of patients with systemic cancer and are also a major cause of neurologic disability.

APPROACH TO THE PATIENT

Primary and Metastatic Tumors of the Nervous System

CLINICAL FEATURES

Brain tumors of any type can present with a variety of symptoms and signs that fall into two categories: general and focal; patients often have a combination of the two **(Table 86-1)**. General or nonspecific symptoms include headache, with or without nausea or vomiting, cognitive difficulties, personality change, and gait disorder. Generalized symptoms arise when the enlarging tumor and its surrounding edema cause an increase in intracranial pressure or compression of cerebrospinal fluid (CSF) circulation leading to hydrocephalus. The classic brain tumor headache predominates in the morning and improves during the day, but this pattern is seen only in a minority of patients. Headaches are often holocephalic but can be ipsilateral to the side of a tumor. Occasionally, headaches have features of a typical migraine with unilateral throbbing pain associated with visual scotoma. Personality changes may include apathy and withdrawal from social situations, mimicking depression. Focal or lateralizing findings include hemiparesis, aphasia, or visual field defect. Lateralizing symptoms are typically subacute and progressive; language difficulties may be mistaken for confusion. Seizures are common, occurring in ~25% of patients with brain metastases or malignant gliomas and are the presenting symptom in up to 90% of patients with a low-grade glioma. All seizures that arise from a brain tumor will have a focal onset whether or not it is apparent clinically.

NEUROIMAGING

Cranial magnetic resonance imaging (MRI) is the preferred diagnostic test for any patient suspected of having a brain tumor and should be performed with gadolinium contrast administration. Computed tomography (CT) scan should be reserved for those patients unable to undergo MRI. Malignant brain tumors—whether primary or metastatic—typically enhance with gadolinium, have central areas of necrosis, and are surrounded by edema of the neighboring white matter. Low-grade gliomas usually do not enhance with gadolinium and are best appreciated on fluid-attenuated inversion recovery (FLAIR) MRIs. Meningiomas have a typical appearance on MRI because they are dural-based enhancing tumors with a dural tail and compress but do not invade the brain. Dural metastases or a dural lymphoma can have a similar appearance. Imaging is characteristic for many primary and metastatic tumors and sometimes will suffice to establish a diagnosis when the location precludes surgical intervention (e.g., brainstem glioma). Functional MRI is useful in presurgical planning to define eloquent sensory, motor, or language cortex. Positron emission tomography (PET) is useful in determining

TABLE 86-1 Symptoms and Signs at Presentation of Brain Tumors

	HIGH-GRADE GLIOMA (%)	LOW-GRADE GLIOMA (%)	MENINGIOMA (%)	METASTASES (%)
Generalized				
Impaired cognitive function	50	10	30	60
Hemiparesis	40	10	36	60
Headache	50	40	37	50
Lateralizing				
Seizures	20	70+	17	18
Aphasia	20	<5	—	18
Visual field deficit	—	—	—	7

the metabolic activity of the lesions seen on MRI; MR perfusion and spectroscopy can provide information on blood flow or tissue composition. These techniques may help distinguish tumor progression from necrotic tissue as a consequence of treatment with radiation and chemotherapy. Neuroimaging is the only test necessary to diagnose a brain tumor. Laboratory tests are rarely useful, although patients with metastatic disease may have elevation of a serum tumor marker (e.g., β human chorionic gonadotropin [β-hCG] from testicular cancer). Additional testing such as cerebral angiogram, electroencephalogram (EEG), or lumbar puncture is rarely indicated or helpful.

TREATMENT

Brain Tumors

Therapy of any intracranial malignancy requires both symptomatic and definitive treatments. Definitive treatment is based on the specific tumor type and includes surgery, radiotherapy, and chemotherapy. However, symptomatic treatments apply to brain tumors of any type. Most high-grade malignancies are accompanied by substantial surrounding edema, which contributes to neurologic disability and raised intracranial pressure. Glucocorticoids are highly effective at reducing perilesional edema and improving neurologic function, often within hours of administration. Dexamethasone has been the glucocorticoid of choice because of its relatively low mineralocorticoid activity; initial doses are 8–16 mg/d. Glucocorticoids rapidly ameliorate symptoms and signs, but their long-term use causes substantial toxicity including insomnia, weight gain, diabetes mellitus, steroid myopathy, and personality changes. Consequently, a taper is indicated as definitive treatment is administered and the patient improves.

Patients with brain tumors who present with seizures require antiepileptic drug therapy. There is no role for prophylactic antiepileptic drugs in patients who have not had a seizure. The agents of choice are those drugs that do not induce the hepatic microsomal enzyme system. These include levetiracetam, topiramate, lamotrigine, valproic acid, and lacosamide **(Chap. 418)**. Other drugs, such as phenytoin and carbamazepine, are used less frequently because they are potent enzyme inducers that can interfere with both glucocorticoid and chemotherapy metabolism. Venous thromboembolic disease occurs in 20–30% of patients with high-grade gliomas or brain metastases. Prophylactic anticoagulants should be used during hospitalization and in nonambulatory patients. Those who have had either a deep vein thrombosis or pulmonary embolus can receive therapeutic doses of anticoagulation safely and without increasing the risk for hemorrhage into the tumor. Inferior vena cava filters are reserved for patients with absolute contraindications to anticoagulation such as recent craniotomy.

PRIMARY BRAIN TUMORS

EPIDEMIOLOGY

No underlying cause has been identified for the majority of primary brain tumors. The only established risk factors are exposure to ionizing radiation (meningiomas, gliomas, and schwannomas) and immunosuppression (primary CNS lymphoma). There is no proven evidence for any association with exposure to electromagnetic fields including cellular telephones, head injury, foods containing *N*-nitroso compounds, or occupational risk factors. A small minority of patients have a family history of brain tumors. Some of these familial cases are associated with genetic syndromes **(Table 86-2)**.

MOLECULAR PATHOGENESIS

As with other neoplasms, brain tumors arise as a result of a multistep process driven by the sequential acquisition of genetic alterations. These include loss of tumor-suppressor genes (e.g., *p53*, cyclin-dependent kinase inhibitor 2A and 2B [*CDKN2A/B*], and phosphatase and tensin homolog on chromosome 10 [*PTEN*]) and amplification and overexpression of protooncogenes such as the epidermal growth factor receptor (*EGFR*) and the platelet-derived growth factor receptors (*PDGFR*). The accumulation of these genetic abnormalities results in uncontrolled cell growth and tumor formation.

Important progress has been made in understanding the molecular pathogenesis of several types of brain tumors, including glioblastoma and medulloblastoma, allowing them to be separated into different subtypes with different prognoses. This has led the World Health Organization (WHO) to issue an update on the classification of CNS tumors in 2016 that for the first time incorporates molecular parameters in addition to traditional histology into the diagnosis of brain tumors.

INTRINSIC "MALIGNANT" TUMORS

DIFFUSE GIOMAS

Gliomas are the most common type of malignant primary brain tumor and are derived, based on their presumed lineage, into astrocytomas and oligodendrogliomas. These tumors are classified based on two highly recurrent molecular alterations, isocitrate dehydrogenase (*IDH*) mutations and 1p/19q codeletion, in addition to more conventional histopathologic parameters. Most lower-grade astrocytomas have *IDH* mutations but intact 1p/19q, and often mutations in *ATRX* and *p53*. Oligodendrogliomas usually have *IDH* mutations and codeletion of 1p/19q.

ASTROCYTOMAS

These are infiltrative tumors with a presumptive glial cell of origin. WHO classifies astrocytomas into four prognostic grades based on histologic features: grade I (pilocytic astrocytoma, subependymal giant cell astrocytoma); grade II (astrocytoma); grade III (anaplastic astrocytoma); and grade IV (glioblastoma). Grades I and II are considered low-grade, and grades III and IV high-grade, astrocytomas.

Low-Grade Astrocytoma • GRADE I ASTROCYTOMAS Pilocytic astrocytomas (WHO grade I) are the most common tumor of childhood. They occur typically in the cerebellum but may also be found elsewhere in the neuraxis, including the optic nerves and brainstem. Frequently they appear as cystic lesions with an enhancing mural nodule. Often they have *BRAF* fusions or mutations. These are well-demarcated lesions that are potentially curable if they can be resected completely. Giant-cell subependymal astrocytomas are usually found in the ventricular wall of patients with tuberous sclerosis. They often do not require intervention but can be treated surgically or with inhibitors of the mammalian target of rapamycin (mTOR).

TABLE 86-2 Genetic Syndromes Associated with Primary Brain Tumors

SYNDROME	INHERITANCE	GENE/PROTEIN	ASSOCIATED TUMORS
Cowden's syndrome	AD	Mutations of *PTEN* (ch10p23)	Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease), meningioma, astrocytoma Breast, endometrial, thyroid cancer, trichilemmomas
Familial schwannomatosis	Sporadic Hereditary	Mutations in *INI1/SNF5* (ch22q11)	Schwannomas, gliomas
Gardner's syndrome	AD	Mutations in *APC* (ch5q21)	Medulloblastoma, glioblastoma, craniopharyngioma Familial polyposis, multiple osteomas, skin and soft tissue tumors
Gorlin syndrome (basal cell nevus syndrome)	AD	Mutations in *Patched 1* gene (ch9q22.3)	Medulloblastomas Basal cell carcinoma
Li-Fraumeni syndrome	AD	Mutations in *p53* (ch17p13.1)	Gliomas, medulloblastomas Sarcomas, breast cancer, leukemias, others
Multiple endocrine neoplasia 1 (Werner's syndrome)	AD	Mutations in *Menin* (ch11q13)	Pituitary adenoma, malignant schwannomas Parathyroid and pancreatic islet cell tumors
NF1	AD	Mutations in *NF1*/neurofibromin (ch17q12-22)	Schwannomas, astrocytomas, optic nerve gliomas, meningiomas Neurofibromas, neurofibrosarcomas, others
NF2	AD	Mutations in *NF2*/merlin (ch22q12)	Bilateral vestibular schwannomas, astrocytomas, multiple meningiomas, ependymomas
TSC (Bourneville disease)	AD	Mutations in *TSC1/TSC2* (ch9q34/16)	Subependymal giant-cell astrocytoma, ependymomas, glioma, ganglioneuroma, hamartoma
Turcot syndrome	AD AR	Mutations in *APC*[a] (ch5) hMLH1 (ch3p21)	Gliomas, medulloblastomas Adenomatous colon polyps, adenocarcinoma
VHL	AD	Mutations in *VHL* gene (ch3p25)	Hemangioblastomas Retinal angiomas, renal cell carcinoma, pheochromocytoma, pancreatic tumors and cysts, endolymphatic sac tumors of the middle ear

[a]Various DNA mismatch repair gene mutations may cause a similar clinical phenotype, also referred to as Turcot syndrome, in which there is a predisposition to nonpolyposis colon cancer and brain tumors.

Abbreviations: AD, autosomal dominant; APC, adenomatous polyposis coli; AR, autosomal recessive; ch, chromosome; NF, neurofibromatosis; PTEN, phosphatase and tensin homologue; TSC, tuberous sclerosis complex; VHL, von Hippel–Lindau.

GRADE II ASTROCYTOMAS These are infiltrative tumors that usually present with seizures in young adults. They appear as nonenhancing tumors with increased T2/FLAIR signal **(Fig. 86-1)**. If feasible, patients should undergo maximal surgical resection, although complete resection is rarely possible because of the invasive nature of the tumor. In patients at higher risk for recurrence (subtotal resection or above the age of 40 years), there is evidence that radiation therapy (RT) followed by PCV (procarbazine, cyclohexylchloroethylnitrosourea [CCNU], and vincristine) chemotherapy may possibly be of benefit. The tumor transforms to a malignant astrocytoma in most patients, leading to variable survival with a median of ~5–10 years. The minority of grade II astrocytomas without *IDH* mutations have a worse prognosis.

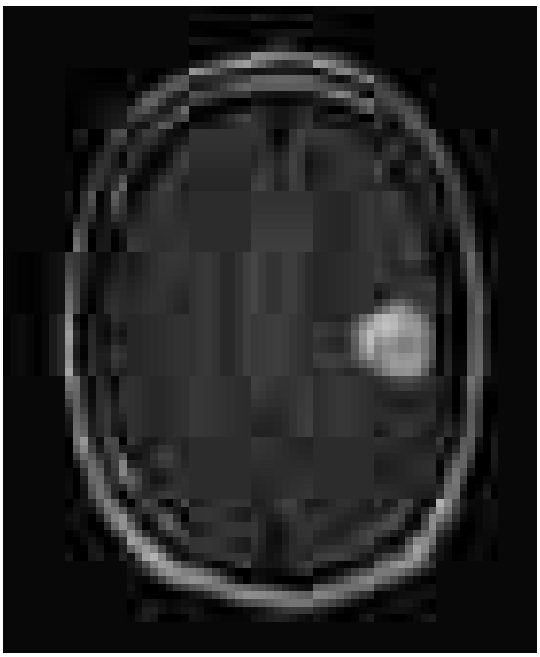

FIGURE 86-1 Fluid-attenuated inversion recovery (FLAIR) MRI of a left frontal low-grade astrocytoma. This lesion did not enhance.

High-Grade Astrocytoma

GRADE III (ANAPLASTIC) ASTROCYTOMA These account for ~15–20% of high-grade astrocytomas. They generally present in the fourth and fifth decades of life as variably enhancing tumors. Treatment is the same as for glioblastoma, consisting of maximal safe surgical resection followed by RT and adjuvant temozolomide alone or RT with concurrent and adjuvant temozolomide.

GRADE IV ASTROCYTOMA (GLIOBLASTOMA) Glioblastoma accounts for the majority of high-grade astrocytomas. Approximately 10% of glioblastoma have *IDH* mutations. These tend to arise from lower-grade tumors (secondary glioblastomas) and have a better prognosis. They are the most common malignant primary brain tumor, with >12,000 cases diagnosed each year in the United States. Patients usually present in the sixth and seventh decades of life with headache, seizures, or focal neurologic deficits. The tumors appear as ring-enhancing masses with central necrosis and surrounding edema **(Fig. 86-2)**. These are highly infiltrative tumors, and the areas of increased T2/FLAIR signal surrounding the main tumor mass contain invading tumor cells. Treatment involves maximal surgical resection followed by partial-field external-beam RT (6000 cGy in thirty 200-cGy fractions) with concomitant temozolomide, followed by 6–12 months of adjuvant temozolomide. With this regimen, median survival is increased to 14.6–18 months compared to only 12 months with RT alone, and 5-year survival is ~10%. Patients whose tumor contains the DNA repair enzyme O^6-methylguanine-DNA methyltransferase (MGMT) are relatively resistant to temozolomide and have a worse prognosis compared to those whose tumors contain low levels of MGMT as a result of silencing of the MGMT gene by promoter hypermethylation. Implantation of biodegradable polymers containing

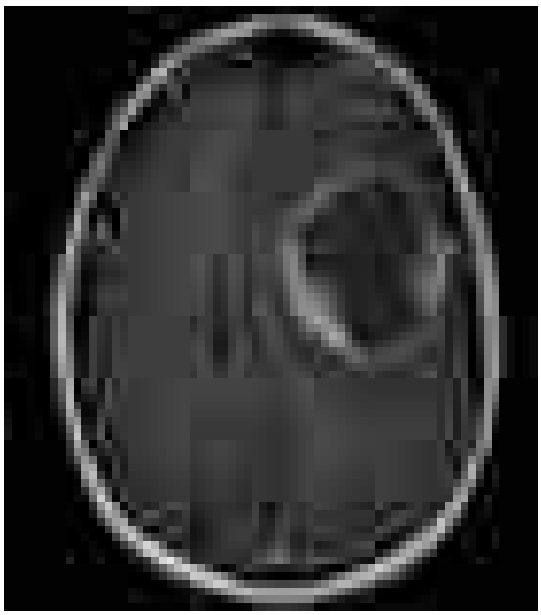

FIGURE 86-2 **Postgadolinium T1 MRI of a large cystic left frontal glioblastoma.**

carmustine chemotherapy into the tumor bed after resection of the tumor, or addition of tumor treating fields (scalp electrodes delivering low intensity electric currents), produces a modest improvement in survival.

For elderly patients aged >65–70 years, a hypofractionated RT regimen of 40 Gy over 3 weeks with temozolomide is well-tolerated and likely leads to similar outcomes as the 6-week standard RT regimen.

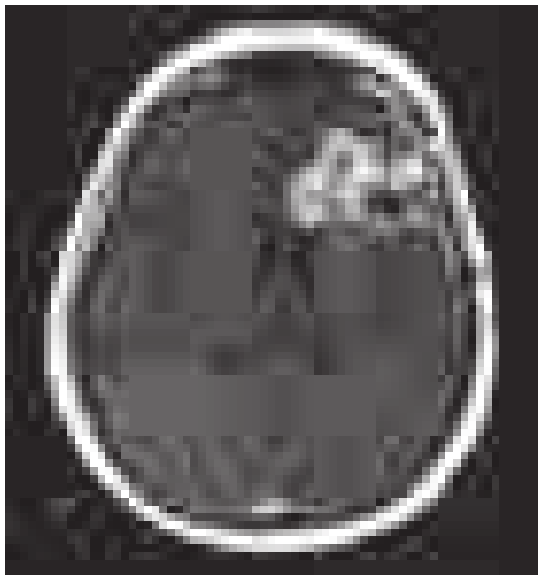
Despite optimal therapy, glioblastomas invariably recur. Treatment options for recurrent disease may include reoperation, carmustine wafers, and alternate chemotherapeutic regimens. Reirradiation is rarely helpful. Bevacizumab, a humanized vascular endothelial growth factor (VEGF) monoclonal antibody, has activity in recurrent glioblastoma, increasing progression-free survival but not overall survival, and reducing peritumoral edema and glucocorticoid use **(Fig. 86-3)**. Treatment decisions for patients with recurrent glioblastoma must be made on an individual basis, taking into consideration such factors as previous therapy, time to relapse, performance status, and quality of life. Whenever feasible, patients with recurrent disease should be enrolled in clinical trials. Novel therapies undergoing evaluation in patients with glioblastoma include targeted molecular agents directed at receptor tyrosine kinases and signal transduction pathways; immunotherapy; oncolytic viruses; antiangiogenic agents; chemotherapeutic agents that cross the blood-brain barrier more effectively than currently available drugs; and infusion of radiolabeled drugs and targeted toxins into the tumor and surrounding brain by means of convection-enhanced delivery.

The most important adverse prognostic factors in patients with glioblastomas are older age, absence of *IDH* mutations, unmethylated MGMT promoter, poor Karnofsky performance status, and unresectable tumor.

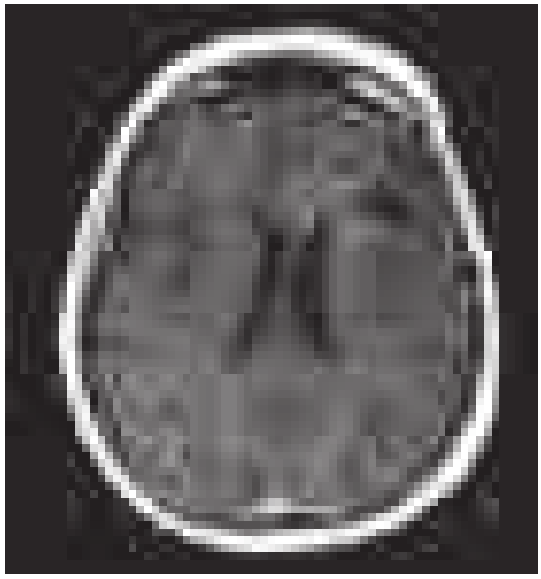
Gliosarcomas are a variant of glioblastoma containing both an astrocytic and a sarcomatous component and are treated in the same way as glioblastomas.

OLIGODENDROGLIOMA

Oligodendrogliomas account for ~15–20% of gliomas. They are characterized by codeletion of 1p/19q and usually have *IDH* mutations. Oligodendrogliomas are classified by the WHO into oligodendrogliomas (grade II) or anaplastic oligodendrogliomas (AOs) (grade III). Oligodendrogliomas have distinctive pathologic features such as perinuclear clearing—giving rise to a "fried-egg" appearance—and a reticular pattern of blood vessel growth. Some tumors have both an oligodendroglial as well as an astrocytic component. With molecular testing, it is now clear that almost all these mixed tumors (oligoastrocytomas) are genetically either astrocytomas or oligodendrogliomas. As a result, the diagnosis of oligoastrocytoma is now rarely made unless molecular testing is not available.



A



B

FIGURE 86-3 **Postgadolinium T1 MRI of a recurrent glioblastoma** before (***A***) and after (***B***) administration of bevacizumab. Note the decreased enhancement and mass effect.

Grade II oligodendrogliomas are generally more responsive to therapy and have a better prognosis than pure astrocytic tumors. These tumors present similarly to grade II astrocytomas in young adults. The tumors are nonenhancing and often partially calcified. They should be treated with surgery and, in patients with residual disease or aged >40 years, RT and chemotherapy. Patients with oligodendrogliomas have a median survival in excess of 10 years.

AOs present in the fourth and fifth decades as variably enhancing tumors. They are more responsive to therapy than grade III astrocytomas. Treatment involves maximal safe resection followed by RT and PCV or temozolomide chemotherapy. Median survival of patients with AO is in excess of 10 years.

EPENDYMOMAS

Ependymomas are tumors derived from ependymal cells that line the ventricular surface. They account for ~5% of childhood tumors and frequently arise from the wall of the fourth ventricle in the posterior fossa. Although adults can have intracranial ependymomas, they occur more commonly in the spine, especially in the filum terminale of the spinal

cord where they have a myxopapillary histology. Ependymomas that can be completely resected are potentially curable. Partially resected ependymomas will recur and require irradiation. The less common anaplastic ependymoma is more aggressive and is treated with resection and RT; chemotherapy has limited efficacy. Subependymomas are slow-growing benign lesions arising in the wall of ventricles that often do not require treatment.

OTHER LESS COMMON GLIOMAS

Gangliogliomas and pleomorphic xanthoastrocytomas occur in young adults. They behave as more indolent forms of grade I gliomas and are usually treated with surgery. Frequently they will have *BRAFV600E* mutations. Brainstem gliomas usually occur in children or young adults. Despite treatment with RT and chemotherapy, the prognosis is poor, with a median survival of only 1 year.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary central nervous system lymphoma (PCNSL) is a rare non-Hodgkin lymphoma accounting for <3% of primary brain tumors. For unclear reasons, its incidence is increasing, particularly in immunocompetent, older individuals.

PCNSL in immunocompetent patients is usually a diffuse large B-cell lymphoma. Immunocompromised patients, especially those infected with the human immunodeficiency virus (HIV) or organ transplant recipients, are at risk for PCNSL that is typically large cell with immunoblastic and more aggressive features. Epstein-Barr virus (EBV) plays an important role in the pathogenesis of PCNSL in this population. These patients are usually severely immunocompromised, with CD4 counts of <50/mL.

Immunocompetent patients with PCNSL are older (median 60 years) compared to those with HIV-related PCNSL (median 31 years). PCNSL usually presents as a mass lesion, with neuropsychiatric symptoms, lateralizing signs, or seizures. Ocular and leptomeningeal involvement each occur in 15–20% of patients.

On contrast-enhanced MRI, PCNSL usually appears as a densely enhancing tumor **(Fig. 86-4)**. Immunocompetent patients have solitary lesions more often than immunosuppressed patients. Frequently there is involvement of the basal ganglia, corpus callosum, or periventricular region. Stereotactic biopsy is necessary to obtain a histologic diagnosis. Whenever possible, glucocorticoids should be withheld until after the biopsy has been obtained because they have a cytolytic effect on lymphoma cells and may lead to nondiagnostic tissue. In addition, patients should be tested for HIV, and the extent of disease should be assessed by performing PET or CT of the body, MRI of the spine, CSF analysis, and slit-lamp examination of the eye. Bone marrow biopsy and testicular ultrasound are occasionally performed.

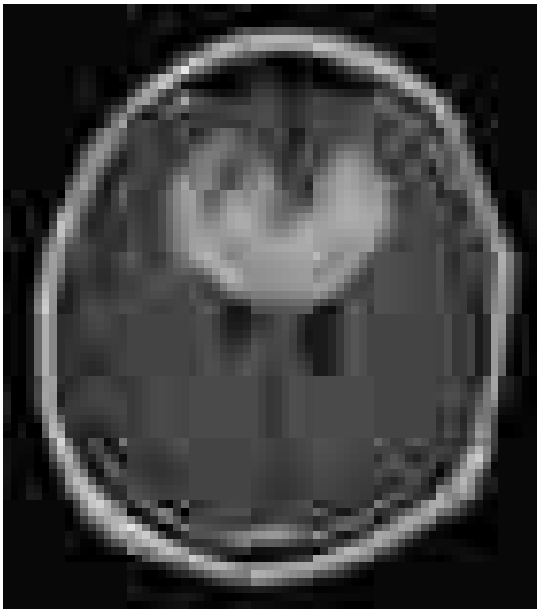


FIGURE 86-4 Postgadolinium T1 MRI demonstrating a large bifrontal primary central nervous system lymphoma (PCNSL). The periventricular location and diffuse enhancement pattern are characteristic of lymphoma.

TREATMENT

Primary Central Nervous System Lymphoma

PCNSL is more sensitive to glucocorticoids, chemotherapy, and RT than other primary brain tumors. Durable complete responses and long-term survival are possible with these treatments. High-dose methotrexate, a folate antagonist that interrupts DNA synthesis, produces response rates ranging from 35 to 80% and median survival of up to 50 months. The combination of methotrexate with other chemotherapeutic agents such as cytarabine increases the response rate to 70–100%. The addition of whole-brain RT to methotrexate-based chemotherapy prolongs progression-free survival but not overall survival, but it is associated with delayed neurotoxicity, especially in patients aged >60 years. As a result, full-dose RT is frequently omitted, but there may be a role for reduced-dose RT. The anti-CD20 monoclonal antibody rituximab has activity in PCNSL and is often incorporated into the chemotherapy regimen. For some patients, high-dose chemotherapy with autologous stem cell rescue may offer the best chance of preventing relapse. At least 50% of patients will eventually develop recurrent disease. Treatment options include RT for patients who have not had prior irradiation, re-treatment with methotrexate, as well as other agents such as temozolomide, rituximab, procarbazine, topotecan, and pemetrexed. High-dose chemotherapy with autologous stem cell rescue may be appropriate in selected patients with relapsed disease.

PCNSL IN IMMUNOCOMPROMISED PATIENTS

PCNSL in immunocompromised patients often produces multiple ring-enhancing lesions that can be difficult to differentiate from metastases or infections such as toxoplasmosis. The diagnosis is usually established by examination of the CSF for cytology and EBV DNA, toxoplasmosis serologic testing, brain PET imaging for hypermetabolism of the lesions which, although nonspecific, can be consistent with tumor, and, if necessary, brain biopsy. Since the advent of highly active antiretroviral drugs, the incidence of HIV-related PCNSL has declined. These patients are preferably treated with high-dose methotrexate-based regimens and initiation of highly active antiretroviral therapy; whole-brain RT is reserved for those who cannot tolerate systemic chemotherapy. In organ transplant recipients, reduction of immunosuppression may improve outcome.

MEDULLOBLASTOMAS

Medulloblastomas are the most common malignant brain tumor of childhood, accounting for ~20% of all primary CNS tumors among children. They arise from granule cell progenitors or from multipotent progenitors from the ventricular zone. Approximately 5% of children with medulloblastoma have an inherited syndrome, such as Gorlin, Turcot, or Li-Fraumeni, which predisposes to the development of medulloblastoma. Histologically, medulloblastomas are highly cellular tumors with abundant dark staining, round nuclei, and rosette formation (Homer-Wright rosettes). In the 2016 WHO pathologic classification, they have been divided into four molecular subgroups: (1) WNT-activated (primarily affects children and has the best outcome); (2) SHH-activated (affects adults, infants, and children with the younger patients having the better outcome and adults doing poorly); (3) non-WNT/non-SHH, group 3 (frequently has disseminated CNS disease at diagnosis and has the worst outcome); and (4) non-WNT/non-SHH, group 4 (30% have metastases at diagnosis, but 5-year progression-free survival is 95%). Regardless of subtype, patients present with headache, ataxia, and signs of brainstem involvement. On MRI they appear as densely enhancing tumors in the posterior fossa, sometimes associated with hydrocephalus. Treatment involves maximal surgical resection, craniospinal irradiation, and chemotherapy with agents such as cisplatin, lomustine, cyclophosphamide, and vincristine. Approximately 70% of

patients overall have long-term survival but usually at the cost of significant neurocognitive impairment. A major goal of current research is to improve survival while minimizing long-term complications, and clinical trials are now being designed for specific molecular subgroups.

PINEAL REGION TUMORS

A large number of tumors can arise in the region of the pineal gland. These typically present with headache, visual symptoms, and hydrocephalus. Patients may have Parinaud's syndrome characterized by impaired upgaze and accommodation. Some pineal tumors such as pineocytomas and benign teratomas can be treated by surgical resection. Germinomas respond to irradiation, whereas pineoblastomas and nongerminomatous germ cell tumors require craniospinal radiation and chemotherapy.

EXTRINSIC "BENIGN" TUMORS

MENINGIOMAS

Meningiomas are diagnosed with increasing frequency as more people undergo neuroimaging for various indications. They are now the most common primary brain tumor, accounting for ~35% of the total. Their incidence increases with age. They tend to be more common in women and in patients with neurofibromatosis type 2 (NF2). They also occur more commonly in patients with a past history of cranial irradiation.

Meningiomas arise from the dura mater and are composed of neoplastic meningothelial (arachnoidal cap) cells. They are most commonly located over the cerebral convexities, especially adjacent to the sagittal sinus, but they can also occur in the skull base and along the dorsum of the spinal cord. Meningiomas are classified by the WHO into three histologic grades of increasing aggressiveness: grade I (benign), grade II (atypical), and grade III (malignant).

Many meningiomas are found incidentally following neuroimaging for unrelated reasons. They can also present with headaches, seizures, or focal neurologic deficits. On imaging studies they have a characteristic appearance usually of a densely enhancing extra-axial tumor arising from the dura **(Fig. 86-5)**. Typically they have a dural tail, consisting of thickened, enhanced dura extending like a tail from the mass. The main differential diagnosis of meningioma is a dural metastasis.

If the meningioma is small and asymptomatic, no intervention is necessary and the lesion can be observed with serial MRI studies. Larger, symptomatic lesions should be resected. If complete resection is achieved, the patient is cured. Incompletely resected tumors tend to recur, although the rate of recurrence can be very slow with grade I tumors. Tumors that cannot be resected, or can only be partially removed, may benefit from external-beam RT or stereotactic radiosurgery (SRS). These treatments may also be helpful in patients whose tumor has recurred after surgery. Hormonal therapy and chemotherapy are currently unproven.

Rarer tumors that resemble meningiomas include hemangiopericytomas and solitary fibrous tumors. Since they share similar molecular alterations, the 2016 WHO classification introduced the combined term solitary fibrous tumor/hemangiopericytoma for this entity. These tumors are treated with surgery and RT but have a higher propensity to recur locally or metastasize systemically.

SCHWANNOMAS

These are generally benign tumors arising from the Schwann cells of cranial and spinal nerve roots. The most common schwannomas, termed *vestibular schwannomas* or *acoustic neuromas*, arise from the vestibular portion of the eighth cranial nerve and account for ~9% of primary brain tumors. Patients with NF2 have a high incidence of vestibular schwannomas that are frequently bilateral. Schwannomas arising from other cranial nerves, such as the trigeminal nerve (cranial nerve V), occur with much lower frequency. Neurofibromatosis type 1 (NF1) is associated with an increased incidence of schwannomas of the spinal nerve roots.

Vestibular schwannomas may be found incidentally on neuroimaging or present with progressive unilateral hearing loss, dizziness, tinnitus, or, less commonly, symptoms resulting from compression of the brainstem and cerebellum. On MRI they appear as densely enhancing lesions, enlarging the internal auditory canal and often extending into the cerebellopontine angle **(Fig. 86-6)**. The differential diagnosis includes meningioma. Very small, asymptomatic lesions can be observed with serial MRIs. Larger lesions should be treated with surgery or SRS. The optimal treatment will depend on the size of the tumor, symptoms, and the patient's preference. In patients with small vestibular schwannomas and relatively intact hearing, early surgical intervention increases the chance of preserving hearing.

PITUITARY TUMORS

These are discussed in detail in **Chap. 373**.

CRANIOPHARYNGIOMAS

Craniopharyngiomas are rare, usually suprasellar, partially calcified, solid, or mixed solid-cystic benign tumors that arise from remnants of Rathke's pouch. They have a bimodal distribution, occurring predominantly in children but also between the ages of 55 and 65 years.

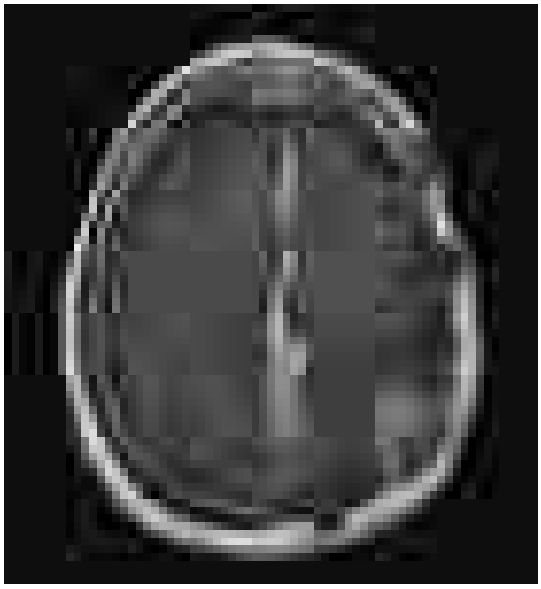

FIGURE 86-5 Postgadolinium T1 MRI demonstrating multiple meningiomas along the falx and left parietal cortex.

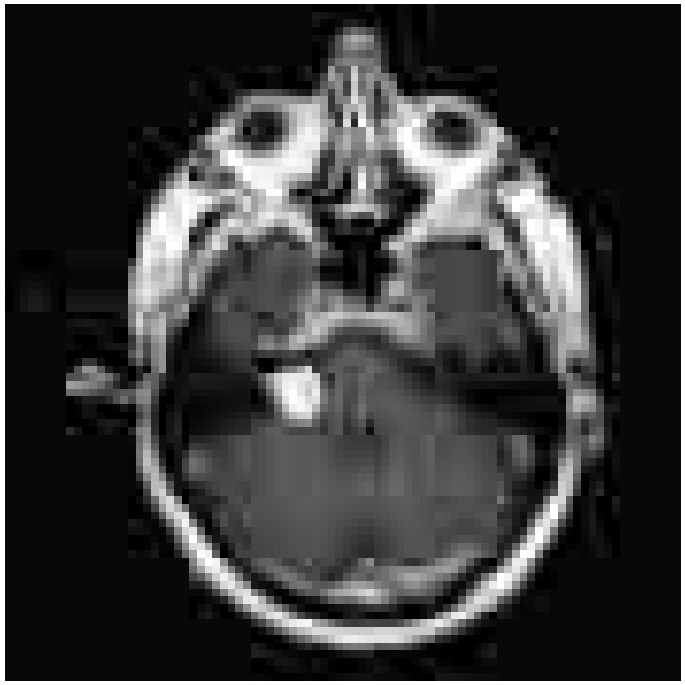

FIGURE 86-6 Postgadolinium MRI of a right vestibular schwannoma. The tumor can be seen to involve the internal auditory canal.

They present with headaches, visual impairment, and impaired growth in children and hypopituitarism in adults. Treatment involves surgery, RT, or a combination of the two.

OTHER BENIGN TUMORS

Dysembryoplastic Neuroepithelial Tumors (DNTs) These are benign, supratentorial tumors, usually in the temporal lobe. They typically occur in children and young adults with a long-standing history of seizures. Surgical resection is curative.

Epidermoid Cysts These consist of squamous epithelium surrounding a keratin-filled cyst. They are usually found in the cerebellopontine angle and the intrasellar and suprasellar regions. They may present with headaches, cranial nerve abnormalities, seizures, or hydrocephalus. MRI demonstrates an extra-axial lesion with characteristics that are similar to CSF but have restricted diffusion. Treatment involves surgical resection.

Dermoid Cysts Like epidermoid cysts, dermoid cysts arise from epithelial cells that are retained during closure of the neural tube. They contain both epidermal and dermal structures such as hair follicles, sweat glands, and sebaceous glands. Unlike epidermoid cysts, these tumors usually have a midline location. They occur most frequently in the posterior fossa, especially the vermis, fourth ventricle, and suprasellar cistern. On MRI, dermoid cysts resemble lipomas, demonstrating T1 hyperintensity and variable signal on T2. Symptomatic dermoid cysts can be treated with surgery.

Colloid Cysts These usually arise in the anterior third ventricle and may present with headaches, hydrocephalus, and, very rarely, sudden death. Surgical resection is curative, or a third ventriculostomy may relieve the obstructive hydrocephalus and be sufficient therapy.

NEUROCUTANEOUS SYNDROMES (PHAKOMATOSES)

A number of genetic disorders are characterized by cutaneous lesions and an increased risk of brain tumors. Most of these disorders have an autosomal dominant inheritance with variable penetrance.

NEUROFIBROMATOSIS TYPE 1 (NF1) (von RECKLINGHAUSEN'S DISEASE)

NF1 is an autosomal dominant disorder with variable penetrance and an incidence of ~1 in 2600–3000. Approximately one-half of cases are familial; the remainder are caused by new mutations arising in patients with unaffected parents. The *NF1* gene on chromosome 17q11.2 encodes neurofibromin, a guanosine triphosphatase (GTPase)-activating protein (GAP) that modulates signaling through the RAS pathway. Mutations of *NF1* result in a large number of nervous system tumors including neurofibromas, plexiform neurofibromas, optic nerve gliomas, astrocytomas, and meningiomas. In addition to neurofibromas, which appear as multiple, soft, rubbery cutaneous tumors, other cutaneous manifestations of NF1 include café-au-lait spots and axillary freckling. NF1 is also associated with hamartomas of the iris termed Lisch nodules, pheochromocytomas, pseudoarthrosis of the tibia, scoliosis, epilepsy, and mental retardation.

NEUROFIBROMATOSIS TYPE 2 (NF2)

NF2 is less common than NF1, with an incidence of 1 in 25,000–40,000. It is an autosomal dominant disorder with full penetrance. As with NF1, approximately one-half of cases arise from new mutations. The *NF2* gene on 22q encodes a cytoskeletal protein, merlin (moesin, ezrin, radixin-like protein) that functions as a tumor suppressor. NF2 is characterized by bilateral vestibular schwannomas in >90% of patients, multiple meningiomas, and spinal ependymomas and astrocytomas. Treatment of bilateral vestibular schwannomas can be challenging because the goal is to preserve hearing for as long as possible. These patients may also have diffuse schwannomatosis that may affect the cranial, spinal, or peripheral nerves; posterior subcapsular lens opacities; and retinal hamartomas.

TUBEROUS SCLEROSIS (BOURNEVILLE DISEASE)

This is an autosomal dominant disorder with an incidence of ~1 in 5000–10,000 live births. It is caused by mutations in either the *TSC1* gene, which maps to chromosome 9q34 and encodes a protein termed hamartin, or the *TSC2* gene, which maps to chromosome 16p13.3 and encodes the protein tuberin. Hamartin forms a complex with tuberin, which inhibits cellular signaling through mTOR, and acts as a negative regulator of the cell cycle. Patients with tuberous sclerosis may have seizures, mental retardation, adenoma sebaceum (facial angiofibromas), shagreen patch, hypomelanotic macules, periungual fibromas, renal angiomyolipomas, and cardiac rhabdomyomas. These patients have an increased incidence of subependymal nodules, cortical tubers, and subependymal giant-cell astrocytomas (SEGAs). Patients frequently require anticonvulsants for seizures. SEGAs do not always require therapeutic intervention, but the most effective therapy is with the mTOR inhibitors sirolimus or everolimus, which often decrease seizures as well as SEGA size.

TUMORS METASTATIC TO THE BRAIN

Brain metastases arise from hematogenous spread and frequently originate from a lung primary or are associated with pulmonary metastases. Most metastases develop at the gray matter–white matter junction in the watershed distribution of the brain where intravascular tumor cells lodge in terminal arterioles. The distribution of metastases in the brain approximates the proportion of blood flow such that ~85% of all metastases are supratentorial and 15% occur in the posterior fossa. The most common sources of brain metastases are lung and breast carcinomas; melanoma has the greatest propensity to metastasize to the brain, being found in 80% of patients at autopsy (Table 86-3). Other tumor types such as ovarian and esophageal carcinoma rarely metastasize to the brain. Prostate and breast cancers also have a propensity to metastasize to the dura and can mimic meningioma. Leptomeningeal metastases are common from hematologic malignancies and also breast and lung cancers. Spinal cord compression primarily arises in patients with prostate and breast cancer, tumors with a strong propensity to metastasize to the axial skeleton.

DIAGNOSIS OF METASTASES

Brain metastases are best visualized on MRI, where they usually appear as well-circumscribed lesions (Fig. 86-7). The amount of perilesional edema can be highly variable, with large lesions causing minimal edema and sometimes very small lesions causing extensive edema. Enhancement may be in a ring pattern or diffuse. Occasionally, intracranial metastases will hemorrhage; although melanoma, thyroid, and kidney cancer have the greatest propensity to hemorrhage, the most common cause of a hemorrhagic metastasis is lung cancer because it accounts for the majority of brain metastases. The radiographic appearance of brain metastasis is nonspecific, and similar-appearing lesions can occur with infection including brain abscesses and also with demyelinating lesions, sarcoidosis, radiation necrosis in a previously treated patient, or a primary brain tumor that may be a second malignancy in a patient with systemic cancer. Biopsy is rarely necessary for diagnosis because imaging alone in the appropriate clinical situation usually suffices. However, in

TABLE 86-3 Frequency of Nervous System Metastases by Common Primary Tumors

	BRAIN (%)	LM (%)	ESCC (%)
Lung	41	17	15
Breast	19	57	22
Melanoma	10	12	4
Prostate	1	1	10
GIT	7	—	5
Renal	3	2	7
Lymphoma	<1	10	10
Sarcoma	7	1	9
Other	11	—	18

Abbreviations: ESCC, epidural spinal cord compression; GIT, gastrointestinal tract; LM, leptomeningeal metastases.

~10% of patients, a systemic cancer may present with a brain metastasis, and if there is not an easily accessible systemic site to biopsy, a brain lesion must be removed for diagnostic purposes.

TREATMENT

Tumors Metastatic to the Brain

DEFINITIVE TREATMENT

The number and location of brain metastases often determine the therapeutic options. The patient's overall condition and current or potential control of systemic disease are also major determinants. Brain metastases are single in approximately one-half of patients and multiple in the other half.

RADIATION THERAPY

The standard treatment for brain metastases has previously been whole-brain radiotherapy (WBRT) usually administered to a total dose of 3000 cGy in 10 fractions. This affords rapid palliation, and ~80% of patients improve with glucocorticoids and RT. However, it is not curative, is associated with neurocognitive toxicity, and produces median survival of only 4–6 months. If feasible, SRS has become the primary radiation oncology approach to brain metastases. It can be delivered through a variety of equally effective techniques including the gamma knife, linear accelerator, proton beam, or CyberKnife, all of which can deliver highly focused doses of RT, usually in a single fraction. SRS can effectively sterilize the visible lesions and afford local disease control in 80–90% of patients. Some patients have been cured of their brain metastases using SRS, whereas this is distinctly rare with WBRT. Traditionally SRS was used only for patients with 1–3 metastases, but recent data suggest that SRS can effectively treat up to 10 lesions. It is, however, confined to lesions of ≤3 cm and is most effective in metastases of ≤1 cm. The addition of WBRT to SRS improves disease control in the nervous system but does not prolong survival and thus is rarely employed.

SURGERY

Randomized controlled trials have demonstrated that surgical extirpation of a single brain metastasis followed by WBRT is superior to WBRT alone. Removal of two lesions or a single symptomatic mass, particularly if compressing the ventricular system, can also be useful. This is particularly important in patients who have highly radioresistant lesions such as renal carcinoma. Surgical resection can produce rapid amelioration of symptoms, improve control of edema, and result in prolonged survival. WBRT administered after complete resection of a brain metastasis improves disease control but does not prolong survival. Some centers administer focal RT or even SRS to a resected cavity, especially if there is concern that tumor has been left behind.

CHEMOTHERAPY

Chemotherapy is becoming increasingly useful for brain metastases. Metastases from tumor types that are highly chemosensitive, such as germ cell tumors or small-cell lung cancer, may respond to chemotherapeutic regimens chosen according to the underlying malignancy. Increasingly, there are data demonstrating responsiveness of brain metastases to chemotherapy including targeted therapy, such as for patients with lung cancer harboring EGFR mutations that sensitize them to EGFR inhibitors. Immunotherapy may also be effective against those primary tumors that are sensitive to this approach, such as melanoma. Antiangiogenic agents such as bevacizumab are also effective in the treatment of CNS metastases in those primary tumors for which it is approved.

LEPTOMENINGEAL METASTASES

Leptomeningeal metastases are also described as carcinomatous meningitis, meningeal carcinomatosis, or in the case of specific tumors, leukemic or lymphomatous meningitis. Among the hematologic malignancies, acute leukemias most commonly metastasize to the subarachnoid space, followed in frequency by aggressive diffuse lymphomas. Among solid tumors, breast and lung carcinomas and melanoma most frequently spread in this fashion. Tumor cells reach the subarachnoid space via the arterial circulation or occasionally through retrograde flow in venous systems that drain metastases along the bony spine or cranium. In addition, leptomeningeal metastases may develop as a direct consequence of prior brain metastases and occur in almost 40% of patients who have a metastasis resected from the cerebellum.

CLINICAL FEATURES

Leptomeningeal metastases are characterized by multilevel symptoms and signs along the neuraxis. Combinations of lumbar and cervical radiculopathies, cranial neuropathies, seizures, confusion, and encephalopathy from hydrocephalus or raised intracranial pressure can be present. Focal deficits such as hemiparesis or aphasia are rarely due

to leptomeningeal metastases unless there is direct brain infiltration. New-onset limb pain in patients with breast cancer, lung cancer, or melanoma should prompt consideration of leptomeningeal spread.

LABORATORY AND IMAGING DIAGNOSIS

Leptomeningeal metastases are particularly challenging to diagnose because identification of tumor cells in the subarachnoid compartment may be elusive. MRI can be definitive when there are clear tumor nodules adherent to the cauda equina or spinal cord, enhancing cranial nerves, or subarachnoid enhancement on brain imaging (Fig. 86-8). Imaging is diagnostic in ~75% of patients and is more often positive in patients with solid tumors. Demonstration of tumor cells in the CSF is definitive and often considered the gold standard. However, CSF cytologic examination is positive in only 50% of patients on the first lumbar puncture and still misses 10% after three CSF samples. New technologies, such as rare cell capture, enhance identification of tumor cells in the CSF. CSF cytologic examination is most useful in hematologic malignancies, especially when combined with flow cytometry to identify a clonal population. Accompanying CSF abnormalities include an elevated protein concentration and an elevated white count; hypoglycorrhachia is noted in <25% of patients but is useful when present. Identification of tumor markers may be helpful in some solid tumors.

B

FIGURE 86-8 Postgadolinium MRI images of extensive leptomeningeal metastases from breast cancer. Nodules along the dorsal surface of the spinal cord (***A***) and cauda equina (***B***) are seen.

TREATMENT

Leptomeningeal Metastases

The treatment of leptomeningeal metastasis is palliative because there is no curative therapy. RT to the symptomatically involved areas, such as skull base for cranial neuropathy, can relieve pain and sometimes improve function. Whole-neuraxis RT is avoided because it has significant toxicity with myelosuppression and gastrointestinal irritation as well as limited effectiveness. Systemic chemotherapy with agents that can penetrate the blood-CSF barrier may be helpful. Alternatively, intrathecal chemotherapy can be effective, particularly in hematologic malignancies. This is optimally delivered through an intraventricular cannula (Ommaya reservoir) rather than by lumbar puncture. Few drugs can be delivered safely into the subarachnoid space, and they have a limited spectrum of antitumor activity, perhaps accounting for the relatively poor response to this approach. In addition, impaired CSF flow dynamics can compromise intrathecal drug delivery. Surgery has a limited role in leptomeningeal metastasis; a ventriculoperitoneal shunt can relieve raised intracranial pressure; however, it compromises delivery of chemotherapy into the CSF.

EPIDURAL METASTASIS

Epidural metastasis occurs in 3–5% of patients with a systemic malignancy and causes neurologic compromise by compressing the spinal cord or cauda equina. The most common cancers that metastasize to the epidural space are those malignancies that spread to bone, such as breast and prostate. Lymphoma can cause bone involvement and compression, but it can also invade an intervertebral foramen and cause spinal cord compression without bone destruction. The thoracic spine is affected most commonly, followed by the lumbar and then cervical spine.

CLINICAL FEATURES

Back pain is the presenting symptom of epidural metastasis in virtually all patients; the pain may precede neurologic findings by weeks or months. The pain is usually exacerbated by lying down; by contrast, arthritic pain is often relieved by recumbency. Leg weakness is seen in ~50% of patients, as is sensory dysfunction. Sphincter problems are present in ~25% of patients at diagnosis.

DIAGNOSIS

Diagnosis is established by imaging, preferably with an MRI of the entire spine (Fig. 86-9). Contrast is not required to identify bony or epidural lesions. Any patient with cancer who has severe back pain should undergo an MRI. Plain films, bone scans, or even CT scans may show bone metastases, but only MRI can reliably delineate epidural tumor. For patients unable to have an MRI, CT myelography should be performed to outline the epidural space. The differential diagnosis of epidural tumor includes epidural abscess, acute or chronic hematomas, epidural lipomatosis and rarely, extramedullary hematopoiesis.

TREATMENT

Epidural Metastasis

Epidural metastasis requires immediate treatment. A randomized controlled trial demonstrated the superiority of surgical resection followed by RT compared to RT alone. However, patients must be able to tolerate surgery, and the surgical procedure of choice is

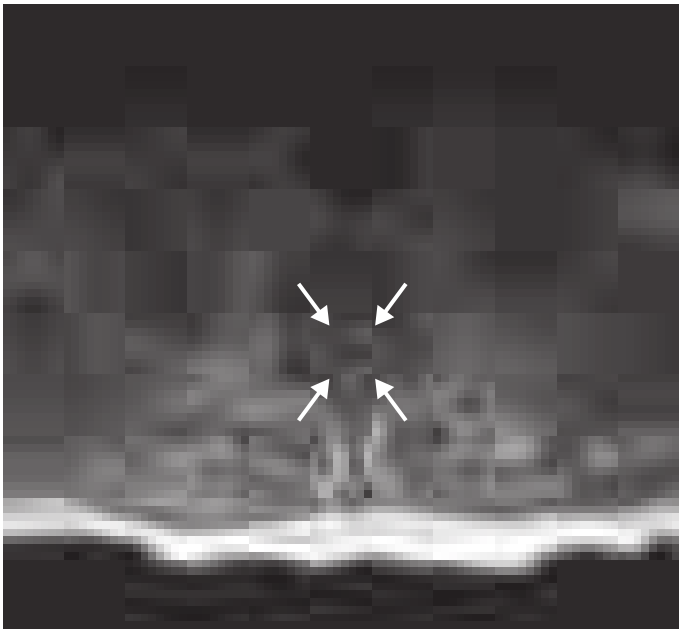

FIGURE 86-9 Postgadolinium T1 MRI showing circumferential epidural tumor around the thoracic spinal cord from esophageal cancer.

a complete removal of the mass, which is typically anterior to the spinal canal, necessitating an extensive approach and resection. Otherwise, RT is the mainstay of treatment and can be used for patients with radiosensitive tumors, such as lymphoma, or for those unable to undergo surgery. SRS is increasingly being used, especially for radioresistant tumor types or for re-irradiation. Chemotherapy is rarely used for epidural metastasis unless the patient has minimal to no neurologic deficit and a highly chemosensitive tumor such as lymphoma or germinoma. Patients generally fare well if treated before there is a severe neurologic deficit. Recovery from paraparesis is better after surgery than with RT alone, but survival is often short due to widespread metastatic tumor.

NEUROLOGIC TOXICITY OF THERAPY

TOXICITY FROM RADIOTHERAPY

RT can cause a variety of toxicities in the CNS. These are usually described based on their relationship in time to the administration of RT: acute (occurring within days of RT), early delayed (months), or late delayed (years). In general, the acute and early delayed syndromes resolve and do not result in persistent deficits, whereas the late delayed toxicities are usually permanent and sometimes progressive.

Acute Toxicity Acute cerebral toxicity may occur during the course of RT to the brain. RT can cause a transient disruption of the blood-brain barrier, resulting in edema and elevated intracranial pressure. This is usually manifest as headache, lethargy, nausea, and vomiting, and can be both prevented and treated with the administration of glucocorticoids. There is no acute RT toxicity that affects the spinal cord.

Early Delayed Toxicity Early delayed toxicity is usually apparent weeks to months after completion of cranial irradiation and is likely due to focal demyelination. Clinically it may be asymptomatic or take the form of worsening or reappearance of a preexisting neurologic deficit. At times a contrast-enhancing lesion can be seen on MRI/CT that can mimic the tumor for which the patient received the RT. For patients with a malignant glioma, this has been described as "pseudoprogression" because it mimics tumor recurrence on MRI but actually represents inflammation and necrotic debris engendered by effective therapy. This is seen with increased frequency when chemotherapy, particularly temozolomide, is given concurrently with RT. Pseudoprogression can resolve on its own or, if very symptomatic, may require resection.

In the spinal cord, early delayed RT toxicity is manifest as a Lhermitte symptom with paresthesias of the limbs or along the spine when the patient flexes the neck. Although frightening, it is benign, resolves on its own, and does not portend more serious problems.

Late Delayed Toxicity Late delayed toxicities are the most serious because they are often irreversible and cause severe neurologic deficits. In the brain, late toxicities can take several forms, the most common of which include radiation necrosis and leukoencephalopathy. Radiation necrosis is a focal mass of necrotic tissue that is contrast enhancing on CT/MRI and may be associated with significant edema. This may appear identical to pseudoprogression but is seen months to years after RT and is always symptomatic. Clinical symptoms and signs include seizures and findings referable to the location of the necrotic mass. The necrosis is caused by the effect of RT on cerebral vasculature with fibrinoid necrosis and occlusion of blood vessels. It can mimic tumor radiographically, but unlike tumor it is typically hypometabolic on a PET scan and has reduced perfusion on perfusion MR sequences. It may require resection for diagnosis and treatment unless it can be managed with glucocorticoids. There are reports of improvement with hyperbaric oxygen or bevacizumab, but symptomatic benefit does not always accompany radiographic improvement.

Leukoencephalopathy is seen most commonly after WBRT as opposed to focal RT. On T2 or FLAIR MR sequences, there is diffusely increased signal seen throughout the hemispheric white matter, often bilaterally and symmetrically. There tends to be a periventricular predominance that may be associated with atrophy and ventricular enlargement. Clinically, patients develop cognitive impairment, a gait disorder, and later urinary incontinence, all of which can progress over time. These symptoms mimic those of normal pressure hydrocephalus, and placement of a ventriculoperitoneal shunt can improve function in some patients but does not reverse the deficits completely. Increased age is a risk factor for leukoencephalopathy but not for radiation necrosis. Necrosis appears to depend on an as yet unidentified predisposition.

Other late neurologic toxicities include endocrine dysfunction if the pituitary or hypothalamus was included in the RT port. An RT-induced neoplasm can occur many years after therapeutic RT for either a prior CNS or a head and neck tumor; accurate diagnosis requires surgical resection or biopsy. In addition, RT causes accelerated atherosclerosis, which can cause stroke either from intracranial vascular disease or carotid plaque from neck irradiation.

The peripheral nervous system is relatively resistant to RT toxicities. Peripheral nerves are rarely affected by RT, but the plexus is more vulnerable. Plexopathy develops more commonly in the brachial than in the lumbosacral distribution. It must be differentiated from tumor progression in the plexus, which is usually visualized by CT/MRI or PET scan demonstrating tumor infiltrating the region. Clinically, tumor progression is usually painful, whereas RT-induced plexopathy is painless. Radiation plexopathy is also more commonly associated with lymphedema of the affected limb. Sensory loss and weakness are seen in both.

TOXICITY FROM CHEMOTHERAPY

Neurotoxicity is second to myelosuppression as the dose-limiting toxicity of chemotherapeutic agents (Table 86-4). Chemotherapy causes peripheral neuropathy from a number of commonly used agents, and the type of neuropathy can vary depending on the drug. Vincristine causes paresthesias but little sensory loss and is associated with motor dysfunction, autonomic impairment (frequently ileus), and, rarely, cranial nerve compromise. Cisplatin causes large fiber sensory loss resulting in sensory ataxia but little cutaneous sensory loss and no weakness. The taxanes also cause a predominately sensory neuropathy. Agents such as bortezomib and thalidomide also cause neuropathy.

Encephalopathy and seizures are common toxicities from chemotherapeutic drugs. Ifosfamide can cause a severe encephalopathy, which is reversible with discontinuation of the drug and the use of methylene blue for severely affected patients. Fludarabine also causes a severe global encephalopathy that may be permanent. Bevacizumab

TABLE 86-4 Neurologic Signs Caused by Agents Commonly Used in Patients with Cancer

Acute encephalopathy (delirium)	Seizures
Methotrexate (high-dose IV, IT)	Methotrexate
Cisplatin	Etoposide (high-dose)
Vincristine	Cisplatin
Asparaginase	Vincristine
Procarbazine	Asparaginase

Cytarabine (high-dose)	Carmustine
Nitrosoureas (high-dose or arterial)	Dacarbazine (intraarterial or high-dose)
Ifosfamide	Busulfan (high-dose)
Etoposide (high-dose)	Myelopathy (IT drugs)
Bevacizumab (PRES)	Methotrexate
Chronic encephalopathy (dementia)	Cytarabine
Methotrexate	Thiotepa
Carmustine	Peripheral neuropathy
Cytarabine	Vinca alkaloids
Fludarabine	Cisplatin
Visual loss	Procarbazine
Tamoxifen	Etoposide
Gallium nitrate	Teniposide
Cisplatin	Cytarabine
Fludarabine	Taxanes
Cerebellar dysfunction/ataxia	Suramin
5-Fluorouracil (± levamisole)	Bortezomib
Cytarabine	
Procarbazine	

Abbreviations: IT, intrathecal; IV, intravenous; PRES, posterior reversible encephalopathy syndrome.

and other anti-VEGF agents can cause posterior reversible encephalopathy syndrome. Cisplatin can cause hearing loss and less frequently vestibular dysfunction. Immunotherapy with monoclonal antibodies such as ipilimumab or nivolumab can cause an autoimmune hypophysitis, Guillain-Barré syndrome, or an autoimmune encephalitis.

87 Soft Tissue and Bone Sarcomas and Bone Metastases

Shreyaskumar R. Patel

Sarcomas are rare (<1% of all malignancies) mesenchymal neoplasms that arise in bone and soft tissues. These tumors are usually of mesodermal origin, although a few are derived from neuroectoderm, and they are biologically distinct from the more common epithelial malignancies. Sarcomas affect all age groups; 15% are found in children <15 years of age, and 40% occur after age 55 years. Sarcomas are one of the most common solid tumors of childhood and are the fifth most common cause of cancer deaths in children. Sarcomas may be divided into two groups, those derived from bone and those derived from soft tissues.

SOFT TISSUE SARCOMAS

Soft tissues include muscles, tendons, fat, fibrous tissue, synovial tissue, vessels, and nerves. Approximately 60% of soft tissue sarcomas arise in the extremities, with the lower extremities involved three times as often as the upper extremities. Thirty percent arise in the trunk, the retroperitoneum accounting for 40% of all trunk lesions. The remaining 10% arise in the head and neck.

INCIDENCE

Approximately 12,310 new cases of soft tissue sarcomas occurred in the United States in 2016. The annual age-adjusted incidence is 3 per 100,000 population, but the incidence varies with age. Soft tissue sarcomas constitute 0.7% of all cancers in the general population and 6.5% of all cancers in children.

EPIDEMIOLOGY

Malignant transformation of a benign soft tissue tumor is extremely rare, with the exception that malignant peripheral nerve sheath tumors (neurofibrosarcoma, malignant schwannoma) can arise from neurofibromas in patients with neurofibromatosis. Several etiologic factors have been implicated in soft tissue sarcomas.

Environmental Factors Trauma or previous injury is rarely involved, but sarcomas can arise in scar tissue resulting from a prior operation, burn, fracture, or foreign body implantation. Chemical carcinogens such as polycyclic hydrocarbons, asbestos, and dioxin may be involved in the pathogenesis.

Iatrogenic Factors Sarcomas in bone or soft tissues occur in patients who are treated with radiation therapy. The tumor nearly always arises in the irradiated field. The risk increases with time.

Viruses Kaposi's sarcoma (KS) in patients with HIV type 1, classic KS, and KS in HIV-negative homosexual men is caused by human herpesvirus (HHV) 8 (Chap. 190). No other sarcomas are associated with viruses.

Immunologic Factors Congenital or acquired immunodeficiency, including therapeutic immunosuppression, increases the risk of sarcoma.

GENETIC CONSIDERATIONS

Li-Fraumeni syndrome is a familial cancer syndrome in which affected individuals have germline abnormalities of the tumor-suppressor gene *p53* and an increased incidence of soft tissue sarcomas and other malignancies, including breast cancer, osteosarcoma, brain tumor, leukemia, and adrenal carcinoma (Chap. 67). Neurofibromatosis 1 (*NF-1*, peripheral form, von Recklinghausen's disease) is characterized by multiple neurofibromas and café-au-lait spots. Neurofibromas occasionally undergo malignant degeneration to become malignant peripheral nerve sheath tumors. The gene for *NF-1*

is located in the pericentromeric region of chromosome 17 and encodes neurofibromin, a tumor-suppressor protein with guanosine 5′-triphosphate (gtp)ase-activating activity that inhibits ras function **(Chap. 86)**. Germline mutation of the *Rb-1* locus (chromosome 13q14) in patients with inherited retinoblastoma is associated with the development of osteosarcoma in those who survive the retinoblastoma and of soft tissue sarcomas unrelated to radiation therapy. Other soft tissue tumors, including desmoid tumors, lipomas, leiomyomas, neuroblastomas, and paragangliomas, occasionally show a familial predisposition.

Ninety percent of synovial sarcomas contain a characteristic chromosomal translocation t(X;18)(p11;q11) involving a nuclear transcription factor on chromosome 18 called *SYT* and two breakpoints on X. Patients with translocations to the second X breakpoint (*SSX2*) may have longer survival than those with translocations involving *SSX1*.

Insulin-like growth factor (IGF) type II is produced by some sarcomas and may act as an autocrine growth factor and as a motility factor that promotes metastatic spread. IGF-II stimulates growth through IGF-I receptors, but its effects on motility are through different receptors. If secreted in large amounts, IGF-II may produce hypoglycemia **(Chaps. 89 and 399)**. A large international sarcoma kindred study including 1162 patients and 6545 Caucasian controls revealed that about half the patients with sarcoma have putatively pathogenic monogenic and polygenic variation in previously reported and new cancer genes, some of them representing therapeutically actionable targets. These patients were diagnosed with sarcoma at an earlier age compared to controls.

CLASSIFICATION

Approximately 20 different groups of sarcomas are recognized on the basis of the pattern of differentiation toward normal tissue. For example, rhabdomyosarcoma shows evidence of skeletal muscle fibers with cross-striations; leiomyosarcomas contain interlacing fascicles of spindle cells resembling smooth muscle; and liposarcomas contain adipocytes. When precise characterization of the group is not possible, the tumors are called *unclassified sarcomas*. All of the primary bone sarcomas can also arise from soft tissues (e.g., extraskeletal osteosarcoma). The entity *malignant fibrous histiocytoma* (*MFH*) includes many tumors previously classified as fibrosarcomas or as pleomorphic variants of other sarcomas and is characterized by a mixture of spindle (fibrous) cells and round (histiocytic) cells arranged in a storiform pattern with frequent giant cells and areas of pleomorphism. As immunohistochemical suggestion of differentiation, particularly myogenic differentiation, may be found in a significant fraction of these patients, many are now characterized as poorly differentiated leiomyosarcomas, and the terms *undifferentiated pleomorphic sarcoma* (UPS) and *myxofibrosarcoma* are replacing MFH and myxoid MFH.

For purposes of treatment, most soft tissue sarcomas can be considered together. However, some specific tumors have distinct features. For example, *liposarcoma* can have a spectrum of behaviors. Pleomorphic liposarcomas and dedifferentiated liposarcomas behave like other high-grade sarcomas; in contrast, well-differentiated liposarcomas (better termed *atypical lipomatous tumors*) lack metastatic potential, and myxoid liposarcomas metastasize infrequently, but, when they do, they have a predilection for unusual metastatic sites containing fat, such as the retroperitoneum, mediastinum, and subcutaneous tissue. Rhabdomyosarcomas, Ewing's sarcoma, and other small-cell sarcomas tend to be more aggressive and are more responsive to chemotherapy than other soft tissue sarcomas.

Gastrointestinal stromal tumors (GISTs), previously classified as gastrointestinal leiomyosarcomas, are now recognized as a distinct entity within soft tissue sarcomas. Its cell of origin resembles the interstitial cell of Cajal, which controls peristalsis. The majority of malignant GISTs have activating mutations of the c-*kit* gene that result in ligand-independent phosphorylation and activation of the KIT receptor tyrosine kinase, leading to tumorigenesis. Approximately 5–10% of tumors will have a mutation in the platelet-derived growth factor receptor α (*PDGFRA*). GISTs that are wild type for both *KIT* and *PDGFRA* mutations may show mutations in *SDH* B, C, or D and may be driven by the IGF-I pathway.

DIAGNOSIS

The most common presentation is an asymptomatic mass. Mechanical symptoms referable to pressure, traction, or entrapment of nerves or muscles may be present. All new and persistent or growing masses should be biopsied, either by a small incision or by a cutting needle (core-needle biopsy) placed so that it can be encompassed in the subsequent excision without compromising a definitive resection. Lymph node metastases occur in 5%, except in synovial and epithelioid sarcomas, clear-cell sarcoma (melanoma of the soft parts), angiosarcoma, and rhabdomyosarcoma, where nodal spread may be seen in 17%. The pulmonary parenchyma is the most common site of metastases. Exceptions are GISTs, which metastasize to the liver; myxoid liposarcomas, which seek fatty tissue; and clear-cell sarcomas, which may metastasize to bones. Central nervous system metastases are rare, except in alveolar soft part sarcoma.

Radiographic Evaluation Imaging of the primary tumor is best with plain radiographs and magnetic resonance imaging (MRI) for tumors of the extremities or head and neck and by computed tomography (CT) for tumors of the chest, abdomen, or retroperitoneal cavity. A radiograph and CT scan of the chest are important for the detection of lung metastases. Other imaging studies may be indicated, depending on the symptoms, signs, or histology.

STAGING AND PROGNOSIS

The histologic grade, relationship to fascial planes, and size of the primary tumor are the most important prognostic factors. The current American Joint Committee on Cancer (AJCC) staging system is shown in **Table 87-1**. Prognosis is related to the stage. Cure is common in the absence of metastatic disease, but a small number of patients with metastases can also be cured. Historically, most patients with stage IV disease used to die within 12 months, but with availability of multiple lines of treatments, median survival in second-line and beyond ranges from 13 to 14 months, and some patients may live with stable or slowly progressive disease for many years.

TREATMENT

Soft Tissue Sarcomas

AJCC stage I patients are adequately treated with surgery alone. Stage II patients are considered for adjuvant radiation therapy. Stage III patients may benefit from adjuvant chemotherapy. Stage IV patients are managed primarily with chemotherapy, with or without other modalities.

SURGERY

Soft tissue sarcomas tend to grow along fascial planes, with the surrounding soft tissues compressed to form a pseudocapsule that gives the sarcoma the appearance of a well-encapsulated lesion. This is invariably deceptive because "shelling out," or marginal excision, of such lesions results in a 50–90% probability of local recurrence. Wide excision with a negative margin, incorporating the biopsy site, is the standard surgical procedure for local disease. The adjuvant use of radiation therapy and/or chemotherapy improves the local control rate and permits the use of limb-sparing surgery with a local control rate (85–90%) comparable to that achieved by radical excisions and amputations. Limb-sparing approaches are indicated except when negative margins are not obtainable, when the risks of radiation are prohibitive, or when neurovascular structures are involved so that resection will result in serious functional consequences to the limb.

RADIATION THERAPY

External-beam radiation therapy is an adjuvant to limb-sparing surgery for improved local control. Preoperative radiation therapy allows the use of smaller fields and smaller doses but results in a higher rate of wound complications. Postoperative radiation therapy must be given to larger fields, because the entire surgical bed must be encompassed, and in higher doses to compensate for hypoxia in

TABLE 87-1 American Joint Committee on Cancer Staging System for Sarcomas

HISTOLOGIC GRADE (G)	TUMOR SIZE (T)	NODE STATUS (N)	METASTASES (M)
Well differentiated (G1)	≤5 cm (T1)	Not involved (N0)	Absent (M0)
Moderately differentiated (G2)	>5 cm (T2)	Involved (N1)	Present (M1)
Poorly differentiated (G3)	Superficial fascial involvement (Ta)		
Undifferentiated (G4)	Deep fascial involvement (Tb)		

DISEASE STAGE	5-YEAR SURVIVAL, %
Stage I A: G1,2; T1a,b; N0; M0 B: G1,2; T2a; N0; M0	98.8
Stage II A: G1,2; T2b; N0; M0 B: G3,4; T1; N0; M0 C: G3,4; T2a; N0; M0	81.8
Stage III: G3,4; T2b; N0; M0	51.7
Stage IV A: any G; any T; N1; M0 B: any G; any T; any N; M1	<20

the operated field. This results in a higher rate of late complications. Brachytherapy or interstitial therapy, in which the radiation source is inserted into the tumor bed, is comparable in efficacy (except in low-grade lesions), less time-consuming, and less expensive.

ADJUVANT CHEMOTHERAPY

Chemotherapy is the mainstay of treatment for Ewing's primitive neuroectodermal tumors (PNET) and rhabdomyosarcomas. Meta-analysis of 14 randomized trials revealed a significant improvement in local control and disease-free survival in favor of doxorubicin-based chemotherapy. Overall survival improvement was 4% for all sites and 7% for the extremity site. An updated meta-analysis including four additional trials with doxorubicin and ifosfamide combination has reported a statistically significant 6% survival advantage in favor of chemotherapy. A chemotherapy regimen including an anthracycline and ifosfamide with growth factor support improved overall survival by 19% for high-risk (high-grade, ≥5 cm primary, or locally recurrent) extremity soft tissue sarcomas. Long-term follow-up of a trial evaluating neo-adjuvant use of the same combination confirms survival advantage and reports a 10-year survival of 61%.

ADVANCED DISEASE

Metastatic soft tissue sarcomas are largely incurable, but up to 20% of patients who achieve a complete response become long-term survivors. The therapeutic intent, therefore, is to produce a complete remission with chemotherapy (<10%) and/or surgery (30–40%). Surgical resection of metastases, whenever possible, is an integral part of the management. Some patients benefit from repeated surgical excision of metastases. The two most active chemotherapeutic agents are doxorubicin and ifosfamide. These drugs show a steep dose-response relationship in sarcomas. Gemcitabine with or without docetaxel has become an established second-line regimen and is particularly active in patients with undifferentiated pleomorphic sarcoma (UPS) and leiomyosarcomas. Dacarbazine also has some modest activity. Taxanes have selective activity in angiosarcomas, and vincristine, etoposide, and irinotecan are effective in rhabdomyosarcomas and Ewing's sarcomas. Pazopanib, an inhibitor of the vascular endothelial growth factor, platelet-derived growth factor (PDGF), and c-kit is now approved for patients with advanced soft tissue sarcomas excluding liposarcomas after failure of chemotherapy. Two additional chemotherapy drugs have gained approval from the Food and Drug Administration (FDA). Trabectedin was compared to dacarbazine in a large phase 3 randomized study in advanced leiomyosarcomas and liposarcomas after failure of an anthracycline, and resulted in significant improvement in progression-free survival. Eribulin was also tested in a similar trial and showed improvement in survival, predominantly in the liposarcoma subgroup and is therefore now approved for that subset. Imatinib targets the KIT and PDGF tyrosine kinase activity and is standard therapy for advanced/metastatic GISTs and dermatofibrosarcoma protuberans. Imatinib is now also indicated as adjuvant therapy for completely resected primary GISTs. Three years of adjuvant imatinib appear to be superior to 1 year of therapy for high-risk GISTs, although the optimal treatment duration remains unknown. Sunitinib and regorafenib are approved for second and third line use respectively in metastatic GIST after failure of or intolerance to imatinib.

Plexiform neurofibromas occurring in neurofibromatosis can be disfiguring and compromise function, particularly when they involve joints. These tumors are characterized by increased RAS-MAPK signaling and may respond to inhibiting MEK1/2 function with selumetinib.

BONE SARCOMAS

INCIDENCE AND EPIDEMIOLOGY

Bone sarcomas are rarer than soft tissue sarcomas; they accounted for only 0.2% of all new malignancies and 3010 new cases in the United States in 2016. Several benign bone lesions have the potential for malignant transformation. Enchondromas and osteochondromas can transform into chondrosarcoma; fibrous dysplasia, bone infarcts, and Paget's disease of bone can transform into either UPS or osteosarcoma.

CLASSIFICATION

Benign Tumors The common benign bone tumors include enchondroma, osteochondroma, chondroblastoma, and chondromyxoid fibroma, of cartilage origin; osteoid osteoma and osteoblastoma, of bone origin; fibroma and desmoplastic fibroma, of fibrous tissue origin; hemangioma, of vascular origin; and giant-cell tumor, of unknown origin.

Malignant Tumors The most common malignant tumors of bone are plasma cell tumors (Chap. 107). The four most common malignant nonhematopoietic bone tumors are osteosarcoma, chondrosarcoma, Ewing's sarcoma, and UPS. Rare malignant tumors include chordoma (of notochordal origin), malignant giant-cell tumor, adamantinoma (of unknown origin), and hemangioendothelioma (of vascular origin).

Musculoskeletal Tumor Society Staging System Sarcomas of bone are staged according to the Musculoskeletal Tumor Society staging system based on grade and compartmental localization. A Roman numeral reflects the tumor grade: stage I is low grade, stage II is high

TABLE 87-2 Staging System for Bone Sarcomas

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	T1	Tumor ≤8 cm in greatest dimension
	T2	Tumor >8 cm in greatest dimension
	T3	Discontinuous tumors in the primary bone site
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis
	M1a	Lung
	M1b	Other distant sites
Histologic grade (G)	GX	Grade cannot be assessed
	G1	Well differentiated—low grade
	G2	Moderately differentiated—low grade
	G3	Poorly differentiated—high grade
	G4	Undifferentiated—high grade (Ewing's is always classed G4)

Stage Grouping				
Stage IA	T1	N0	M0	G1,2 low grade
Stage IB	T2	N0	M0	G1,2 low grade
Stage IIA	T1	N0	M0	G3,4 high grade
Stage IIB	T2	N0	M0	G3,4 high grade
Stage III	T3	N0	M0	Any G
Stage IVA	Any T	N0	M1a	Any G
Stage IVB	Any T	N1	Any M	Any G
	Any T	Any N	M1b	Any G

grade, and stage III includes tumors of any grade that have lymph node or distant metastases. In addition, the tumor is given a letter reflecting its compartmental localization. Tumors designated A are intracompartmental (i.e., confined to the same soft tissue compartment as the initial tumor), and tumors designated B are extracompartmental (i.e., extending into the adjacent soft tissue compartment or into bone). The tumor-node-metastasis (TNM) staging system is shown in Table 87-2.

OSTEOSARCOMA

Osteosarcoma, accounting for almost 45% of all bone sarcomas, is a spindle cell neoplasm that produces osteoid (unmineralized bone) or bone. Approximately 60% of all osteosarcomas occur in children and adolescents in the second decade of life, and ~10% occur in the third decade of life. Osteosarcomas in the fifth and sixth decades of life are frequently secondary to either radiation therapy or transformation in a preexisting benign condition, such as Paget's disease. Males are affected 1.5–2 times as often as females. Osteosarcoma has a predilection for metaphyses of long bones; the most common sites of involvement are the distal femur, proximal tibia, and proximal humerus. The classification of osteosarcoma is complex, but 75% of osteosarcomas fall into the "classic" category, which include osteoblastic, chondroblastic, and fibroblastic osteosarcomas. The remaining 25% are classified as "variants" on the basis of (1) clinical characteristics, as in the case of osteosarcoma of the jaw, postradiation osteosarcoma, or Paget's osteosarcoma; (2) morphologic characteristics, as in the case of telangiectatic osteosarcoma, small-cell osteosarcoma, or epithelioid osteosarcoma; or (3) location, as in parosteal or periosteal osteosarcoma. Diagnosis usually requires a synthesis of clinical, radiologic, and pathologic features. Patients typically present with pain and swelling of the affected area. A plain radiograph reveals a destructive lesion with a moth-eaten appearance, a spiculated periosteal reaction (sunburst appearance), and a cuff of periosteal new bone formation at the margin of the soft tissue mass (Codman's triangle). A CT scan of the primary tumor is best for defining bone destruction and the pattern of calcification, whereas MRI is better for defining intramedullary and soft tissue extension. A chest radiograph and CT scan are used to detect lung metastases. Metastases to the bony skeleton should be imaged by a bone scan or by fluorodeoxyglucose positron emission tomography (FDG-PET). Almost all osteosarcomas are hypervascular and PET-avid. Pathologic diagnosis is established either with a core-needle biopsy, where feasible, or with an open biopsy with an appropriately placed incision that does not compromise future limb-sparing resection. Most osteosarcomas are high-grade. The most important prognostic factor for long-term survival is response to chemotherapy. Preoperative chemotherapy followed by limb-sparing surgery (which can be accomplished in >80% of patients) followed by postoperative chemotherapy is standard management. The effective drugs are doxorubicin, ifosfamide, cisplatin, and high-dose methotrexate with leucovorin rescue. The various combinations of these agents that have been used have all been about equally successful. Long-term survival rates in extremity osteosarcoma range from 60 to 80%. Osteosarcoma is radioresistant; radiation therapy has no role in the routine management. UPS is considered a part of the spectrum of osteosarcoma and is managed similarly.

CHONDROSARCOMA

Chondrosarcoma, which constitutes ~20–25% of all bone sarcomas, is a tumor of adulthood and old age with a peak incidence in the fourth to sixth decades of life. It has a predilection for the flat bones, especially the shoulder and pelvic girdles, but can also affect the diaphyseal portions of long bones. Chondrosarcomas can arise de novo or as a malignant transformation of an enchondroma or, rarely, of the cartilaginous cap of an osteochondroma. Chondrosarcomas have an indolent natural history and typically present as pain and swelling. Radiographically, the lesion may have a lobular appearance with mottled or punctate or annular calcification of the cartilaginous matrix. It is difficult to distinguish low-grade chondrosarcoma from benign lesions by x-ray or histologic examination. The diagnosis is therefore influenced by clinical history and physical examination. A new onset of pain, signs of inflammation, and progressive increase in the size of the mass suggest malignancy. The histologic classification is complex, but most tumors fall within the classic category. Like other bone sarcomas, high-grade chondrosarcomas spread to the lungs. Most chondrosarcomas are resistant to chemotherapy, and surgical resection of primary or recurrent tumors, including pulmonary metastases, is the mainstay of therapy. This rule does not hold for two histologic variants. Dedifferentiated chondrosarcoma has a high-grade osteosarcoma or a malignant fibrous histiocytoma component that responds to chemotherapy. Mesenchymal chondrosarcoma, a rare variant composed of a small-cell element, also is responsive to systemic chemotherapy and is treated like Ewing's sarcoma.

EWING'S SARCOMA

Ewing's sarcoma, which constitutes ~10–15% of all bone sarcomas, is common in adolescence and has a peak incidence in the second decade of life. It typically involves the diaphyseal region of long bones and also has an affinity for flat bones. The plain radiograph may show a characteristic "onion peel" periosteal reaction with a generous soft tissue mass, which is better demonstrated by CT or MRI. This mass is composed of sheets of monotonous, small, round, blue cells and can be confused with lymphoma, embryonal rhabdomyosarcoma, and small-cell carcinoma. The presence of p30/32, the product of the *mic-2* gene (which maps to the pseudoautosomal region of the X and Y chromosomes), is a cell-surface marker for Ewing's sarcoma (and other members of the Ewing's family of tumors, previously also called PNETs). Most PNETs arise in soft tissues; they include peripheral neuroepithelioma, Askin's tumor (chest wall), and esthesioneuroblastoma. Glycogen-filled cytoplasm detected by staining with periodic acid–Schiff is also characteristic of Ewing's sarcoma cells. The classic cytogenetic abnormality associated with this disease is a reciprocal translocation of the long arms of chromosomes 11 and 22, t(11;22), which creates a chimeric gene product of unknown function with components from the *fli-1* gene on chromosome 11 and *ews* on 22.

This disease is very aggressive, and it is therefore considered a systemic disease. Common sites of metastases are lung, bones, and bone marrow. Systemic chemotherapy is the mainstay of therapy, often being used before surgery. Doxorubicin, cyclophosphamide or ifosfamide, etoposide, vincristine, and dactinomycin are active drugs. Topotecan or irinotecan in combination with an alkylating agent is often used in relapsed patients. Targeted therapy with an anti-IGF-I receptor antibody in combination with an inhibitor of mammalian target of rapamycin (mTOR) has shown promising activity in refractory cases. Local treatment for the primary tumor includes surgical resection, usually with limb salvage or radiation therapy. Patients with lesions below the elbow and below the mid-calf have a 5-year survival rate of 80% with effective treatment. Ewing's sarcoma at first presentation is a curable tumor, even in the presence of obvious metastatic disease, especially in children <11 years old.

TUMORS METASTATIC TO BONE

Bone is a common site of metastasis for carcinomas of the prostate, breast, lung, kidney, bladder, and thyroid and for lymphomas and sarcomas. Prostate, breast, and lung primaries account for 80% of all bone metastases. Metastatic tumors of bone are more common than primary bone tumors. Tumors usually spread to bone hematogenously, but local invasion from soft tissue masses also occurs. In descending order of frequency, the sites most often involved are the vertebrae, proximal femur, pelvis, ribs, sternum, proximal humerus, and skull. Bone metastases may be asymptomatic or may produce pain, swelling, nerve root or spinal cord compression, pathologic fracture, or myelophthisis (replacement of the marrow). Symptoms of hypercalcemia may be noted in cases of bony destruction.

Pain is the most frequent symptom. It usually develops gradually over weeks, is usually localized, and often is more severe at night. When patients with back pain develop neurologic signs or symptoms, emergency evaluation for spinal cord compression is indicated **(Chap. 71)**. Bone metastases exert a major adverse effect on quality of life in cancer patients.

Cancer in the bone may produce osteolysis, osteogenesis, or both. Osteolytic lesions result when the tumor produces substances that can directly elicit bone resorption (vitamin D–like steroids, prostaglandins, or parathyroid hormone–related peptide) or cytokines that can induce the formation of osteoclasts (interleukin 1 and tumor necrosis factor). Osteoblastic lesions result when the tumor produces cytokines that activate osteoblasts. In general, purely osteolytic lesions are best detected by plain radiography, but they may not be apparent until they are >1 cm. These lesions are more commonly associated with hypercalcemia and with the excretion of hydroxyproline-containing peptides indicative of matrix destruction. When osteoblastic activity is prominent, the lesions may be readily detected using radionuclide bone scanning (which is sensitive to new bone formation), and the radiographic appearance may show increased bone density or sclerosis. Osteoblastic lesions are associated with higher serum levels of alkaline phosphatase and, if extensive, may produce hypocalcemia. Although some tumors may produce mainly osteolytic lesions (e.g., kidney cancer) and others mainly osteoblastic lesions (e.g., prostate cancer), most metastatic lesions produce both types of lesion and may go through stages where one or the other predominates.

In older patients, particularly women, it may be necessary to distinguish metastatic disease of the spine from osteoporosis. In osteoporosis, the cortical bone may be preserved, whereas cortical bone destruction is usually noted with metastatic cancer.

TREATMENT

Metastatic Bone Disease

Treatment of metastatic bone disease depends on the underlying malignancy and the symptoms. Some metastatic bone tumors are curable (lymphoma, Hodgkin's disease), and others are treated with palliative intent. Pain may be relieved by local radiation therapy. Hormonally responsive tumors are responsive to hormone inhibition (antiandrogens for prostate cancer, antiestrogens for breast cancer). Strontium-89, samarium-153, and radium-223 are bone-seeking radionuclides that can exert antitumor effects and relieve symptoms. Denosumab, a monoclonal antibody that binds to RANK ligand, inhibits osteoclastic activity and increases bone mineral density. Bisphosphonates such as pamidronate may relieve pain and inhibit bone resorption, thereby maintaining bone mineral density and reducing risk of fractures in patients with osteolytic metastases from breast cancer and multiple myeloma. Careful monitoring of serum electrolytes and creatinine is recommended. Monthly administration prevents bone-related clinical events and may reduce the incidence of bone metastases in women with breast cancer. When the integrity of a weight-bearing bone is threatened by an expanding metastatic lesion that is refractory to radiation therapy, prophylactic internal fixation is indicated. Overall survival is related to the prognosis of the underlying tumor. Bone pain at the end of life is particularly common; an adequate pain relief regimen including sufficient amounts of narcotic analgesics is required. **The management of hypercalcemia is discussed in Chap. 403**.

88 Carcinoma of Unknown Primary

Gauri R. Varadhachary, James L. Abbruzzese

Carcinoma of unknown primary (CUP) is a biopsy-proven malignancy for which the anatomic site of origin remains unidentified after a focused search. CUP is one of the 10 most frequently diagnosed cancers worldwide, accounting for 3–5% of all cancers. Most investigators limit CUP to epithelial and undifferentiated cancers and do not include lymphomas, metastatic melanomas, and metastatic sarcomas because these cancers have specific histology- and stage-based treatments that guide management even in the absence of a primary cancer.

The emergence of sophisticated imaging, robust immunohistochemistry (IHC), and genomic and proteomic tools has challenged the "unknown" designation. Additionally, effective targeted therapies in several cancers have moved the paradigm from empiricism to considering a personalized approach to CUP management. The reasons cancers present as CUP remain unclear. One hypothesis is that the primary

tumor either regresses after seeding the metastasis or remains so small that it is not detected. It is possible that CUP falls on the continuum of cancer presentation where the primary has been contained or eliminated by the natural body defenses. Alternatively, CUP may represent a specific malignant event that results in an increase in metastatic spread or survival relative to the primary. Whether the CUP metastases truly define a clone that is genetically and phenotypically unique to this diagnosis remains to be determined. Of note, the incidence of intrahepatic cholangiocarcinoma (ICC) is increasing whereas the incidence of CUP is declining during this same time period. Because the liver is a common site of CUP presentation, ICC can be misdiagnosed as CUP. Improvements in diagnostic technologies and awareness among clinicians to differentiate the two are contributing to an increased recognized incidence of ICC.

CUP BIOLOGY

Studies looking for unique signature abnormalities in CUP tumors have not been positive. Abnormalities in chromosomes 1 and 12 and other complex cytogenetic abnormalities have been reported. Aneuploidy has been described in 70% of CUP patients with metastatic adenocarcinoma or undifferentiated carcinoma. The overexpression of various genes, including *Ras*, *bcl-2* (40%), *her-2* (11%), and *p53* (26–53%), has been identified in CUP samples, but they have no effect on response to therapy or survival. The extent of angiogenesis in CUP relative to that in metastases from known primaries has also been evaluated, but no consistent findings have emerged. Current focus is on comprehensive genomic profiling that may identify targeted therapeutic approaches to improve outcomes for this disease as discussed below. Additionally, ongoing profiling efforts may also provide insights into CUP biology through recognition of molecular aberrations that especially drive metastatic growth.

CLINICAL EVALUATION

Initial CUP evaluation has two goals: search for the primary tumor based on pathologic evaluation of the metastases and determine the extent of disease. Obtaining a thorough medical history from CUP patients is essential, including paying particular attention to previous surgeries, removed lesions, and family medical history to assess potential hereditary cancers. Adequate physical examination, including a digital rectal examination in men and breast and pelvic examinations in women, should be performed based on clinical presentation.

Role of Serum Tumor Markers and Cytogenetics Most tumor markers, including CEA, CA-125, CA 19-9, and CA 15-3, when elevated, are nonspecific and not helpful in determining the primary tumor site. Men who present with adenocarcinoma and predominant osteoblastic metastasis should undergo a prostate-specific antigen (PSA) test. In patients with undifferentiated or poorly differentiated carcinoma (especially with a midline tumor), elevated β-human chorionic gonadotropin (β-hCG) and α fetoprotein (AFP) levels suggest the possibility of an extragonadal germ cell (testicular) tumor. AFP should also be considered in patients with a potential diagnosis of hepatoma. With the availability of IHC, cytogenetic studies are rarely needed.

Role of Imaging Studies In the absence of contraindications, a baseline IV contrast computed tomography (CT) scan of the chest, abdomen, and pelvis is the standard of care. This helps to search for the primary tumor, evaluate the extent of disease, and select the most accessible biopsy site. Older studies suggested that the primary tumor site is detected in 20–35% of patients who undergo a CT scan of the abdomen and pelvis, although by current definition, these patients do not have CUP. With precise imaging and reporting, latent primary cancers, defined as appearance of a new primary cancer after a latent period of several months to years, is uncommon and seen in ≤5% of CUP patients, usually in patients with very indolent presentations and/or highly responsive metastatic cancers that allows a latent primary to emerge (grow) over time.

Mammography should be performed in all women who present with metastatic adenocarcinoma, especially in those with adenocarcinoma and isolated axillary lymphadenopathy. Magnetic resonance imaging (MRI) of the breast is a follow-up modality in patients with axillary adenopathy and suspected occult primary breast carcinoma following a negative mammography and ultrasound. The results of these imaging modalities can influence surgical management; a negative MRI of the breast result predicts a low tumor yield at mastectomy.

A conventional workup for a squamous cell carcinoma and cervical CUP (neck lymphadenopathy with no known primary tumor) includes a CT scan or MRI and invasive studies, including indirect and direct laryngoscopy, bronchoscopy, and upper endoscopy. Ipsilateral (or bilateral) staging tonsillectomy has been recommended for these patients. 18-Fluorodeoxyglucose positron emission tomography (18-FDG-PET) scans are useful in this patient population and may help guide the biopsy; determine the extent of disease; facilitate the appropriate treatment, including planning radiation fields; and help with disease surveillance. A smaller radiation field encompassing the primary (when found) and metastatic adenopathy decreases the risk of chronic xerostomia. Several studies have evaluated the utility of PET in patients with squamous cervical CUP, and head and neck primary tumors were identified in ~21–30%.

The diagnostic contribution of PET to the evaluation of other CUP presentations (outside of the neck adenopathy indication) remains controversial and is not routinely recommended. PET-CT can be helpful for patients who are candidates for surgical intervention for solitary metastatic disease because the identification of disease in addition to the solitary metastatic site may affect surgical planning.

Invasive studies, including upper endoscopy, colonoscopy, and bronchoscopy, should be limited to symptomatic patients or those with laboratory, imaging, or pathologic abnormalities that suggest that these techniques will result in a high yield in finding a primary cancer.

Role of Pathologic Studies A detailed pathologic examination of the most accessible biopsied tissue specimen is mandatory in CUP patients. Pathologic evaluation typically consists of hematoxylin and eosin stains and immunohistochemical tests.

LIGHT MICROSCOPY EVALUATION Adequate tissue obtained preferably by excisional biopsy or core-needle biopsy (instead of only a fine-needle aspiration) is stained with hematoxylin and eosin and subjected to light microscopic examination. On light microscopy, 60–65% of CUP is adenocarcinoma, and 5% is squamous cell carcinoma. The remaining 30–35% is poorly differentiated adenocarcinoma, poorly differentiated carcinoma, or poorly differentiated neoplasm. A small percentage of lesions are diagnosed as neuroendocrine cancers (2%), mixed tumors (adenosquamous or sarcomatoid carcinomas), or undifferentiated neoplasms (Table 88-1).

ROLE OF IMMUNOHISTOCHEMICAL ANALYSIS Immunohistochemical stains are peroxidase-labeled antibodies against specific tumor antigens that are used to define tumor lineage. The number of available immunohistochemical stains is ever-increasing and unfortunately, we lack a tiered and uniform approach to tissue evaluation in the CUP setting. For CUP cases, more is not necessarily better, and immunohistochemical stains should be used in conjunction with the patient's clinical presentation and imaging studies to select the best therapy. Communication between the clinician and pathologist is essential. No stain is 100% specific, and overinterpretation should be avoided. PSA and thyroglobulin tissue markers, which are positive in prostate and thyroid cancer, respectively, are the most specific of the current marker panel. However, these cancers rarely present as CUP, so the yield of these tests may be low. Figure 88-1 delineates a simple algorithm for immunohistochemical staining in CUP cases. Table 88-2 lists additional

TABLE 88-1 Major Histologies in Carcinoma of Unknown Primary

HISTOLOGY	PROPORTION, %
Well to moderately differentiated adenocarcinoma	60
Squamous cell cancer	5
Poorly differentiated adenocarcinoma, poorly differentiated carcinoma	30
Neuroendocrine	2
Undifferentiated malignancy	3

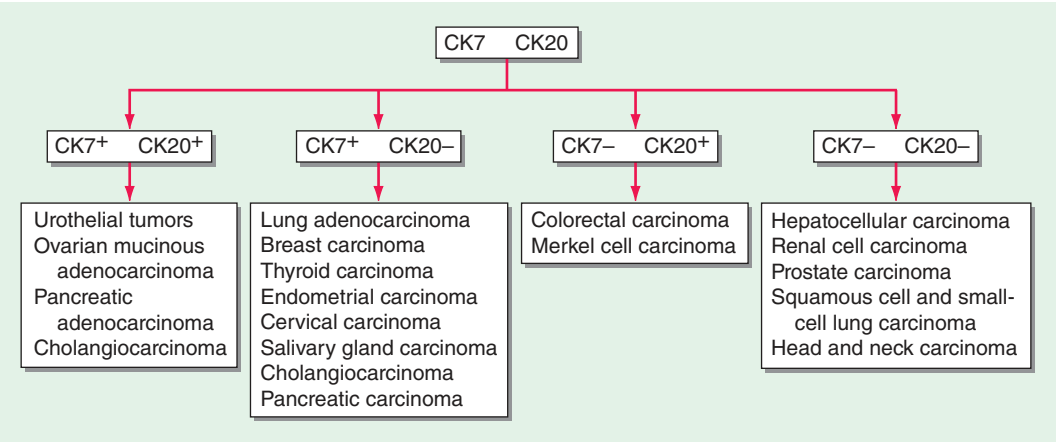

FIGURE 88-1 Approach to cytokeratin (CK7 and CK20) markers used in adenocarcinoma of unknown primary.

tests that may be useful to further define the tumor lineage. A more comprehensive algorithm may improve the diagnostic accuracy but can make the process complex and increase cost. With the use of immunohistochemical markers, electron microscopic analysis, which is time-consuming and expensive, is rarely needed.

There are >20 subtypes of cytokeratin (CK) intermediate filaments with different molecular weights and differential expression in various cell types and cancers. Monoclonal antibodies to specific CK subtypes have been used to help classify tumors according to their site of origin; commonly used CK stains in adenocarcinoma CUP are CK7 and CK20. CK7 is found in tumors of the lung, ovary, endometrium, breast, and upper gastrointestinal tract including pancreaticobiliary cancers, whereas CK20 is normally expressed in the gastrointestinal epithelium, urothelium, and Merkel cells. The nuclear CDX-2 transcription factor, which is the product of a homeobox gene necessary for intestinal organogenesis, is often used to aid in the diagnosis of gastrointestinal adenocarcinomas.

TABLE 88-2 Select Immunohistochemical Stains Useful in the Diagnosis of CUP

LIKELY PRIMARY PROFILE	COMMONLY CONSIDERED IHC TO ASSIST IN DIFFERENTIAL DIAGNOSIS OF CUP[a]
Breast	ER, GCDFP-15, mammaglobin, Her-2/neu, GATA3
Ovarian/mullerian	ER, *WT1* gene, CK7, PAX8, PAX2
Lung adenocarcinoma	TTF-1; nuclear staining, napsin A, SP-A1
Germ cell	β-HCG, AFP, OCT3/4, CKIT, CD30 (embryonal), SALL4
Prostate	PSA, α-methylacyl CoA racemase/P504S (AMACR/P504S), P501S (prostein), and PSMA, NKX3-1
Intestinal	CK7, CK20, CDX-2, CEA
Neuroendocrine	Chromogranin, synaptophysin, CD56
Sarcoma	Desmin (desmoid tumors), factor VIII (angiosarcomas), CD31, smooth muscle actin (leiomyosarcoma), MyoD1 (rhabdomyosarcoma)
Renal	RCC, CD10, PAX8, CD10
Hepatocellular carcinoma	Hep Par-1, Arg-1, glypican-3
Melanoma	S100, SOX-10, vimentin, HMB-45, tyrosinase and melan-A
Urothelial	CK7, CK20, thrombomodulin, uroplakin III
Mesothelioma	Calretinin, *WT1*, D2-40, mesothelin
Lymphoma	LCA, CD3, CD4, CD5, CD20, CD45
SCC	p63, p40 (lung SCC), CK5/6

[a]Patterns emerging from coexpression of stains are better than individual stains to suggest putative primary site. Even with optimization, no IHC panel is 100% sensitive or specific (e.g., ovarian mucinous carcinoma can exhibit positivity with intestinal markers).

Abbreviations: AFP, α fetoprotein; Arg-1, arginase-1; β-hCG, β-human chorionic gonadotropin; CEA, carcinoembryonic antigen; CUP, carcinoma of unknown primary; ER, estrogen receptor; GCDFP-15, gross cystic disease fibrous protein-15; IHC, immunohistochemistry; LCA, leukocyte common antigen; PSA, prostate-specific antigen; PSMA, prostate-specific membrane antigen; SCC, squamous cell carcinoma; SP-A1, surfactant protein A precursor; TTF, thyroid transcription factor; WT, Wilms' tumor.

Thyroid transcription factor 1 (TTF-1) nuclear staining is frequently positive in lung and thyroid cancers. Approximately 68% of adenocarcinomas and 25% of squamous cell lung cancers stain positive for TTF-1, which helps differentiate a lung primary tumor from metastatic adenocarcinoma in a pleural effusion, the mediastinum, or the lung parenchyma.

Gross cystic disease fibrous protein-15, a 15-kDa monomer protein, is a marker of apocrine differentiation that is detected in 62–72% of breast carcinomas. GATA3 is being increasingly used in the CUP setting when there is concern for a breast primary, and can be particularly useful as a marker for metastatic breast carcinoma, especially triple-negative and metaplastic carcinomas, which lack specific endocrine markers of mammary origin. UROIII, high-molecular-weight cytokeratin, thrombomodulin, and CK20 are the markers used to diagnose lesions of urothelial origin.

IHC performs the best when used in groups that give rise to patterns that are strongly indicative of certain profiles. For example, the TTF-1/CK7+ and CK20+/CDX-2+/CK7– phenotypes have been reported as very suggestive of lung and lower gastrointestinal cancer profiles, respectively. Despite their practical utility, these patterns have not been validated prospectively in CUP patients. IHC is not without its limitations; several factors affect tissue antigenicity (antigen retrieval, specimen processing, and fixation), interpretation of stains in tumor (nuclear, cytoplasmic, membrane) versus normal tissue, inter- and intraobserver variability, variable performance of different antibodies said to recognize the same antigen, and tissue heterogeneity and inadequacy (given small biopsy sizes). Communication with the pathologist is critical to determine if additional tissue will be beneficial in the pathologic evaluation. Pathologic features should supersede clinical or radiologic findings when considering testing for biomarkers of therapeutic response (e.g., epidermal growth factor receptor [EGFR], Alk mutations, human epidermal growth factor receptor 2 [HER-2]).

ROLE OF CANCER CLASSIFIER MOLECULAR PROFILING In the absence of a known primary, developing therapeutic strategies for CUP is challenging. The current diagnostic yield with imaging and immunochemistry is ~20–30% for CUP patients. To reduce diagnostic uncertainty, sophisticated molecular analytics have been applied to CUP samples. These include gene expression profiling, messenger RNA (mRNA), microRNA, and epigenetic profiling to classify the CUP cancer.

Gene expression profiles are most commonly generated using quantitative reverse transcriptase polymerase chain reaction (RT-PCR) or DNA microarray. Neural network programs are then used to develop predictive algorithms from the gene expression profiles. Typically, a training set of gene profiles from known cancers (preferably from metastatic sites) is used to train the software. Comprehensive gene expression databases that have become available for common malignancies are then applied to CUP samples and the program can then be used to predict the putative origin of a CUP sample.

mRNA- or microRNA-based tissue of origin cancer classifier assays have also been studied in prospective and retrospective CUP trials. More recently, a classifier based on microarray DNA methylation signatures has been studied and validated in known cancers. The DNA methylation profiling predicted a primary cancer in 87% of the 216 CUP patients.

Despite the sophistication of the cancer classifier molecular assays, most of the CUP studies have evaluated assay *performance*, although the challenge with validating the accuracy of an assay for CUP is that, by definition, the primary cancer diagnosis cannot be verified. Thus, current estimates of tissue of origin test accuracy have relied on indirect metrics, including comparison with pathology/IHC, clinical presentation, appearance of latent primaries, and autopsies. Using these measures, the assays suggest a plausible primary in ~70–80% of patients studied. The only outcomes-based study is a single-arm study reporting a median survival of 12.5 months for patients who received assay-directed site-specific therapy. Firm conclusions of therapeutic impact cannot be drawn from this study given the nonrandomized design, statistical biases, confounding variables including use of subsequent lines of (empiric) therapy, and the heterogeneity of the CUP cancers. Additional studies are needed to better understand the clinical influence of tissue of origin profiling tools and how these assays complement IHC and help guide therapy.

ROLE OF NEXT GENERATION SEQUENCING A significant push is being made toward personalized medicine across all cancer types with the goal of identifying driver mutation(s) in a patient who can be treated with targeted agents independent of the site of origin. A retrospective study of 200 CUP tumor specimens reported on genomic alterations (GA) using the hybrid-capture–based FoundationOne assay. The authors reported that a large number of CUP samples (85%) harbored at least one clinically relevant GA with the potential to influence and personalize therapy. The mean number of GAs was 4.2 per tumor, and the most common GAs included *TP53* (55%), *KRAS* (20%), *CDKN2A* (19%), and *ARID1A* (11%). The adenocarcinoma CUP tumors were more frequently driven by GAs in the receptor tyrosine kinase (RTK)/Ras/mitogen-activated protein kinase (MAPK) signaling pathway than nonadenocarcinoma CUP tumors.

Ongoing histology and cellular-context agnostic prospective clinical trials are studying the presence of actionable mutations and matching patients to the right targeted drug. Should this approach eventually be appropriately validated, CUP would be a natural fit for GA-based targeted therapy independent of tumor site.

TREATMENT

Carcinoma of Unknown Primary

GENERAL CONSIDERATIONS

The treatment of CUP continues to evolve, albeit slowly. The median survival duration of most patients with disseminated CUP is ~6–10 months. Systemic chemotherapy is the primary treatment modality in most patients with disseminated disease, but the careful integration of surgery, radiation therapy, and even periods of observation is important in the overall management of this condition **(Figs. 88-2 and 88-3)**. Prognostic factors include performance status, site and number of metastases, response to chemotherapy, and serum lactate dehydrogenase (LDH) levels. Culine and colleagues developed a prognostic model using performance status and serum LDH levels, which allowed the assignment of patients into two subgroups with divergent outcomes. Future prospective trials using this prognostic model are warranted. Clinically, some CUP diagnoses fall into a favorable prognostic subset. Others, including those with disseminated CUP, do not and have a more unfavorable prognosis.

TREATMENT OF FAVORABLE CUP SUBSETS

Women with Isolated Axillary Adenopathy Women with isolated axillary adenopathy with adenocarcinoma or carcinoma are usually treated for stage II or III breast cancer based on pathologic findings. These patients should undergo a breast MRI if mammogram and ultrasound are negative. Radiation therapy to the ipsilateral breast is indicated if the MRI of the breast is positive. Chemotherapy and/or hormonal therapy are indicated based on patient's age (premenopausal or postmenopausal), nodal disease bulk, and hormone receptor status **(Chap. 75)**. It is important to verify that the pathology suggests a breast cancer profile (morphology, immunohistochemical breast markers including estrogen receptor, mammaglobin, GCDFP-15, GATA3, HER-2 gene expression) before embarking on a breast cancer therapeutic program.

WOMEN WITH PERITONEAL CARCINOMATOSIS

The term *primary peritoneal papillary serous carcinoma* (PPSC) has been used to describe CUP with carcinomatosis with the pathologic and laboratory (elevated CA-125 antigen) characteristics of ovarian cancer but no ovarian primary tumor identified on transvaginal sonography or laparotomy. Studies suggest that ovarian cancer and PPSC, which are both of müllerian origin, have similar gene expression profiles. Similar to patients with ovarian cancer, patients with PPSC are candidates for cytoreductive surgery, followed by adjuvant taxane- and platinum-based chemotherapy. In one retrospective study of 258 women with peritoneal carcinomatosis who had undergone cytoreductive surgery and chemotherapy, 22% of patients had a complete response to chemotherapy; the median survival duration was 18 months (range 11–24 months). However, not all peritoneal carcinomatosis in women is PPSC. Careful pathologic evaluation can help diagnose a colon cancer profile (CDX-2+, CK-20+, CK7–) or a pancreaticobiliary cancer or even a mislabeled peritoneal mesothelioma (calretinin positive).

POORLY DIFFERENTIATED CARCINOMA WITH MIDLINE ADENOPATHY **(CHAP. 84)**

Men with poorly differentiated or undifferentiated carcinoma that presents with midline adenopathy should be evaluated for extragonadal germ cell malignancy. If diagnosed and treated as such, they often experience a good response to treatment with platinum-based combination chemotherapy. Response rates of >50% have been noted, and long-term survival rates of 10–15% long have been reported. Older patients, especially smokers, who present with mediastinal adenopathy are more likely to have a lung or head-and-neck cancer profile.

NEUROENDOCRINE CARCINOMA **(CHAP. 80)**

Low-grade neuroendocrine tumor (NET) often has an indolent course, and treatment decisions are based on symptoms and tumor bulk. Urine 5-HIAA and serum chromogranin may be elevated and can be followed as markers. Often, the patient is treated with somatostatin analogues alone for hormone-related symptoms (diarrhea, flushing, nausea). Specific local therapies or systemic therapy would only be indicated if the patient is symptomatic with local pain secondary to significant growth of the metastasis or the hormone-related symptoms are not controlled with endocrine therapy. Novel therapy options have demonstrated benefit in patients with low-grade NET, including sunitinib (which targets the vascular endothelial growth factor pathway) and everolimus (which inhibits the mammalian target of rapamycin). Patients with high-grade NET are treated with platinum-based doublet therapy; 20–25% show a complete response, and up to 10% patients with limited/oligo presentations survive for >5 years.

SQUAMOUS CELL CARCINOMA PRESENTING AS NECK ADENOPATHY

Patients with early-stage squamous cell carcinoma involving the cervical lymph nodes are candidates for node dissection and radiation therapy, which can result in long-term survival. The role of chemotherapy in these patients is undefined, although chemoradiation therapy or induction chemotherapy is often used and is beneficial in bulky N2/N3 lymph node disease.

SOLITARY METASTATIC SITE

Patients with solitary metastases can also experience good treatment outcomes. Some patients who present with locoregional disease are candidates for aggressive trimodality management—both prolonged disease-free survival, and, occasionally, cure is possible.

MEN WITH BLASTIC SKELETAL METASTASES AND ELEVATED PSA **(CHAP. 83)**

Blastic bone-only metastasis is a rare presentation, and elevated serum PSA or tumor staining with PSA may provide confirmatory evidence of prostate cancer in these patients. Those with elevated levels are candidates for hormonal therapy for prostate cancer, although it is important to rule out other primary tumors (lung most common).

MANAGEMENT OF DISSEMINATED CUP

Patients who present with liver, brain, and adrenal metastatic disease usually have a poor prognosis. Patients with peritoneal carcinomatosis secondary to metastatic adenocarcinoma have a broad differential diagnosis, which includes mainly gastrointestinal cancers including gastric, appendiceal, colon, and pancreaticobiliary cancers.

Traditionally, platinum-based combination chemotherapy regimens have been used to treat CUP. Several broadly used regimens have been studied in the last two decades; these include paclitaxel-carboplatin, gemcitabine-cisplatin, gemcitabine-oxaliplatin, and irinotecan and fluoropyrimidine-based therapies. These chemotherapeutic agents used as empiric regimens have shown a response rate of 25–40%, and their use obtains median survival times of 6–13 months.

Outside of favorable subsets, there is a small group of patients with a "definitive" IHC profile. These patients usually have a single diagnosis based on their clinicopathologic presentation and are often treated for the putative primary tumor. This does not guarantee a response, although it increases the probability of response when select drugs are chosen from a class of drugs known to be effective in that cancer type. Patients who do not fall into those categories are candidates for broad-spectrum platinum-based regimens, clinical trials, and additional trial-based genomic and proteomic tests. Today, we do not have many effective drugs for several CUP cancer profiles, and treatments overlap for some cancers. However, as novel therapies are developed for known cancers, these agents will likely impact management of CUP patients.

SUMMARY

Patients with CUP should undergo a directed diagnostic search for the primary tumor on the basis of clinical and pathologic data. Subsets of patients have prognostically favorable disease, as defined by clinical or histologic criteria, and may substantially benefit from aggressive treatment and prolonged survival can be expected. However, for most patients who present with advanced CUP, the prognosis remains poor with early resistance to available cytotoxic therapy. The current focus has shifted away from empirical chemotherapeutic trials to

understanding the metastatic phenotype, tissue of origin profiling in select patients, and next-generation sequencing to evaluate actionable mutations in CUP patients.

89 Paraneoplastic Syndromes: Endocrinologic/Hematologic

J. Larry Jameson, Dan L. Longo

Neoplastic cells can produce a variety of products that can stimulate hormonal, hematologic, dermatologic, rheumatologic, renal, and neurologic responses. *Paraneoplastic syndromes* is the term used to refer to the disorders that accompany benign or malignant tumors but are not directly related to mass effects or invasion. Tumors of neuroendocrine origin, such as small-cell lung carcinoma (SCLC) and carcinoids are common causes of paraneoplastic syndromes, and produce a wide array of peptide hormones and antibodies. However, almost every type of tumor has the potential to produce hormones or to induce cytokine and immunologic responses. Careful studies of the prevalence of paraneoplastic syndromes indicate that they are more common than is generally appreciated. The signs, symptoms, and metabolic alterations associated with paraneoplastic disorders may be overlooked in the context of a malignancy and its treatment. Consequently, atypical clinical manifestations in a patient with cancer should prompt consideration of a paraneoplastic syndrome. The most common hormonal and hematologic syndromes associated with underlying neoplasia will be discussed here.

ENDOCRINE PARANEOPLASTIC SYNDROMES

Etiology Hormones can be produced from eutopic or ectopic sources. *Eutopic* refers to the expression of a hormone from its normal tissue of origin, whereas *ectopic* refers to hormone production from an atypical tissue source. For example, adrenocorticotropic hormone (ACTH) is expressed eutopically by the corticotrope cells of the anterior pituitary, but it can be expressed ectopically in SCLC. Many hormones are produced at low levels from a wide array of tissues in addition to the classic endocrine source. Thus, ectopic expression is often a quantitative change rather than an absolute change in tissue expression. Nevertheless, the term *ectopic expression* is firmly entrenched and conveys the abnormal physiology associated with hormone production by neoplastic cells. In addition to high levels of hormones, ectopic expression is often characterized by abnormal regulation of hormone production (e.g., defective feedback control) and peptide processing (resulting in large, unprocessed precursors).

A diverse array of molecular mechanisms has been suggested to explain ectopic hormone production. In rare instances, genetic rearrangements account for aberrant hormone expression. For example, translocation of the parathyroid hormone (*PTH*) gene can result in high levels of PTH expression in tissues other than the parathyroid gland because the genetic rearrangement brings the *PTH* gene under the control of atypical regulatory elements. A related phenomenon is well documented in many forms of leukemia and lymphoma, in which somatic genetic rearrangements confer a growth advantage and alter cellular differentiation and function. Although genetic rearrangements cause selected cases of ectopic hormone production, this mechanism is rare, as many tumors are associated with excessive production of numerous peptides. Cellular dedifferentiation probably underlies most cases of ectopic hormone production. Many cancers are poorly differentiated, and certain tumor products, such as human chorionic gonadotropin (hCG), PTH–related protein (PTHrP), and α fetoprotein, are characteristic of gene expression at earlier developmental stages. In contrast, the propensity of certain cancers to produce particular hormones (e.g., squamous cell carcinomas produce PTHrP) suggests that dedifferentiation is partial or that selective pathways are derepressed. These expression profiles probably reflect epigenetic modifications that alter transcriptional repression, microRNA expression, and other pathways that govern cell differentiation.

In SCLC, the pathway of differentiation has been relatively well defined. The neuroendocrine phenotype is dictated in part by the basic-helix-loop-helix (bHLH) transcription factor human achaete-scute homologue 1 (hASH-1), which is expressed at abnormally high levels in SCLC associated with ectopic ACTH. The activity of hASH-1 is inhibited by hairy enhancer of split 1 (HES-1) and by Notch proteins, which also are capable of inducing growth arrest. Thus, abnormal expression of these developmental transcription factors appears to provide a link between cell proliferation and differentiation.

Ectopic hormone production might be considered merely epiphenomenon associated with cancer if it did not result in clinical manifestations. Excessive and unregulated production of hormones such as ACTH, PTHrP, and vasopressin can lead to substantial morbidity and complicate the cancer treatment plan. Moreover, the paraneoplastic endocrinopathies may be a presenting clinical feature of underlying malignancy and prompt the search for an unrecognized tumor.

A large number of paraneoplastic endocrine syndromes have been described, linking overproduction of particular hormones with specific types of tumors. However, certain recurring syndromes emerge from this group **(Table 89-1)**. The most common paraneoplastic endocrine syndromes include hypercalcemia from overproduction of PTHrP and other factors, hyponatremia from excess vasopressin, and Cushing's syndrome from ectopic ACTH.

HYPERCALCEMIA CAUSED BY ECTOPIC PRODUCTION OF PTHRP

(See also Chap. 403)

Etiology Humoral hypercalcemia of malignancy (HHM) occurs in up to 20% of patients with cancer. HHM is most common in cancers of the lung, head and neck, skin, esophagus, breast, and genitourinary tract and in multiple myeloma and lymphomas. There are several distinct humoral causes of HHM, but it is caused most commonly by overproduction of PTHrP. In addition to acting as a circulating humoral factor, bone metastases (e.g., breast, multiple myeloma) may produce PTHrP, leading to local osteolysis and hypercalcemia. PTHrP may also affect the initiation and progression of tumors by acting through pro-survival and chemokine pathways.

TABLE 89-1 Paraneoplastic Syndromes Caused by Ectopic Hormone Production

PARANEOPLASTIC SYNDROME	ECTOPIC HORMONE	TYPICAL TUMOR TYPES[a]
Common		
Hypercalcemia of malignancy	Parathyroid hormone–related protein (PTHrP)	Squamous cell (head and neck, lung, skin), breast, genitourinary, gastrointestinal
	1,25-dihydroxyvitamin D	Lymphomas
	Parathyroid hormone (PTH) (rare)	Lung, ovary
	Prostaglandin E_2 (PGE_2) (rare)	Renal, lung
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)	Vasopressin	Lung (squamous, small cell), gastrointestinal, genitourinary, ovary
Cushing's syndrome	Adrenocorticotropic hormone (ACTH)	Lung (small cell, bronchial carcinoid, adenocarcinoma, squamous), thymus, pancreatic islet, medullary thyroid carcinoma, pheochromocytoma
	Corticotropin-releasing hormone (CRH) (rare)	Pancreatic islet, carcinoid, lung, prostate
	Ectopic expression of gastric inhibitory peptide (GIP), luteinizing hormone (LH)/human chorionic gonadotropin (hCG), other G protein–coupled receptors (rare)	Macronodular adrenal hyperplasia
Less Common		
Non–islet cell hypoglycemia	Insulin-like growth factor type II (IGF-II)	Mesenchymal tumors, sarcomas, adrenal, hepatic, gastrointestinal, kidney, prostate
	Insulin (rare)	Cervix (small-cell carcinoma)
Male feminization	hCG[b]	Testis (embryonal, seminomas), germinomas, choriocarcinoma, lung, hepatic, pancreatic islet
Diarrhea or intestinal hypermotility	Calcitonin[c]	Lung, colon, breast, medullary thyroid carcinoma
	Vasoactive intestinal peptide (VIP)	Pancreas, pheochromocytoma, esophagus
Rare		
Oncogenic osteomalacia	Phosphatonin (fibroblast growth factor 23 [FGF23])	Hemangiopericytomas, osteoblastomas, fibromas, sarcomas, giant cell tumors, prostate, lung
Acromegaly	Growth hormone–releasing hormone (GHRH)	Pancreatic islet, bronchial, and other carcinoids
	Growth hormone (GH)	Lung, pancreatic islet
Hyperthyroidism	Thyroid-stimulating hormone (TSH)	Hydatidiform mole, embryonal tumors, struma ovarii
Hypertension	Renin	Juxtaglomerular tumors, kidney, lung, pancreas, ovary
Consumptive hypothyroidism	Type 3 deiodinase	Hepatic hemangiomas

[a]Only the most common tumor types are listed. For most ectopic hormone syndromes, an extensive list of tumors has been reported to produce one or more hormones. [b]hCG is produced eutopically by trophoblastic tumors. Certain tumors produce disproportionate amounts of the hCG α or hCG β subunit. High levels of hCG rarely cause hyperthyroidism because of weak binding to the TSH receptor. [c]Calcitonin is produced eutopically by medullary thyroid carcinoma and is used as a tumor marker.

PTHrP is structurally related to PTH and binds to the PTH receptor, explaining the similar biochemical features of HHM and hyperparathyroidism. PTHrP plays a key role in skeletal development and regulates cellular proliferation and differentiation in other tissues, including skin, bone marrow, breast, and hair follicles. The mechanism of PTHrP induction in malignancy is incompletely understood; however, tumor-bearing tissues commonly associated with HHM normally produce PTHrP during development or cell renewal. PTHrP expression is stimulated by hedgehog pathways and Gli transcription factors that are active in many malignancies. Transforming growth factor β (TGF-β), which is produced by many tumors, also stimulates PTHrP. Mutations in certain oncogenes, such as *Ras*, also can activate PTHrP expression, as does loss of the tumor suppressor, p53. In addition to its role in HHM, the PTHrP pathway may also provide a potential target for therapeutic intervention to impede cancer growth.

Another relatively common cause of HHM is excess production of 1,25-dihydroxyvitamin D. Like granulomatous disorders associated with hypercalcemia, lymphomas can produce an enzyme that converts 25-hydroxyvitamin D to the more active 1,25-dihydroxyvitamin D, leading to enhanced gastrointestinal calcium absorption. Other causes of HHM include tumor-mediated production of osteolytic cytokines and inflammatory mediators.

Clinical Manifestations The typical presentation of HHM is a patient with a known malignancy who is found to be hypercalcemic on routine laboratory tests. Less often, hypercalcemia is the initial presenting feature of malignancy. Particularly when calcium levels are markedly increased (>3.5 mmol/L [>14 mg/dL]), patients may experience fatigue, mental status changes, dehydration, or symptoms of nephrolithiasis.

Diagnosis Features that favor HHM, as opposed to primary hyperparathyroidism, include known malignancy, recent onset of hypercalcemia, and very high serum calcium levels. Like hyperparathyroidism, hypercalcemia caused by PTHrP is accompanied by hypercalciuria and hypophosphatemia. Patients with HHM typically have metabolic alkalosis rather than hyperchloremic acidosis, as is seen in hyperparathyroidism. Measurement of PTH is useful to exclude primary hyperparathyroidism; the PTH level should be suppressed in HHM. An elevated PTHrP level confirms the diagnosis, and it is increased in ~80% of hypercalcemic patients with cancer. 1,25-Dihydroxyvitamin D levels may be increased in patients with lymphoma.

TREATMENT

Humoral Hypercalcemia of Malignancy

The management of HHM begins with removal of excess calcium in the diet, medications, or IV solutions. Saline rehydration (typically 200–500 mL/h) is used to dilute serum calcium and promote calciuresis; exercise caution in patients with cardiac, hepatic, or renal insufficiency. Forced diuresis with furosemide (20–80 mg IV in escalating doses) or other loop diuretics can enhance calcium excretion but provides relatively little value except in life-threatening hypercalcemia. When used, loop diuretics should be administered only after complete rehydration and with careful monitoring of fluid balance. Oral phosphorus (e.g., 250 mg Neutra-Phos 3–4 times daily) should be given until serum phosphorus is >1 mmol/L (>3 mg/dL). Bisphosphonates such as pamidronate (60–90 mg IV), zoledronate (4–8 mg IV), and etidronate (7.5 mg/kg per day PO for

3–7 consecutive days) can reduce serum calcium within 1–2 days and suppress calcium release for several weeks. Bisphosphonate infusions can be repeated, or oral bisphosphonates can be used for chronic treatment. Dialysis should be considered in severe hypercalcemia when saline hydration and bisphosphonate treatments are not possible or are too slow in onset. Previously used agents such as calcitonin and mithramycin have little utility now that bisphosphonates are available. Calcitonin (2–8 U/kg SC every 6–12 h) should be considered when rapid correction of severe hypercalcemia is needed. Hypercalcemia associated with lymphomas, multiple myeloma, or leukemia may respond to glucocorticoid treatment (e.g., prednisone 40–100 mg PO in four divided doses).

ECTOPIC VASOPRESSIN: TUMOR-ASSOCIATED SIADH

(See also Chap. 49)

Etiology Vasopressin is an antidiuretic hormone normally produced by the posterior pituitary gland. Ectopic vasopressin production by tumors is a common cause of the syndrome of inappropriate antidiuretic hormone (SIADH), occurring in at least half of patients with SCLC. SIADH also can be caused by a number of nonneoplastic conditions, including central nervous system (CNS) trauma, infections, and medications (Chap. 374). Compensatory responses to SIADH, such as decreased thirst, may mitigate the development of hyponatremia. However, with prolonged production of excessive vasopressin, the osmostat controlling thirst and hypothalamic vasopressin secretion may become reset. In addition, intake of free water, orally or intravenously, can quickly worsen hyponatremia because of reduced renal diuresis.

Tumors with neuroendocrine features, such as SCLC and carcinoids, are the most common sources of ectopic vasopressin production, but it also occurs in other forms of lung cancer and with CNS lesions, head and neck cancer, and genitourinary, gastrointestinal, and ovarian cancers. The mechanism of activation of the vasopressin gene in these tumors is unknown but often involves concomitant expression of the adjacent oxytocin gene, suggesting derepression of this locus.

Clinical Manifestations Most patients with ectopic vasopressin secretion are asymptomatic and are identified because of the presence of hyponatremia on routine chemistry testing. Symptoms may include weakness, lethargy, nausea, confusion, depressed mental status, and seizures. The severity of symptoms reflects the rapidity of onset as well as the severity of hyponatremia. Hyponatremia usually develops slowly but may be exacerbated by the administration of IV fluids or the institution of new medications.

Diagnosis The diagnostic features of ectopic vasopressin production are the same as those of other causes of SIADH (Chaps. 49 and 374). Hyponatremia and reduced serum osmolality occur in the setting of an inappropriately normal or increased urine osmolality. Urine sodium excretion is normal or increased unless volume depletion is present. Other causes of hyponatremia should be excluded, including renal, adrenal, or thyroid insufficiency. Physiologic sources of vasopressin stimulation (CNS lesions, pulmonary disease, nausea), adaptive circulatory mechanisms (hypotension, heart failure, hepatic cirrhosis), and medications, including many chemotherapeutic agents, also should be considered as possible causes of hyponatremia. Vasopressin measurements are not usually necessary to make the diagnosis.

TREATMENT

Ectopic Vasopressin: Tumor-Associated SIADH

Most patients with ectopic vasopressin production develop hyponatremia over several weeks or months. The disorder should be corrected gradually unless mental status is altered or there is risk of seizures. Treatment of the underlying malignancy may reduce ectopic vasopressin production, but this response is slow if it occurs at all. Fluid restriction to less than urine output, plus insensible losses, is often sufficient to correct hyponatremia partially. However, strict monitoring of the amount and types of liquids consumed or administered intravenously is required for fluid restriction to be effective. Salt tablets and saline are not helpful unless volume depletion is also present. Demeclocycline (150–300 mg orally three to four times daily) can be used to inhibit vasopressin action on the renal distal tubule, but its onset of action is relatively slow (1–2 weeks). The vaptan class of drugs act by inhibiting vasopressin receptors (V_{1A}, V_{1B}, V_2). Conivaptan, a nonpeptide V_2-receptor antagonist, can be administered either PO (20–120 mg bid) or IV (10–40 mg) and is particularly effective when used in combination with fluid restriction in euvolemic hyponatremia. Tolvaptan (15 mg PO daily) is another vasopressin antagonist. The dose can be increased to 30–60 mg/d based on response. Severe hyponatremia (Na <115 meq/L) or mental status changes may require treatment with hypertonic (3%) or normal saline infusion together with furosemide to enhance free water clearance. The rate of sodium correction should be slow (0.5–1 meq/L per hour) to prevent rapid fluid shifts and the possible development of central pontine myelinolysis.

CUSHING'S SYNDROME CAUSED BY ECTOPIC ACTH PRODUCTION

(See also Chap. 379)

Etiology Ectopic ACTH production accounts for 10–20% of cases of Cushing's syndrome. The syndrome is particularly common in neuroendocrine tumors. SCLC is the most common cause of ectopic ACTH, followed by bronchial and thymic carcinoids, islet cell tumors, other carcinoids, and pheochromocytomas. Ectopic ACTH production is caused by increased expression of the proopiomelanocortin (*POMC*) gene, which encodes ACTH, along with melanocyte-stimulating hormone (MSH), β lipotropin, and several other peptides. In many tumors, there is abundant but aberrant expression of the *POMC* gene from an internal promoter, proximal to the third exon, which encodes ACTH. However, because this product lacks the signal sequence necessary for protein processing, it is not secreted. Increased production of ACTH arises instead from less abundant, but unregulated, *POMC* expression from the same promoter site used in the pituitary. Because tumors lack many of the enzymes needed to process the POMC polypeptide, it is typically released as multiple large, biologically inactive fragments along with relatively small amounts of fully processed, active ACTH.

Rarely, corticotropin-releasing hormone (CRH) is produced by pancreatic islet cell tumors, SCLC, medullary thyroid cancer, carcinoids, or prostate cancer. When levels are high enough, CRH can cause pituitary corticotrope hyperplasia and Cushing's syndrome. Tumors that produce CRH sometimes also produce ACTH, raising the possibility of a paracrine mechanism for ACTH production.

A distinct mechanism for ACTH-independent Cushing's syndrome involves ectopic expression of various G protein–coupled receptors in the adrenal nodules. Ectopic expression of the gastric inhibitory peptide (GIP) receptor is the best-characterized example of this mechanism. In this case, meals induce GIP secretion, which inappropriately stimulates adrenal growth and glucocorticoid production.

Clinical Manifestations The clinical features of hypercortisolemia are detected in only a fraction of patients with documented ectopic ACTH production. Patients with ectopic ACTH syndrome generally exhibit less marked weight gain and centripetal fat redistribution, probably because the exposure to excess glucocorticoids is relatively brief and because cachexia reduces the propensity for weight gain and fat deposition. The ectopic ACTH syndrome is associated with several clinical features that distinguish it from other causes of Cushing's syndrome (e.g., pituitary adenomas, adrenal adenomas, iatrogenic glucocorticoid excess). The metabolic manifestations of ectopic ACTH syndrome are dominated by fluid retention and hypertension, hypokalemia, metabolic alkalosis, glucose intolerance, and occasionally steroid psychosis. The very high ACTH levels often cause

increased pigmentation, reflecting increased activity of MSH derived from the POMC precursor peptide. The extraordinarily high glucocorticoid levels in patients with ectopic sources of ACTH can lead to marked skin fragility and easy bruising. In addition, the high cortisol levels often overwhelm the renal 11β-hydroxysteroid dehydrogenase type II enzyme, which normally inactivates cortisol and prevents it from binding to renal mineralocorticoid receptors. Consequently, in addition to the excess mineralocorticoids produced by ACTH stimulation of the adrenal gland, high levels of cortisol exert activity through the mineralocorticoid receptor, leading to severe hypokalemia.

Diagnosis The diagnosis of ectopic ACTH syndrome is usually not difficult in the setting of a known malignancy. Urine-free cortisol levels fluctuate but are typically greater than two to four times normal, and the plasma ACTH level is usually >22 pmol/L (>100 pg/mL). A suppressed ACTH level excludes this diagnosis and indicates an ACTH-independent cause of Cushing's syndrome (e.g., adrenal or exogenous glucocorticoid). In contrast to pituitary sources of ACTH, most ectopic sources of ACTH do not respond to glucocorticoid suppression. Therefore, high-dose dexamethasone (8 mg PO) suppresses 8:00 A.M. serum cortisol (50% decrease from baseline) in ~80% of pituitary ACTH-producing adenomas but fails to suppress ectopic ACTH in ~90% of cases. Bronchial and other carcinoids are well-documented exceptions to these general guidelines, as these ectopic sources of ACTH may exhibit feedback regulation indistinguishable from pituitary adenomas, including suppression by high-dose dexamethasone, and ACTH responsiveness to adrenal blockade with metyrapone. If necessary, petrosal sinus catheterization can be used to evaluate a patient with ACTH-dependent Cushing's syndrome when the source of ACTH is unclear. After CRH stimulation, a 3:1 petrosal sinus:peripheral ACTH ratio strongly suggests a pituitary ACTH source. Imaging studies (computed tomography or magnetic resonance imaging) are also useful in the evaluation of suspected carcinoid lesions, allowing biopsy and characterization of hormone production using special stains. If available, positron emission tomography or octreotide scanning may identify some sources of ACTH production.

TREATMENT

Cushing's Syndrome Caused by Ectopic ACTH Production

The morbidity associated with the ectopic ACTH syndrome can be substantial. Patients may experience depression or personality changes because of extreme cortisol excess. Metabolic derangements, including diabetes mellitus and hypokalemia, can worsen fatigue. Poor wound healing and predisposition to infections can complicate the surgical management of tumors, and opportunistic infections caused by organisms such as *Pneumocystis carinii* and mycoses are often the cause of death in patients with ectopic ACTH production. These patients likely have increased risk of venous thromboembolism reflecting the combination of malignancy and altered coagulation factor profiles. Depending on prognosis and treatment plans for the underlying malignancy, measures to reduce cortisol levels are often indicated. Treatment of the underlying malignancy may reduce ACTH levels but is rarely sufficient to reduce cortisol levels to normal. Adrenalectomy is not practical for most of these patients but should be considered during surgery for the malignancy or if the underlying tumor is not resectable and the prognosis is otherwise favorable (e.g., carcinoid). Medical therapy with ketoconazole (300–600 mg PO bid), metyrapone (250–500 mg PO every 6 h), mitotane (3–6 g PO in four divided doses, tapered to maintain low cortisol production), or other agents that block steroid synthesis or action is often the most practical strategy for managing the hypercortisolism associated with ectopic ACTH production. Glucocorticoid replacement should be provided to prevent adrenal insufficiency (Chap. 379). Unfortunately, many patients eventually progress despite medical blockade.

TUMOR-INDUCED HYPOGLYCEMIA CAUSED BY EXCESS PRODUCTION OF IGF-II

(See also Chap. 399) Mesenchymal tumors, hemangiopericytomas, hepatocellular tumors, adrenal carcinomas, and a variety of other large tumors have been reported to produce excessive amounts of insulin-like growth factor type II (IGF-II) precursor, which binds weakly to insulin receptors and more strongly to IGF-I receptors, leading to insulin-like actions. The gene encoding IGF-II resides on chromosome 11p15, a locus that is normally imprinted (that is, expression is exclusively from a single parental allele). Biallelic expression of the IGF-II gene occurs in a subset of tumors, suggesting loss of methylation and loss of imprinting as a mechanism for gene induction. In addition to increased IGF-II production, IGF-II bioavailability is increased due to complex alterations in circulating binding proteins. Increased IGF-II suppresses growth hormone (GH) and insulin, resulting in reduced IGF binding protein 3 (IGFBP-3), IGF-I, and acid-labile subunit (ALS). The reduction in ALS and IGFBP-3, which normally sequester IGF-II, causes it to be displaced to a small circulating complex that has greater access to insulin target tissues. For this reason, circulating IGF-II levels may not be markedly increased despite causing hypoglycemia. In addition to IGF-II–mediated hypoglycemia, tumors may occupy enough of the liver to impair gluconeogenesis.

In most cases, a tumor causing hypoglycemia is clinically apparent (usually >10 cm in size), and hypoglycemia develops in association with fasting. The diagnosis is made by documenting low serum glucose and suppressed insulin levels in association with symptoms of hypoglycemia. Serum IGF-II levels may not be increased (IGF-II assays may not detect IGF-II precursors). Increased IGF-II mRNA expression is found in most of these tumors. Any medications associated with hypoglycemia should be eliminated. Treatment of the underlying malignancy, if possible, may reduce the predisposition to hypoglycemia. Frequent meals and IV glucose, especially during sleep or fasting, are often necessary to prevent hypoglycemia. Glucagon and glucocorticoids have also been used to enhance glucose production.

HUMAN CHORIONIC GONADOTROPIN

hCG is composed of α and β subunits and can be produced as intact hormone, which is biologically active, or as uncombined biologically inert subunits. Ectopic production of intact hCG occurs most often in association with testicular embryonal tumors, germ cell tumors, extragonadal germinomas, lung cancer, hepatoma, and pancreatic islet tumors. Eutopic production of hCG occurs with trophoblastic malignancies. hCG α subunit production is particularly common in lung cancer and pancreatic islet cancer. In men, high hCG levels stimulate steroidogenesis and aromatase activity in testicular Leydig cells, resulting in increased estrogen production and the development of gynecomastia. Precocious puberty in boys or gynecomastia in men should prompt measurement of hCG and consideration of a testicular tumor or another source of ectopic hCG production. Most women are asymptomatic. hCG is easily measured. Treatment should be directed at the underlying malignancy.

ONCOGENIC OSTEOMALACIA

Hypophosphatemic oncogenic osteomalacia, also called tumor-induced osteomalacia (TIO), is characterized by markedly reduced serum phosphorus and renal phosphate wasting, leading to muscle weakness, bone pain, and osteomalacia. Serum calcium and PTH levels are normal, and 1,25-dihydroxyvitamin D is low. Oncogenic osteomalacia is usually caused by benign mesenchymal tumors, such as hemangiopericytomas, fibromas, and giant cell tumors, often of the skeletal extremities or head. It has also been described in sarcomas and in patients with prostate or lung cancer. Resection of the tumor reverses the disorder, confirming its humoral basis. The circulating phosphaturic factor was originally called *phosphatonin*—a factor that inhibits renal tubular reabsorption of phosphate and renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. Phosphatonin has been identified as fibroblast growth factor 23 (FGF23). FGF23 levels are increased in some, but not all, patients with osteogenic osteomalacia. FGF23 forms a ternary complex with the klotho protein and renal FGF

receptors to reduce renal phosphate reabsorption. Treatment involves removal of the tumor, if possible, and supplementation with phosphate and vitamin D. Octreotide treatment reduces phosphate wasting in some patients with tumors that express somatostatin receptor subtype 2. Octreotide scans may also be useful in detecting these tumors.

CONSUMPTIVE HYPOTHYROIDISM

Newborns with hepatic hemangiomas can develop a rare form of hypothyroidism caused by overexpression of type 3 deiodinase (D3), an enzyme that degrades and inactivates T4 and T3. The very high expression of D3, and consumption of thyroid hormones, apparently outstrips the thyroid gland's rate of hormone production. The disorder is characterized by low T4, low T3, high TSH, and markedly elevated reverse T3 (rT3), reflecting the degradation of T4 to rT3. In addition to treating the underlying hemangioma (rarely other tumor types), patients are treated with l-thyroxine replacement, titrated to normalize TSH. Steroids and propranolol may provide benefit, perhaps by inhibiting growth factor pathways thought to stimulate D3 production.

HEMATOLOGIC SYNDROMES

The elevation of granulocyte, platelet, and eosinophil counts in most patients with myeloproliferative disorders is caused by the proliferation of the myeloid elements due to the underlying disease rather than to a paraneoplastic syndrome. The paraneoplastic hematologic syndromes in patients with solid tumors are less well characterized than are the endocrine syndromes because the ectopic hormone(s) or cytokines responsible have not been identified in most of these tumors (Table 89-2). The extent of the paraneoplastic syndromes parallels the course of the cancer.

ERYTHROCYTOSIS

Ectopic production of erythropoietin by cancer cells causes most paraneoplastic erythrocytosis. The ectopically produced erythropoietin stimulates the production of red blood cells (RBCs) in the bone marrow and raises the hematocrit. Other lymphokines and hormones produced by cancer cells may stimulate erythropoietin release but have not been proved to cause erythrocytosis.

Most patients with erythrocytosis have an elevated hematocrit (>52% in men, >48% in women) that is detected on a routine blood count. Approximately 3% of patients with renal cell cancer, 10% of patients with hepatoma, and 15% of patients with cerebellar hemangioblastomas have erythrocytosis. In most cases, the erythrocytosis is asymptomatic.

Patients with erythrocytosis due to a renal cell cancer, hepatoma, or CNS cancer should have measurement of red cell mass. If the red cell mass is elevated, the serum erythropoietin level should be measured. Patients with an appropriate cancer, elevated erythropoietin levels, and no other explanation for erythrocytosis (e.g., hemoglobinopathy that causes increased O_2 affinity; Chap. 59) have the paraneoplastic syndrome.

TABLE 89-2 Paraneoplastic Hematologic Syndromes

SYNDROME	PROTEINS	CANCERS TYPICALLY ASSOCIATED WITH SYNDROME
Erythrocytosis	Erythropoietin	Renal cancers, hepatocarcinoma, cerebellar hemangioblastomas
Granulocytosis	G-CSF, GM-CSF, IL-6	Lung cancer, gastrointestinal cancer, ovarian cancer, genitourinary cancer, Hodgkin's disease
Thrombocytosis	IL-6	Lung cancer, gastrointestinal cancer, breast cancer, ovarian cancer, lymphoma
Eosinophilia	IL-5	Lymphoma, leukemia, lung cancer
Thrombophlebitis	Unknown	Lung cancer, pancreatic cancer, gastrointestinal cancer, breast cancer, genitourinary cancer, ovarian cancer, prostate cancer, lymphoma

Abbreviations: G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin.

TREATMENT

Erythrocytosis

Successful resection of the cancer usually resolves the erythrocytosis. If the tumor cannot be resected or treated effectively with radiation therapy or chemotherapy, phlebotomy may control any symptoms related to erythrocytosis.

GRANULOCYTOSIS

Approximately 30% of patients with solid tumors have granulocytosis (granulocyte count >8000/μL). In about half of patients with granulocytosis and cancer, the granulocytosis has an identifiable nonparaneoplastic etiology (infection, tumor necrosis, glucocorticoid administration, etc.). The other patients have proteins in urine and serum that stimulate the growth of bone marrow cells. Tumors and tumor cell lines from patients with lung, ovarian, and bladder cancers have been documented to produce granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and/or interleukin 6 (IL-6). However, the etiology of granulocytosis has not been characterized in most patients.

Patients with granulocytosis are nearly all asymptomatic, and the differential white blood cell count does not have a shift to immature forms of neutrophils. Granulocytosis occurs in 40% of patients with lung and gastrointestinal cancers, 20% of patients with breast cancer, 30% of patients with brain tumors and ovarian cancers, 20% of patients with Hodgkin's disease, and 10% of patients with renal cell carcinoma. Patients with advanced-stage disease are more likely to have granulocytosis than are those with early-stage disease.

Paraneoplastic granulocytosis does not require treatment. The granulocytosis resolves when the underlying cancer is treated.

THROMBOCYTOSIS

Some 35% of patients with thrombocytosis (platelet count >400,000/μL) have an underlying diagnosis of cancer. IL-6, a candidate molecule for the etiology of paraneoplastic thrombocytosis, stimulates the production of platelets in vitro and in vivo. Some patients with cancer and thrombocytosis have elevated levels of IL-6 in plasma. Another candidate molecule is thrombopoietin, a peptide hormone that stimulates megakaryocyte proliferation and platelet production. The etiology of thrombocytosis has not been established in most cases.

Patients with thrombocytosis are nearly all asymptomatic. Thrombocytosis is not clearly linked to thrombosis in patients with cancer. Thrombocytosis is present in 40% of patients with lung and gastrointestinal cancers; 20% of patients with breast, endometrial, and ovarian cancers; and 10% of patients with lymphoma. Patients with thrombocytosis are more likely to have advanced-stage disease and have a poorer prognosis than do patients without thrombocytosis. In ovarian cancer, IL-6 has been shown to directly promote tumor growth. Paraneoplastic thrombocytosis does not require treatment other than treatment of the underlying tumor.

EOSINOPHILIA

Eosinophilia is present in ~1% of patients with cancer. Tumors and tumor cell lines from patients with lymphomas or leukemia may produce IL-5, which stimulates eosinophil growth. Activation of IL-5 transcription in lymphomas and leukemias may involve translocation of the long arm of chromosome 5, to which the genes for IL-5 and other cytokines map.

Patients with eosinophilia are typically asymptomatic. Eosinophilia is present in 10% of patients with lymphoma, 3% of patients with lung cancer, and occasional patients with cervical, gastrointestinal, renal, and breast cancer. Patients with markedly elevated eosinophil counts (>5000/μL) can develop shortness of breath and wheezing. A chest radiograph may reveal diffuse pulmonary infiltrates from eosinophil infiltration and activation in the lungs.

TREATMENT

Eosinophilia

Definitive treatment is directed at the underlying malignancy: Tumors should be resected or treated with radiation or chemotherapy. In most patients who develop shortness of breath related to eosinophilia, symptoms resolve with the use of oral or inhaled glucocorticoids. IL-5 antagonists exist but have not been evaluated in this clinical setting.

THROMBOPHLEBITIS AND DEEP VENOUS THROMBOSIS

Deep venous thrombosis and pulmonary embolism are the most common thrombotic conditions in patients with cancer. Migratory or recurrent thrombophlebitis may be the initial manifestation of cancer. Nearly 15% of patients who develop deep venous thrombosis or pulmonary embolism have a diagnosis of cancer **(Chap. 113)**. The coexistence of peripheral venous thrombosis with visceral carcinoma, particularly pancreatic cancer, is called *Trousseau's syndrome*.

Pathogenesis Patients with cancer are predisposed to thromboembolism because they are often at bed rest or immobilized, and tumors may obstruct or slow blood flow. Postoperative deep venous thrombosis is twice as common in cancer patients who undergo surgery. Chronic IV catheters also predispose to clotting. In addition, clotting may be promoted by release of procoagulants or cytokines from tumor cells or associated inflammatory cells or by platelet adhesion or aggregation. The specific molecules that promote thromboembolism have not been identified.

Chemotherapeutic agents, particularly those associated with endothelial damage, can induce venous thrombosis. The annual risk of venous thrombosis in patients with cancer receiving chemotherapy is about 11%, sixfold higher than the risk in the general population. Bleomycin, L-asparaginase, nitrogen mustard, thalidomide analogues, cisplatin-based regimens, and high doses of busulfan and carmustine are all associated with an increased risk.

In addition to cancer and its treatment causing secondary thrombosis, primary thrombophilic diseases may be associated with cancer. For example, the antiphospholipid antibody syndrome is associated with a wide range of pathologic manifestations **(Chap. 350)**. About 20% of patients with this syndrome have cancers. Among patients with cancer and antiphospholipid antibodies, 35–45% develop thrombosis.

Clinical Manifestations Patients with cancer who develop deep venous thrombosis usually develop swelling or pain in the leg, and physical examination reveals tenderness, warmth, and redness. Patients who present with pulmonary embolism develop dyspnea, chest pain, and syncope, and physical examination shows tachycardia, cyanosis, and hypotension. Some 5% of patients with no history of cancer who have a diagnosis of deep venous thrombosis or pulmonary embolism will have a diagnosis of cancer within 1 year. The most common cancers associated with thromboembolic episodes include lung, pancreatic, gastrointestinal, breast, ovarian, and genitourinary cancers; lymphomas; and brain tumors. Patients with cancer who undergo surgical procedures requiring general anesthesia have a 20–30% risk of deep venous thrombosis.

Diagnosis The diagnosis of deep venous thrombosis in patients with cancer is made by impedance plethysmography or bilateral compression ultrasonography of the leg veins. Patients with a noncompressible venous segment have deep venous thrombosis. If compression ultrasonography is normal and there is a high clinical suspicion for deep venous thrombosis, venography should be done to look for a luminal filling defect. Elevation of D-dimer is not as predictive of deep venous thrombosis in patients with cancer as it is in patients without cancer; elevations are seen in people over age 65 years without concomitant evidence of thrombosis, probably as a consequence of increased thrombin deposition and turnover in aging.

Patients with symptoms and signs suggesting a pulmonary embolism should be evaluated with a chest radiograph, electrocardiogram, arterial blood gas analysis, and ventilation-perfusion scan. Patients with mismatched segmental perfusion defects have a pulmonary embolus. Patients with equivocal ventilation-perfusion findings should be evaluated as described above for deep venous thrombosis in their legs. If deep venous thrombosis is detected, they should be anticoagulated. If deep venous thrombosis is not detected, they should be considered for a pulmonary angiogram.

Patients without a diagnosis of cancer who present with an initial episode of thrombophlebitis or pulmonary embolus need no additional tests for cancer other than a careful history and physical examination. In light of the many possible primary sites, diagnostic testing in asymptomatic patients is wasteful. However, if the clot is refractory to standard treatment or is in an unusual site or if the thrombophlebitis is migratory or recurrent, efforts to find an underlying cancer are indicated.

TREATMENT

Thrombophlebitis and Deep Venous Thrombosis

Patients with cancer and a diagnosis of deep venous thrombosis or pulmonary embolism should be treated initially with IV unfractionated heparin or low-molecular-weight heparin for at least 5 days, and warfarin should be started within 1 or 2 days. The warfarin dose should be adjusted so that the international normalized ratio (INR) is 2–3. Patients with proximal deep venous thrombosis and a relative contraindication to heparin anticoagulation (hemorrhagic brain metastases or pericardial effusion) should be considered for placement of a filter in the inferior vena cava (Greenfield filter) to prevent pulmonary embolism. Warfarin should be administered for 3–6 months. An alternative approach is to use low-molecular-weight heparin for 6 months. The new oral anticoagulants (factor Xa and thrombin inhibitors) are attractive because they do not require close monitoring of the prothrombin time and are not affected by dietary factors. However, data on their use in patients with cancer are not yet mature. Patients with cancer who undergo a major surgical procedure should be considered for heparin prophylaxis or pneumatic boots. Breast cancer patients undergoing chemotherapy and patients with implanted catheters should be considered for prophylaxis. Guidelines recommend that hospitalized patients with cancer and patients receiving a thalidomide analogue receive prophylaxis with low-molecular-weight heparin or low-dose aspirin. Use of prophylaxis routinely during chemotherapy is controversial and not recommended by the American Society of Clinical Oncology.

MISCELLANEOUS REMOTE EFFECTS OF CANCER

Patients with cancer can develop paraneoplastic autoimmune disorders (e.g., thrombocytopenia) and dysfunction of organs not directly invaded or involved with the cancer (rheumatologic and renal abnormalities are among the most frequent). The pathogenesis of these disorders is undefined, but often the conditions reverse if the tumor is removed or successfully treated.

Cutaneous paraneoplastic syndromes are discussed in Chap. 54. Neurologic paraneoplastic syndromes are discussed in Chap. 90.

90 Paraneoplastic Neurologic Syndromes and Autoimmune Encephalitis

Josep Dalmau, Myrna R. Rosenfeld

Paraneoplastic neurologic disorders (PNDs) are cancer-related syndromes that can affect any part of the nervous system (Table 90-1). They are caused by mechanisms other than metastasis or by any of the complications of cancer such as coagulopathy, stroke, metabolic and nutritional conditions, infections, and side effects of cancer therapy. In 60% of patients, the neurologic symptoms precede the cancer diagnosis. Clinically disabling PNDs occur in 0.5–1% of all cancer patients, but they affect 2–3% of patients with neuroblastoma or small-cell lung cancer (SCLC) and 30–50% of patients with thymoma.

PATHOGENESIS

Most PNDs are mediated by immune responses triggered by neuronal proteins (onconeuronal antigens) expressed by tumors. In PNDs of the central nervous system (CNS), many antibody-associated immune responses have been identified (Table 90-2). These antibodies react with both neurons and the patient's tumor, and their detection in serum or cerebrospinal fluid (CSF) usually predicts the presence of cancer. When the antigens are intracellular, most syndromes are associated with extensive infiltrates of CD4+ and CD8+ T cells, microglial activation, gliosis, and variable neuronal loss. The infiltrating T cells are often in close contact with neurons undergoing degeneration, suggesting a primary pathogenic role. T cell–mediated cytotoxicity may contribute directly to cell death in these PNDs. Thus both humoral and cellular immune mechanisms participate in the pathogenesis of many PNDs. This complex immunopathogenesis may underlie the resistance of many of these conditions to therapy.

In contrast to the disorders associated with immune responses against intracellular antigens, those associated with antibodies to antigens expressed on the neuronal cell surface of the CNS or at the neuromuscular junction are more responsive to immunotherapy (Table 90-3, Fig. 90-1). These disorders occur with and without a cancer association and may affect children and young adults, and there is evidence demonstrating a pathogenic role of the antibodies.

Other PNDs are likely immune-mediated, although their antigens are unknown. These include several syndromes of inflammatory neuropathies and myopathies. In addition, many patients with typical PND syndromes are antibody-negative.

For still other PNDs, the cause remains quite obscure. These include, among others, several neuropathies that occur in the terminal stages of cancer and a number of neuropathies associated with plasma cell dyscrasias or lymphoma without evidence of inflammatory infiltrates or deposits of immunoglobulin, cryoglobulin, or amyloid.

TABLE 90-1 Paraneoplastic Syndromes of the Nervous System

CLASSIC SYNDROMES: USUALLY OCCUR WITH CANCER ASSOCIATION	NONCLASSIC SYNDROMES: MAY OCCUR WITH AND WITHOUT CANCER ASSOCIATION
Encephalomyelitis	Brainstem encephalitis
Limbic encephalitis	Stiff-person syndrome
Cerebellar degeneration (adults)	Progressive encephalomyelitis with rigidity and myoclonus
Opsoclonus-myoclonus	Necrotizing myelopathy
Subacute sensory neuronopathy	Motor neuron disease
Gastrointestinal paresis or pseudo-obstruction	Guillain-Barré syndrome
Dermatomyositis (adults)	Subacute and chronic mixed sensory-motor neuropathies
Lambert-Eaton myasthenic syndrome	Neuropathy associated with plasma cell dyscrasias and lymphoma
Cancer- or melanoma-associated retinopathy	Vasculitis of nerve
	Pure autonomic neuropathy
	Acute necrotizing myopathy
	Polymyositis
	Optic neuropathy
	BDUMP
	Peripheral nerve hyperexcitability (neuromyotonia)
	Myasthenia gravis

Abbreviation: BDUMP, bilateral diffuse uveal melanocytic proliferation.

TABLE 90-2 Antibodies to Intracellular Antigens, Syndromes, and Associated Cancers

ANTIBODY	ASSOCIATED NEUROLOGIC SYNDROME(S)	TUMORS
Anti-Hu (ANNA1)	Encephalomyelitis, subacute sensory neuronopathy	SCLC
Anti-Yo (PCA1)	Cerebellar degeneration	Ovary, breast
Anti-Ri (ANNA2)	Cerebellar degeneration, opsoclonus, brainstem encephalitis	Breast, gynecologic, SCLC
Anti-CRMP5 (CV2)	Encephalomyelitis, chorea, optic neuritis, uveitis, peripheral neuropathy	SCLC, thymoma, other
Anti-Ma proteins	Limbic, hypothalamic, brainstem encephalitis	Testicular (Ma2), other (Ma)
Anti-amphiphysin[a]	Stiff-person syndrome, encephalomyelitis	Breast, SCLC
Recoverin, bipolar cell antibodies, others[b]	Cancer-associated retinopathy (CAR) Melanoma-associated retinopathy (MAR)	SCLC (CAR), melanoma (MAR)
Anti-GAD	Stiff-person, cerebellar syndrome, limbic encephalitis	Infrequent tumor association (thymoma and several cancers)

[a]Amphiphysin is likely exposed to the cell surface during synaptic vesicle endocytosis. [b]A variety of target antigens have been identified.

Abbreviations: CRMP, collapsing response-mediator protein; SCLC, small-cell lung cancer.

APPROACH TO THE PATIENT

Paraneoplastic Neurologic Disorders

Three key concepts are important for the diagnosis and management of PNDs. First, it is common for symptoms to appear before the presence of a tumor is known; second, the neurologic syndrome usually develops rapidly, producing severe deficits in a short period of time; and third, there is evidence that prompt tumor control improves the neurologic outcome. Therefore, the major concern of the physician is to recognize a disorder promptly as paraneoplastic and to identify and treat the tumor.

TABLE 90-3 Antibodies to Cell Surface or Synaptic Antigens, Syndromes, and Associated Tumors

ANTIBODY	NEUROLOGIC SYNDROME	TUMOR TYPE WHEN ASSOCIATED
Anti-AChR (muscle)[a]	Myasthenia gravis	Thymoma
Anti-AChR (neuronal)[a]	Autonomic ganglionopathy	SCLC
Anti-VGCC[a]	LEMS, cerebellar degeneration	SCLC
Anti-NMDAR[a]	Anti-NMDAR encephalitis	Teratoma in young women (children and men rarely have tumors)
Anti-LGI1[b]	Limbic encephalitis, hyponatremia, faciobrachial tonic or dystonic seizures	Rarely thymoma
Anti-Caspr2[b]	Morvan's syndrome, neuromyotonia, limbic encephalitis	Thymoma, prostate cancer
Anti-$GABA_BR$[c]	Limbic encephalitis, seizures	SCLC, neuroendocrine
Anti-$GABA_AR$[a]	Encephalitis with prominent seizures and status epilepticus; less often opsoclonus and stiff-person syndrome	Thymoma in ~30% of patients
Anti-AMPAR[a]	Limbic encephalitis with relapses	SCLC, thymoma, breast
Glycine receptor	PERM, stiff-person syndrome	Rarely, thymoma, lung, Hodgkin lymphoma
Anti-DPPX[a]	Agitation, myoclonus, tremor, seizures, hyperekplexia, encephalomyelitis with rigidity	No cancer, but frequent diarrhea or cachexia suggesting paraneoplasia
Anti-Neurexin 3alpha	Autoimmune encephalitis without distinctive features	No cancer association
Anti-Dopamine-2R	Basal ganglia encephalitis	No cancer association
Anti-Tr (DNER)	Cerebellar syndrome	Hodgkin lymphoma, or no tumor
Anti-mGluR1	Cerebellar syndrome	Hodgkin lymphoma, or no tumor
Anti-mGluR5	Autoimmune encephalitis without distinctive features	Hodgkin lymphoma, or no tumor
IgLON5	NREM and REM sleep disorder, and brainstem dysfunction	No tumor association

[a]A direct pathogenic role of these antibodies has been demonstrated in cultured neurons or animal models. [b]Previously named voltage-gated potassium channel antibodies (VGKC); currently included under the term VGKC-complex proteins. Of note, the significance of antibodies to VGKC-complex proteins other than LGI1 and Caspr2 is uncertain (the antigens are unknown, and the response to immunotherapy is variable) [c]This antibody is strongly suspected to be pathogenic.

Abbreviations: AChR, acetylcholine receptor; AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; Caspr2, contactin-associated protein-like 2; DNER, delta/notch-like epidermal growth factor-related receptor; DPPX, dipeptidyl-peptidase-like protein-6; $GABA_BR$, γ-aminobutyric acid B receptor; GAD, glutamic acid decarboxylase; mGluR, metabotropic glutamate receptor; LEMS, Lambert-Eaton myasthenic syndrome; LGI1, leucine-rich glioma-inactivated 1; NMDAR, *N*-methyl-D-aspartate receptor; NREM, non-rapid eye movement; PERM, progressive encephalomyelitis with rigidity and myoclonus; REM, rapid eye movement; SCLC, small-cell lung cancer; VGCC, voltage-gated calcium channel.

PND OF THE CENTRAL NERVOUS SYSTEM AND DORSAL ROOT GANGLIA

When symptoms involve brain, spinal cord, or dorsal root ganglia, the suspicion of PND is usually based on a combination of clinical, radiologic, and CSF findings. Presence of antineuronal antibodies (Tables 90-2 and 90-3) may help in the diagnosis, but only 60–70% of PNDs of the CNS and <20% of those involving the peripheral nervous system have neuronal or neuromuscular junction antibodies that can be used as diagnostic tests.

Magnetic resonance imaging (MRI) and CSF studies are important to rule out neurologic complications due to the direct spread of cancer, particularly metastatic and leptomeningeal disease. In most PNDs, the MRI findings are nonspecific. Paraneoplastic limbic encephalitis is usually associated with characteristic MRI abnormalities in the mesial temporal lobes (see below), but similar findings can occur with other disorders (e.g., nonparaneoplastic autoimmune limbic encephalitis and human herpesvirus type 6 [HHV-6] encephalitis) **(Fig. 90-2)**. The CSF profile of patients with PND of the CNS or dorsal root ganglia typically consists of mild to moderate pleocytosis (<200 mononuclear cells, predominantly lymphocytes), an increase in the protein concentration, and a variable presence of oligoclonal bands. There are no specific electrophysiologic tests that are diagnostic of PND. Moreover, a biopsy of the affected tissue is often difficult to obtain, and although useful to rule out other disorders (e.g., metastasis) the pathologic findings are not specific for PND.

PND OF NERVE AND MUSCLE

If symptoms involve peripheral nerve, neuromuscular junction, or muscle, the diagnosis of a specific PND is usually established on clinical, electrophysiologic, and pathologic grounds. The clinical history, accompanying symptoms (e.g., anorexia, weight loss), and type of syndrome dictate the studies and degree of effort needed to demonstrate a neoplasm. For example, the frequent association of Lambert-Eaton myasthenic syndrome (LEMS) with SCLC should lead to a chest and abdomen computed tomography (CT) or body positron emission tomography (PET) scan and, if negative, periodic tumor screening for at least 3 years after the neurologic diagnosis. In contrast, the weak association of polymyositis with cancer calls into question, the need for repeated cancer screenings in this situation. Serum and urine immunofixation studies should be considered in patients with peripheral neuropathy of unknown cause; detection of a monoclonal gammopathy suggests the need for additional studies to uncover a B cell or plasma cell malignancy. In paraneoplastic neuropathies, diagnostically useful antineuronal antibodies are limited to CRMP5 and Hu (ANNA1).

For any type of PND, if antineuronal antibodies are negative, the diagnosis relies on the demonstration of cancer and the exclusion of other cancer-related or independent neurologic disorders. Combined CT and PET scans often uncover tumors undetected by other tests. For germ cell tumors of the testis and teratomas of the ovary, ultrasound and CT or MRI of the abdomen and pelvis may reveal tumors undetectable by PET.

SPECIFIC PARANEOPLASTIC NEUROLOGIC SYNDROMES

PARANEOPLASTIC ENCEPHALOMYELITIS AND FOCAL ENCEPHALITIS WITH ANTIBODIES AGAINST INTRACELLULAR NEURONAL PROTEINS

The term *encephalomyelitis* describes an inflammatory process with multifocal involvement of the nervous system, including brain, brainstem, cerebellum, and spinal cord. It is often associated with dorsal root ganglia and autonomic dysfunction. For any given patient, the clinical manifestations are determined by the areas predominantly involved, but pathologic studies almost always reveal abnormalities beyond the symptomatic regions. Several clinicopathologic syndromes may occur alone or in combination: (1) *cortical encephalitis*, which may present as "epilepsia partialis continua"; (2) *limbic encephalitis*, characterized by confusion, depression, agitation, anxiety, severe deficits in forming new memories, partial complex seizures, and sometimes dementia (the MRI usually shows unilateral or bilateral medial temporal lobe abnormalities, best seen with T2 and fluid-attenuated inversion recovery sequences); (3) *brainstem encephalitis*, resulting in eye movement disorders (nystagmus, opsoclonus, supranuclear or nuclear paresis), cranial nerve paresis, dysarthria, dysphagia, and central autonomic dysfunction; (4) *cerebellar gait and limb ataxia*; (5) *myelitis*, which may cause lower or upper motor neuron symptoms, myoclonus, muscle rigidity, and spasms; and (6) *autonomic dysfunction* as a result of involvement of the neuraxis at multiple levels, including hypothalamus, brainstem, and autonomic nerves (see "Paraneoplastic Peripheral Neuropathies," below). Cardiac arrhythmias, postural hypotension, and central hypoventilation are frequent causes of death in patients with encephalomyelitis.

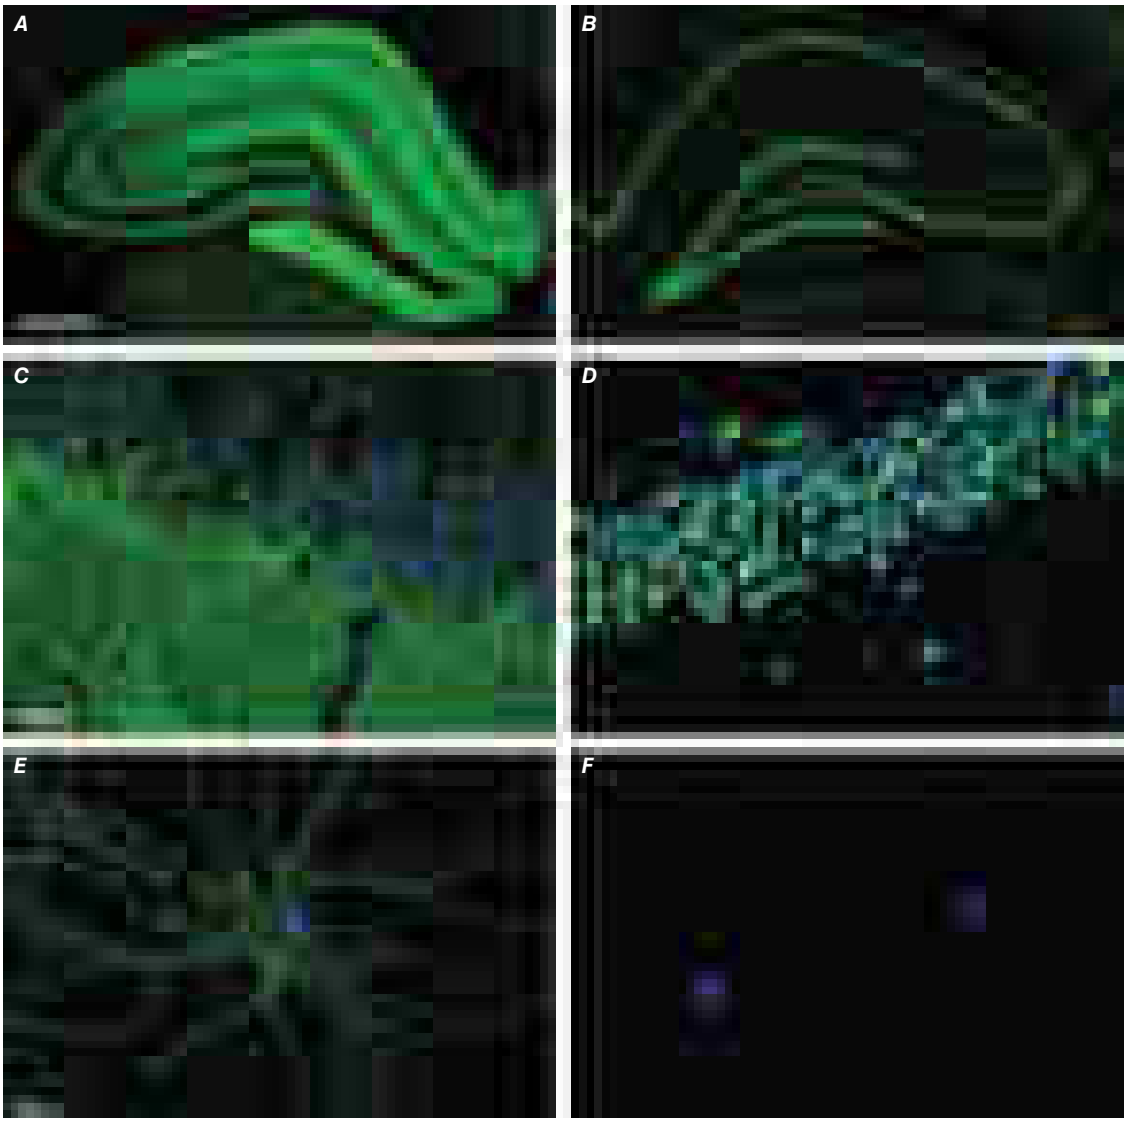

FIGURE 90-1 Comparison of brain and neuronal reactivity of antibodies against a neuronal cell surface, and an intracellular antigen. Coronal section of rat hippocampus immunolabeled with antibodies against a cell surface antigen (*N*-methyl-D-aspartate; NMDA receptor) from a patient with anti-NMDA receptor encephalitis (***A***), compared with the antibodies against an intracellular antigen (Hu) from a patient with small-cell lung cancer and paraneoplastic encephalitis (***B***). Magnification of the reactivity is shown in ***C*** and ***D*** respectively. Compared with the NMDA receptor antibodies that show intense reactivity with the neuropil of hippocampus, the Hu antibodies only show intracellular reactivity after tissue permeabilization. In cultures of dissociated rat hippocampal neurons, only the NMDA receptor antibodies react with the antigen in live non-permeabilized neurons (***E***). The Hu antibodies do not reach the target intracellular antigen in live neurons (***F***). Scale bars: ***A, B*** = 500 μm; ***C, D*** = 20 μm; ***E, F*** = 10 μm. *(From J Dalmau et al: Physiol Rev 97:839, 2017, with permission.)*

Paraneoplastic encephalomyelitis and focal encephalitis are usually associated with SCLC, but many other cancers have been implicated. Patients with SCLC and these syndromes usually have anti-Hu antibodies in serum and CSF. Anti-CRMP5 antibodies occur less frequently; some of these patients may develop chorea, uveitis, or optic neuritis. Antibodies to Ma proteins are associated with limbic, hypothalamic, and brainstem encephalitis and occasionally with cerebellar symptoms; some patients develop hypersomnia, cataplexy, and severe hypokinesia. MRI abnormalities are frequent, including those described with limbic encephalitis and variable involvement of the hypothalamus, basal ganglia, or upper brainstem. The oncologic associations of these antibodies are shown in Table 90-2.

TREATMENT

Encephalomyelitis and Focal Encephalitis

Most types of paraneoplastic encephalitis and encephalomyelitis in which the antigens are intracellular respond poorly to treatment. Stabilization of symptoms or partial neurologic improvement may occur, particularly if there is a satisfactory response of the tumor to treatment. Controlled trials of therapy are lacking, but many reports and the opinion of experts suggest that therapies aimed to remove antibodies against intracellular antigens, such as intravenous immunoglobulin (IVIg) or plasma exchange, usually fail. The main concern should be to treat the tumor and consider immunotherapies, such as cyclophosphamide or tacrolimus, aimed at controlling pathogenic cytotoxic T-cell responses. Approximately 30% of patients with anti-Ma2-associated encephalitis respond to treatment of the tumor (usually a germ cell neoplasm of the testis) and immunotherapy.

ENCEPHALITIDES WITH ANTIBODIES TO CELL-SURFACE OR SYNAPTIC PROTEINS (TABLE 90-3)

These disorders are important for three reasons: (1) they can occur with and without tumor association, (2) some syndromes predominate in young individuals and children, and (3) despite the severity of the symptoms patients usually respond to treatment of the tumor, if found, and immunotherapy (e.g., glucocorticoids, IVIg, plasma exchange, rituximab, or cyclophosphamide).

Encephalitis with N-*methyl*-D-*aspartate (NMDA) receptor antibodies* (Fig. 90-1) usually occurs in young women and children, but men

FIGURE 90-2 Fluid-attenuated inversion recovery sequence magnetic resonance imaging of a patient with limbic encephalitis and LGI1 antibodies. Note the abnormal hyperintensity involving the medial aspect of the temporal lobes.

and older patients of both sexes can be affected. The disorder has a characteristic pattern of symptom progression that includes a prodrome resembling a viral process, followed in a few days by the onset of severe psychiatric symptoms, sleep dysfunction (usually insomnia), reduced verbal output, memory loss, seizures, decreased level of consciousness, abnormal movements (orofacial, limb, and trunk dyskinesias, dystonic postures), autonomic instability, and frequent hypoventilation. Monosymptomatic episodes, such as pure psychosis, occur in 4% of the patients. Clinical relapses occur in 12–24% of patients (12% during the first 2 years after initial presentation). Most patients have intrathecal synthesis of antibodies, likely by infiltrating plasma cells in brain and meninges **(Fig. 90-3*A*)**. The syndrome may be misdiagnosed as a viral or idiopathic encephalitis, neuroleptic malignant syndrome, or encephalitis lethargica, and some patients are initially evaluated by psychiatrists with the suspicion of acute psychosis. The detection of an associated teratoma is dependent on age and gender: 46% of female patients aged ≥12 years have uni- or bilateral ovarian teratomas whereas <7% of girls aged <12 have a teratoma **(Fig. 90-3*B*)**. In male patients, the detection of a tumor is rare. Patients aged >45 years are more frequently male; about 20% of these patients have tumors (e.g., cancer of the breast, ovary, or lung).

Approximately 20% of patients with herpes simplex encephalitis develop a form of autoimmune encephalitis that in children usually associates with abnormal movements (choreoathetosis post-herpes simplex encephalitis) and in adults with cognitive and psychiatric symptoms. This disorder develops a few weeks after the viral infection has resolved, associates with new synthesis of antibodies against the NMDA receptor and other neuronal cell surface proteins, and is usually less responsive to immunotherapy than anti-NMDA receptor encephalitis.

Encephalitis with leucine-rich glioma-inactivated 1 (LGI1) antibodies predominates in patients aged >50 years (65% male) and frequently presents with memory loss and seizures (limbic encephalopathy), along with hyponatremia and sleep dysfunction. In some patients, the encephalitis is preceded by or occurs with myoclonic-like movements called faciobrachial dystonic seizures. Less than 10% of patients have thymoma.

Encephalitis with contactin-associated protein-like 2 (Caspr2) antibodies predominates in patients aged >50 years and is associated with Morvan's syndrome (encephalitis, insomnia, confusion, hallucinations, autonomic dysfunction, and neuromyotonia), or a form of encephalitis with 3 or more of the following core symptoms: encephalopathy, cerebellar symptoms, peripheral nervous system hyperexcitability, dysautonomia, insomnia, neuropathic pain or weight loss. About 20% of patients have thymoma; in patients with Morvan's syndrome the frequency of thymoma appears to be higher.

Encephalitis with γ-aminobutyric acid type B ($GABA_B$) receptor antibodies is usually associated with limbic encephalitis and seizures. In rare instances, patients develop cerebellar symptoms and opsoclonus. Fifty percent of patients have SCLC or a neuroendocrine tumor of the lung. Patients may have additional antibodies to glutamic acid decarboxylase (GAD), which are of unclear significance. Other antibodies to non-neuronal proteins are often found in these patients as well as in patients with α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor antibodies, indicating a general tendency to autoimmunity.

Encephalitis with $GABA_A$ receptor antibodies may affect children and adults, and associates with prominent seizures and status epilepticus, often requiring pharmacologically induced coma. In ~80% of patients, the brain MRI shows multifocal, asynchronous, cortical-subcortical T2/FLAIR abnormalities predominantly involving temporal and frontal lobes, but also basal ganglia and other regions **(Fig. 90-4)**. Most patients do not have an underlying tumor, but some may have thymoma.

Encephalitis with AMPA receptor antibodies affects middle-aged women, who develop acute limbic dysfunction or, less frequently, prominent psychiatric symptoms; 70% of the patients have an underlying tumor

in the lung, breast, or thymus. Neurologic relapses may occur; these also respond to immunotherapy and are not necessarily associated with tumor recurrence.

Encephalitis with glycine receptor (GlyR) antibodies has been described in adults with progressive encephalomyelitis with rigidity and myoclonus (PERM) and stiff-person spectrum of symptoms (with or without GAD antibodies). The disorder usually occurs without tumor association, although some patients have lung cancer, thymoma, or Hodgkin's lymphoma.

Encephalitis with dipeptidyl-peptidase-like protein-6 (or DPPX) antibodies results in symptoms of CNS hyperexcitability including agitation, hallucinations, paranoid delusions, tremor, myoclonus, nystagmus, seizures, and hyperekplexia. Some patients develop progressive encephalomyelitis with rigidity and myoclonus. Diarrhea, other gastrointestinal symptoms, and substantial loss of weight often suggest the presence of an underlying tumor, but in most patients no tumor is identified.

Encephalitis with metabotropic glutamate receptor 5 (mGluR5) antibodies is characterized by the development of encephalopathy associated with Hodgkin lymphoma (Ophelia syndrome). Patients show confusion, agitation, memory loss, delusions, paranoid ideation, hallucinations, psychosis, or seizures that are highly responsive to immunotherapy and tumor treatment.

Encephalitis with antibodies against neurexin 3 alpha does not have distinctive clinical features; the experience is limited and the disorder does not appear to associate with cancer.

Encephalitis with antibodies against the dopamine-2 receptor has been reported in some patients with abnormal movements, gait disturbance, psychiatric symptoms, and evidence of basal ganglia encephalitis. The disorder is rare and does not appear to associate with cancer.

Anti-IgLON5 disease is a chronic or subacute encephalopathy that characteristically associates with non-REM and REM parasomnia, brainstem dysfunction, breathing difficulty, and obstructive sleep apnea. It does not associate with cancer, but shows a strong association with HLA-DRB1*10:01 and HLA-DQB1*05:01. The response to immunotherapy is poor. Neuropathological studies show a neuronal tauopathy predominantly involving hypothalamus and tegmentum of the brainstem.

With the exception of patients with anti-IgLON 5 disease, who rarely respond to treatment, most patients with autoimmune or paraneoplastic encephalopathies associated with antibodies against cell surface or synaptic proteins respond to immunotherapy and treatment of the tumor (if appropriate). Although there are no standardized treatment protocols, the most frequent approach employs progressive escalation of immunotherapy using first a combination of glucocorticoids, IVIg or plasma exchange, and if there is no response, either rituximab or cyclophosphamide.

PARANEOPLASTIC CEREBELLAR DEGENERATION

This disorder is often preceded by a prodrome that may include dizziness, oscillopsia, blurry or double vision, nausea, and vomiting. A few days or weeks later, patients develop dysarthria, gait and limb ataxia, and variable dysphagia. The examination usually shows downbeating nystagmus and, rarely, opsoclonus. Brainstem dysfunction, upgoing toes, or a mild neuropathy may occur. Early in the course, MRI studies are usually normal; later, the MRI reveals cerebellar atrophy. The disorder results from extensive degeneration of Purkinje cells, with variable involvement of other cerebellar cortical neurons, deep cerebellar nuclei, and spinocerebellar tracts. The tumors more frequently involved are SCLC, cancer of the breast and ovary, and Hodgkin's lymphoma.

Anti-Yo (PCA1) antibodies in patients with breast or gynecologic cancers typically associate with prominent or pure cerebellar degeneration. A variable degree of cerebellar dysfunction can be associated with virtually any of the antibodies and PND of the CNS shown in Table 90-2. A number of single case reports have described neurologic improvement after tumor removal, plasma exchange, IVIg, cyclophosphamide, rituximab, or glucocorticoids. However, most patients with paraneoplastic cerebellar degeneration and any of the antibodies shown in Table 90-2 do not improve with treatment.

A cerebellar syndrome can also occur with antibodies against cell-surface or synaptic proteins, including P/Q-type voltage-gated calcium channels (VGCC), Tr (DNER), or mGluR1 (Table 90-3). The frequency and type of tumor association varies with the type of antibody. The cerebellar syndrome of patients with mGluR1 antibodies is highly responsive to treatment of the tumor and immunotherapy, whereas the syndrome of patients with Tr or VGCC antibodies is less treatment responsive.

PARANEOPLASTIC OPSOCLONUS-MYOCLONUS SYNDROME

Opsoclonus is a disorder of eye movement characterized by involuntary, chaotic saccades that occur in all directions of gaze; it is frequently associated with myoclonus and ataxia. Opsoclonus-myoclonus may be cancer-related or idiopathic. When the cause is paraneoplastic, the tumors involved are usually cancer of the lung and breast in adults, neuroblastoma in children, and ovarian teratoma in adolescents and young women. The pathologic substrate of opsoclonus-myoclonus is unclear, but studies suggest that disinhibition of the fastigial nucleus of the cerebellum is involved. Most patients do not have antineuronal antibodies. A small subset of patients with ataxia, opsoclonus, and other eye-movement disorders develop anti-Ri antibodies; these patients may also develop muscle rigidity, laryngeal spasms, and autonomic dysfunction. The tumors most frequently involved in anti-Ri-associated syndromes are breast and ovarian cancer. If the tumor is not successfully treated, the syndrome in adults often progresses to encephalopathy, coma, and death. In addition to treating the tumor, symptoms may respond to immunotherapy (glucocorticoids, plasma exchange, and/or IVIg).

At least 50% of children with opsoclonus-myoclonus have an underlying neuroblastoma. Hypotonia, ataxia, behavioral changes, and irritability are frequent accompanying symptoms. Neurologic symptoms often improve with treatment of the tumor and glucocorticoids, adrenocorticotropic hormone (ACTH), plasma exchange, IVIg, rituximab, or cyclophosphamide. Many patients are left with psychomotor retardation and behavioral and sleep problems.

PARANEOPLASTIC SYNDROMES OF THE SPINAL CORD

The number of reports of paraneoplastic spinal cord syndromes, such as *subacute motor neuronopathy* and *acute necrotizing myelopathy*, has decreased in recent years. This may represent a true decrease in incidence, due to improved and prompt oncologic interventions, or the

identification of nonparaneoplastic etiologies. Some patients with cancer develop *upper* or *lower motor neuron dysfunction* or both, resembling amyotrophic lateral sclerosis. It is unclear whether these disorders have a paraneoplastic etiology or simply coincide with the presence of cancer. There are isolated case reports of cancer patients with motor neuron dysfunction who had neurologic improvement after tumor treatment. A search for lymphoma should be undertaken in patients with a rapidly progressive motor neuron syndrome and a monoclonal protein in serum or CSF.

Paraneoplastic myelitis may present with upper or lower motor neuron symptoms, segmental myoclonus, and rigidity, and can be the first manifestation of encephalomyelitis. *Neuromyelitis optica (NMO) with aquaporin 4 antibodies* may occur in rare instances as a paraneoplastic manifestation of a cancer.

PARANEOPLASTIC STIFF-PERSON SYNDROME

This disorder is characterized by progressive muscle rigidity, stiffness, and painful spasms triggered by auditory, sensory, or emotional stimuli. Rigidity mainly involves the lower trunk and legs, but it can affect the upper extremities and neck. Sometimes, only one extremity is affected (*stiff-limb syndrome*). Symptoms improve with sleep and general anesthetics. Electrophysiologic studies demonstrate continuous motor unit activity. The associated antibodies target proteins (GAD, amphiphysin) involved in the function of inhibitory synapses using γ-aminobutyric acid (GABA) or glycine as neurotransmitters. The presence of amphiphysin antibodies usually indicates a paraneoplastic etiology related to SCLC and breast cancer. By contrast, GAD antibodies may occur in some cancer patients but are much more frequently present in the nonparaneoplastic disorder. GlyR antibodies may occur in some patients with stiff-person syndrome; these antibodies are also detectable in patients with PERM **(Fig. 90-5)**.

Optimal treatment of stiff-person syndrome requires therapy of the underlying tumor, glucocorticoids, and symptomatic use of drugs that enhance GABA-ergic transmission (diazepam, baclofen, sodium valproate, tiagabine, vigabatrin). IVIg and plasma exchange are transiently effective in some patients, and there are reports of responses to rituximab in patients who did not respond to other treatments.

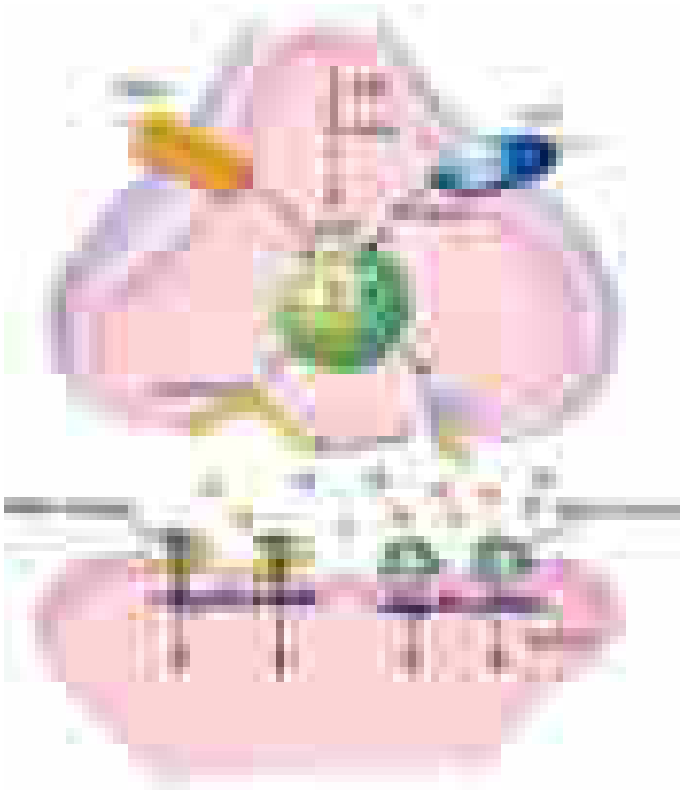

FIGURE 90-5 Autoantibodies in stiff-person spectrum disorders. Schematic representation of an inhibitory synapse including the three main targets of autoantibodies in patients with stiff-person spectrum disorders: the presynaptic proteins GAD and amphiphysin, and the postsynaptic glycine receptor (GlyR). *(From J Dalmau et al: Physiol Rev 97:839, 2017.)*

PARANEOPLASTIC SENSORY NEURONOPATHY OR DORSAL ROOT GANGLIONOPATHY

This syndrome is characterized by sensory deficits that may be symmetric or asymmetric, painful dysesthesias, radicular pain, and decreased or absent reflexes. All modalities of sensation and any part of the body including face and trunk can be involved. Specialized sensations such as taste and hearing can also be affected. Electrophysiologic studies show decreased or absent sensory nerve potentials with normal or near-normal motor conduction velocities. Symptoms result from an inflammatory, likely immune-mediated, process that targets the dorsal root ganglia, causing neuronal loss and secondary degeneration of the posterior columns of the spinal cord. The dorsal and, less frequently, the anterior nerve roots and peripheral nerves may also be involved. This disorder often precedes or is associated with encephalomyelitis and autonomic dysfunction and has the same immunologic and oncologic associations (Hu antibodies, SCLC).

As with anti-Hu-associated encephalomyelitis, the therapeutic approach focuses on prompt treatment of the tumor and use of immune suppressants such as cyclophosphamide or tacrolimus. Glucocorticoids occasionally produce clinical stabilization or improvement. The benefit of IVIg and plasma exchange is not proven.

PARANEOPLASTIC PERIPHERAL NEUROPATHIES

These disorders may develop any time during the course of the neoplastic disease. Neuropathies occurring at late stages of cancer or lymphoma usually cause mild to moderate sensorimotor deficits due to axonal degeneration of unclear etiology. These neuropathies are often masked by concurrent neurotoxicity from chemotherapy and other cancer therapies. In contrast, the neuropathies that develop in the early stages of cancer frequently show a rapid progression, sometimes with a relapsing and remitting course, and evidence of inflammatory infiltrates and axonal loss or demyelination. If demyelinating features predominate **(Chaps. 438 and 439)**, IVIg, plasma exchange, or glucocorticoids may improve symptoms. Occasionally anti-CRMP5 antibodies are present; detection of anti-Hu suggests concurrent dorsal root ganglionitis.

Guillain-Barré syndrome and *brachial plexitis* have occasionally been reported in patients with lymphoma, but there is no clear evidence of a paraneoplastic association **(Chap. 439)**.

Monoclonal gammopathies associated with multiple myeloma, cryoglobulinemia, amyloidosis, Waldenstrom macroglobulinemia, or POEMS (polyneuropathy, organomegaly, endocrinopathy, M-protein spike, and skin manifestations) syndrome among others, may cause neuropathy by a variety of mechanisms, including compression of roots and plexuses by metastasis to vertebral bodies and pelvis, by deposits of amyloid in peripheral nerves, or through a direct interaction of the abnormal immunoglobulin with peripheral nerve antigens. In other patients, the mechanisms underlying the neuropathy remain unknown. Neuropathies more often occur with IgM gammopathies than with IgG and IgA isotypes. The phenotype of the neuropathy and likelihood of improvement with successful treatment of the gammopathy is dependent on the underlying hematologic disorder.

Vasculitis of the nerve and muscle causes a painful symmetric or asymmetric distal axonal sensorimotor neuropathy with variable proximal weakness. It predominantly affects elderly men and is associated with an elevated erythrocyte sedimentation rate and increased CSF protein concentration. SCLC and lymphoma are the primary tumors involved. Glucocorticoids and cyclophosphamide often result in neurologic improvement.

Peripheral nerve hyperexcitability (*neuromyotonia,* or *Isaacs' syndrome*) is characterized by spontaneous and continuous muscle fiber activity of peripheral nerve origin. Clinical features include cramps, muscle twitching (fasciculations or myokymia), stiffness, delayed muscle relaxation (pseudomyotonia), and spontaneous or evoked carpal or pedal spasms. The involved muscles may be hypertrophic, and some patients develop paresthesias and hyperhidrosis. CNS dysfunction,

including mood and behavioral changes, sleep disorder, hallucinations, and autonomic symptoms may occur. The electromyogram (EMG) shows fibrillations; fasciculations; and doublet, triplet, or multiplet single-unit (myokymic) discharges that have a high intraburst frequency. Some patients have Caspr2 antibodies usually in the context of Morvan's syndrome, but most patients with isolated neuromyotonia are antibody negative. The disorder often occurs without cancer; if paraneoplastic, benign and malignant thymomas and SCLC are the usual tumors. Phenytoin, carbamazepine, and plasma exchange improve symptoms.

Paraneoplastic autonomic neuropathy usually develops as a component of other disorders, such as LEMS and encephalomyelitis. It may rarely occur as a pure or predominantly autonomic neuropathy with cholinergic or adrenergic dysfunction at the pre- or postganglionic levels. Patients can develop several life-threatening complications, such as gastrointestinal paresis with pseudo-obstruction, cardiac dysrhythmias, and postural hypotension. Other clinical features include abnormal pupillary responses, dry mouth, anhidrosis, erectile dysfunction, and problems in sphincter control. The disorder occurs in association with several tumors, including SCLC, cancer of the pancreas or testis, carcinoid tumors, and lymphoma. Because autonomic symptoms can be the presenting feature of encephalomyelitis, serum anti-Hu and anti-CRMP5 antibodies should be sought. Antibodies to ganglionic (alpha3-type) neuronal acetylcholine receptors are the cause of autoimmune autonomic ganglionopathy, a disorder that frequently occurs without cancer association **(Chap. 432)**.

LAMBERT-EATON MYASTHENIC SYNDROME

LEMS is discussed in Chap. 440.

MYASTHENIA GRAVIS

Myasthenia gravis is discussed in Chap. 440.

POLYMYOSITIS-DERMATOMYOSITIS

Polymyositis and dermatomyositis are discussed in detail in Chap. 358.

ACUTE NECROTIZING MYOPATHY

Patients with this syndrome develop myalgias and rapid progression of weakness involving the extremities, neck, pharyngeal, respiratory, and sometimes cardiac muscles. Serum muscle enzymes are elevated, and muscle biopsy shows extensive necrosis with minimal or absent inflammation and sometimes deposits of complement. The disorder may occur without a cancer association (sometimes as a result of statin exposure, connective tissue disease, or HIV) or with cancer. Patients with antibodies against 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) and seronegative patients are more likely to have an underlying cancer than those with antibodies against signal recognition particle. No specific type of cancer has been found to predominate. Successful treatment of the tumor and aggressive immunotherapy (glucocorticoids, IVIg, and steroid-sparing immunosuppressants) may lead to complete or substantial recovery.

PARANEOPLASTIC VISUAL SYNDROMES

This group of disorders involves the retina and, less frequently, the uvea and optic nerves. The term *cancer-associated retinopathy* is used to describe paraneoplastic cone and rod dysfunction characterized by photosensitivity, progressive loss of vision and color perception, central or ring scotomas, night blindness, and attenuation of photopic and scotopic responses in the electroretinogram (ERG). The most commonly associated tumor is SCLC. *Melanoma-associated retinopathy* affects patients with metastatic cutaneous melanoma. Patients develop acute onset of night blindness and shimmering, flickering, or pulsating photopsias that often progress to visual loss. The ERG shows reduced b-waves with normal dark adapted a-waves. Paraneoplastic optic neuritis and uveitis can develop in association with encephalomyelitis. Patients with paraneoplastic uveitis and optic neuritis may harbor CRMP5 antibodies.

Some paraneoplastic retinopathies are associated with serum antibodies that specifically react with the subset of retinal cells undergoing degeneration, supporting an immune-mediated pathogenesis (Table 90-2). Paraneoplastic retinopathies rarely show substantial improvement after treatment of the tumor and immunotherapy, however, stabilization of symptoms and partial responses to a variety of immunotherapies (glucocorticoids, plasma exchange, IVIg, rituximab or alemtuzumab) have been reported.

91 Late Consequences of Cancer and Its Treatment

Carl E. Freter, Dan L. Longo

There are over 10 million American cancer survivors. The vast majority of these will bear some mark of their cancer and its treatment, and a large proportion will experience long-term consequences including medical problems, psychosocial dysfunction, economic hardship, sexual dysfunction, and discrimination regarding employment and insurance. Many of these problems are directly related to cancer treatment. As patients survive longer from more types of malignancies, we are increasingly recognizing the biologic toll our very imperfect therapies take in terms of morbidity and mortality. The human face of these consequences of therapy confronts the cancer specialist who treats them every day. Although long-term survivors of childhood leukemias, Hodgkin's lymphoma, and testicular cancer, as examples, have taught us much about the consequences of cancer treatment, we keep learning more as patients survive longer with newer therapies. Newer "targeted" chemotherapy drugs have their own, often unique, long-term toxicities about which we remain in a learning process. Cancer "survivorship" clinics are increasing to expressly follow patients for long-term toxicities of cancer treatment.

The pace of developing therapies that mitigate treatment-related consequences has been slow, partly due to an understandable aversion to alter regimens that work and partly due to a lack of new, effective, less toxic therapeutic agents with less "collateral damage" to replace known agents with known toxicities. The types of damage from cancer treatment vary. Often, a final common pathway is irreparable damage to DNA. Surgery can create dysfunction, including blind gut loops with absorption problems and loss of function of removed body parts. Radiation may damage end-organ function, for example, loss of potency in prostate cancer patients, pulmonary fibrosis, and neurocognitive impairment, and may act as a direct carcinogen. Cancer chemotherapy can be a direct carcinogen and has a kaleidoscope of other toxicities discussed in this chapter. **Table 91-1** lists the late effects of cancer treatment.

The first goal of therapy is to eradicate or control the malignancy. Late treatment consequences are, indeed, testimony to the increasing success of such treatment. Their occurrence sharply underlines the necessity to develop more effective therapies with less long-term morbidity and mortality. At the same time, a sense of perspective and relative risk is necessary; fear of long-term complications should not prevent the application of effective, particularly curative, cancer treatment.

TABLE 91-1 Late Effects of Cancer Therapy

Surgical Procedure	Effect
Amputation	Functional loss
Lymph node dissection	Risk of lymphedema
Ostomy	Psychosocial impact
Splenectomy	Risk of sepsis
Adhesions	Risk of obstruction
Bowel anastomoses	Malabsorption syndromes
Radiation Therapy	**Effect**
Organ	
Bone	Premature termination of growth, osteonecrosis
Soft tissues	Atrophy, fibrosis
Brain	Neuropsychiatric deficits, cognitive dysfunction
Thyroid	Hypothyroidism, Graves' disease, cancer
Salivary glands	Dry mouth, caries, dysgeusia
Eyes	Cataracts
Heart	Pericarditis, myocarditis, coronary artery disease
Lung	Pulmonary fibrosis
Kidney	Decreased function, hypertension
Liver	Decreased function
Intestine	Malabsorption, stricture
Gonads	Infertility, premature menopause
Any	Secondary neoplasia

Chemotherapy		Effect
Organ	**Drug**	
Bone	Glucocorticoids	Osteoporosis, avascular necrosis
Brain	Methotrexate, cytarabine, others	Neuropsychiatric deficits, cognitive decline?
Peripheral nerves	Vincristine, platinum, taxanes	Neuropathy, hearing loss
Eyes	Glucocorticoids	Cataracts
Heart	Anthracyclines, trastuzumab	Cardiomyopathy
Lung	Bleomycin	Pulmonary fibrosis
	Methotrexate	Pulmonary hypersensitivity
Kidney	Platinum, others	Decreased function, hypomagnesemia
Liver	Various	Altered function
Gonads	Alkylating agents, others	Infertility, premature menopause
Bone marrow	Various	Aplasia, myelodysplasia, secondary leukemia

CARDIOVASCULAR DYSFUNCTION

CHEMOTHERAPEUTIC AGENTS

Cardiovascular toxicity of cancer chemotherapeutic agents includes dysrhythmias, cardiac ischemia, cardiomyopathic congestive heart failure (CHF), pericardial disease, and peripheral vascular disease. Because these cardiac toxicities are difficult to distinguish from disease that is not associated with cancer treatment, clear etiologic implication of cancer chemotherapeutic agents may be difficult. Cardiovascular complications occurring in an unexpected clinical setting in patients who have undergone cancer therapy are often important in raising suspicion. Dose-dependent myocardial toxicity of anthracyclines with characteristic myofibrillar dropout is pathologically pathognomonic on endomyocardial biopsy. Anthracycline cardiotoxicity occurs through a root mechanism of chemical free radical damage. Fe^{3+}-doxorubicin complexes damage DNA, nuclear and cytoplasmic membranes, and mitochondria. About 5% of patients receiving >450–550 mg/m^2 of doxorubicin will develop CHF. Cardiotoxicity in relation to the dose of anthracycline is clearly not a step function, but rather a continuous function, and occasional patients are seen with CHF at substantially lower doses. Advanced age, other concomitant cardiac disease, hypertension, diabetes, and thoracic radiation therapy are all important cofactors in promoting anthracycline-associated CHF. The risk of cardiac failure appears to be substantially lower when doxorubicin is administered by continuous infusion. Anthracycline-related CHF is difficult to reverse and has a mortality rate as high as 50%, making prevention crucial. Some anthracyclines such as mitoxantrone are associated with less cardiotoxicity, and continuous-infusion regimens and liposomally encapsulated doxorubicin are associated with less cardiotoxicity. Dexrazoxane, an intracellular iron chelator, may limit anthracycline toxicity, but the concern of limiting chemotherapeutic efficacy has somewhat limited its use. Monitoring patients for cardiac toxicity typically involves periodic gated nuclear cardiac blood pool ejection fraction testing (multigated acquisition scan [MUGA]) or cardiac ultrasonography. More recently, cardiac magnetic resonance imaging (MRI) has been used, but MRI is not standard or widespread. Testing is performed more frequently at higher cumulative doses, with additional risk factors, and certainly for any newly developing CHF or other symptoms of cardiac dysfunction.

After anthracyclines, trastuzumab is the next most frequent cardiotoxic drug currently in use. Trastuzumab is frequently used as adjuvant breast cancer therapy, sometimes in conjunction with anthracyclines, which is believed to result in additive or possibly synergistic toxicity. In contrast to anthracyclines, cardiotoxicity is not dose-related, is usually reversible, is not associated with pathologic changes of anthracyclines on cardiac myofibrils, and has a different biochemical mechanism inhibiting intrinsic cardiac repair mechanisms. Toxicity is typically routinely monitored every 3–4 doses using functional cardiac testing as mentioned earlier for anthracyclines.

Other cardiotoxic drugs include lapatinib, phosphoramide mustards (cyclophosphamide), ifosfamide, interleukin 2, ponatinib, imatinib, and sunitinib.

RADIATION THERAPY

Radiation therapy that includes the heart can cause interstitial myocardial fibrosis, acute and chronic pericarditis, valvular disease, and accelerated premature atherosclerotic coronary artery disease. Repeated or high (>6000 cGy) radiation doses are associated with greater risk, as is concomitant or distant cardiotoxic cancer chemotherapy exposure. Symptoms of acute pericarditis, which peaks about 9 months after treatment, include dyspnea, chest pain, and fever. Chronic constrictive pericarditis may develop 5–10 years following radiation therapy. Cardiac valvular disease includes aortic insufficiency from fibrosis or papillary muscle dysfunction resulting in mitral regurgitation. A threefold increased risk of fatal myocardial infarction is associated with mantle field radiation with accelerated coronary artery disease. Carotid radiation similarly increases the risk of embolic stroke.

TREATMENT

Chemotherapeutic/Radiation-Induced Cardiovascular Disease

Therapy for chemotherapeutic/radiation-induced cardiovascular disease is essentially the same as therapy for disease not associated with cancer treatment. Discontinuation of the offending agent is the first step. Diuretics, fluid and sodium restriction, and antiarrhythmic agents are often useful for acute symptoms. Afterload reduction with angiotensin-converting enzyme (ACE) inhibitors or, in some cases, β-adrenergic blockers (carvedilol) often is of significant benefit, and digitalis may be helpful as well.

A hybrid discipline of "cardio-oncology" has been developing in clinics to expressly follow chemotherapy-treated patients for cardiotoxicity. The goals are early intervention using more sensitive techniques, management of cardiotoxicity before it becomes symptomatic, and using clinical trials to identify cardioprotective strategies.

PULMONARY DYSFUNCTION

CHEMOTHERAPEUTIC AGENTS

Bleomycin generates activated free radical oxygen species and causes pneumonitis associated with a radiographic or interstitial ground-glass appearance diffusely throughout both lungs, often worse in the lower lobes. A nonproductive cough with or without fever may be an early sign. This toxicity is dose-related and dose-limiting. The diffusion capacity of the lungs for carbon dioxide (DL_{CO}) is a sensitive measure of toxicity and recovery, and a baseline value is generally obtained for future comparison prior to bleomycin therapy. Additive or synergistic risk factors include age, prior lung disease, and concomitant use of other chemotherapy, lung irradiation, and high concentrations of inspired oxygen. Other chemotherapeutic agents notable for pulmonary toxicity include mitomycin, nitrosoureas, doxorubicin with radiation, gemcitabine combined with weekly docetaxel, methotrexate, and fludarabine. High-dose alkylating agents, cyclophosphamide, ifosfamide, and melphalan are frequently used in the hematopoietic stem cell transplant setting, often with whole-body radiation. This therapy may result in severe pulmonary fibrosis and/or pulmonary venoocclusive disease.

RADIATION THERAPY

Risk factors for radiation pneumonitis include advanced age, poor performance status, preexisting compromised pulmonary function, and radiation volume and dose. The dose "threshold" is thought to be in the range of 5–20 Gy. Hypoxemia and dyspnea on exertion are characteristic. Fine, high-pitched "Velcro rales" may be an accompanying physical finding, and fever, cough, and pleuritic chest pain are common symptoms. The DL_{CO} is the most sensitive measure of pulmonary functional impairment, and ground-glass infiltrates often correspond with relatively sharp edges to the irradiated volume, although the pneumonitis may progress beyond the field and even occasionally involve the contralateral unirradiated lung.

TREATMENT

Pulmonary Dysfunction

Chemotherapy- and radiation-induced pneumonitis is generally very corticosteroid responsive, except in the case of nitrosoureas. Prednisone 1 mg/kg is often used to control acute symptoms and pulmonary dysfunction with a generally slow taper. Prolonged glucocorticoid therapy requires gastrointestinal protection with proton pump inhibitors, management of hyperglycemia, heightened infection management, and treatment of steroid-induced osteoporosis. Antibiotics, bronchodilators, oxygen in only necessary doses, and diuretics may all play an important role in management of pneumonitis, and consultation with a pulmonologist should be routinely undertaken. Amifostine has been studied as a pulmonary radioprotectant, with inconclusive results, and is associated with skin rash, fatigue, and nausea; hence, it is not considered standard therapy at this time. Transforming growth factor β (TGF-β) is believed to be a major inducer of radiation fibrosis and represents a therapeutic target for development of anti-TGF-β therapies.

NEUROLOGIC DYSFUNCTION

CHEMOTHERAPEUTIC AGENTS

Chemotherapy- and radiation-induced neurologic dysfunction is unfortunately increasing in both incidence and severity as a result of improved supportive care leading to more aggressive regimens and longer cancer survivorship allowing the development of late toxicity. Direct effects on myelin, glial cells, and neurons have all been implicated, with alterations in cellular cytoskeleton, axonal transport, and cellular metabolism as mechanisms.

Vinca alkaloids produce a characteristic "stocking-glove" neuropathy with numbness and tingling advancing to loss of motor function, which is highly dose related. Distal sensorimotor polyneuropathy prominently involves loss of deep tendon reflexes with initially loss of pain and temperature sensation, followed by proprioceptive and vibratory loss. This requires careful patient history and physical examination by experienced oncologists to decide when the drug must be stopped due to toxicity. Milder toxicity often slowly completely resolves. Vinca alkaloids may sometimes be associated with jaw claudication, autonomic neuropathy, ileus, cranial nerve palsies, and, in severe cases, encephalopathy, seizures, and coma.

Cisplatin is associated with sensorimotor neuropathy and hearing loss, especially at doses >400 mg/m^2, requiring audiometry in patients with preexisting hearing compromise. Carboplatin is often substituted in such cases given its lesser effect on hearing.

Many of the agents that target kinase enzymes in tumor cells and 5-fluorouracil congeners produce dysesthesias and painful hands and feet known as hand-foot syndrome or palmar-plantar erythrodysesthesia. Symptoms usually abate when the agent is stopped.

Neurocognitive dysfunction has been well described in childhood survivors of acute lymphoblastic leukemia (ALL) treatment, including intrathecal methotrexate or cytosine arabinoside in conjunction with prophylactic cranial irradiation. Methotrexate alone may cause acute leukoencephalopathy characterized by somnolence and confusion that is often reversible. Acute toxicity is dose related, especially at doses >3 g/m^2, with younger patients being at greater risk. Subacute methotrexate toxicity occurs weeks after therapy and is often ameliorated with glucocorticoid therapy. Chronic methotrexate toxicity (leukoencephalopathy) develops months or years after treatment and is characterized clinically as progressive loss of cognitive function and focal neurologic signs, which are irreversible, promoted by synchronous or metachronous radiation therapy, and more pronounced at a younger age.

Neurocognitive decline following chemotherapy alone occurs notably in breast cancer patients receiving adjuvant chemotherapy; this has been referred to as "chemo brain." It is clinically associated with impaired memory, learning, attention, and speed of information processing. There is no clear mechanistic explanation for its cause and no clearly effective therapy. This entity is justifiably attracting more attention and clearly needs to be studied to develop effective therapy or prophylaxis.

Many cancer patients experience intrusive or debilitating concerns about cancer recurrence following successful therapy. In addition, these patients may experience job, insurance, stress, relationship, financial, and sexual difficulties. Oncologists need to ask about and address these issues explicitly with patients and provide appropriate counseling or support systems. Suicidal ideation and suicide have an increased incidence in cancer patients and survivors.

RADIATION THERAPY

Acute radiation central nervous system (CNS) toxicity occurs within weeks; is characterized by nausea, drowsiness, hypersomnia, and ataxia; and is most often associated with recovery. Early delayed toxicity occurring weeks to 3 months following therapy is associated with similar symptoms as acute toxicity and is pathologically associated with reversible demyelination. Chronic, late radiation injury occurs 9 months to up to 10 years following therapy. Focal necrosis is a common pathologic finding, and glucocorticoid therapy may be helpful. Diffuse radiation injury is associated with global CNS neurologic dysfunction and diffuse white matter changes on computed tomography (CT) or MRI. Pathologically, small vessel changes are prominent. Glucocorticoids may be symptomatically useful but do not alter the course. Necrotizing encephalopathy is the most severe form of radiation injury and almost always is associated with chemotherapy, notably methotrexate.

Cranial radiation may also be associated with an array of endocrine abnormalities with disruption of normal pituitary/hypothalamic axis function, and a high index of suspicion needs to be maintained to identify and treat this toxicity.

Radiation-associated spinal cord injury (myelopathy) is highly dose-dependent and rarely occurs with modern radiation therapy. An early, self-limited form involving electric sensations down the spine on neck flexion (Lhermitte's sign) is seen 6–12 weeks after treatment and

generally resolves over weeks. Peripheral nerve toxicity is quite rare owing to relative radiation resistance.

HEPATIC DYSFUNCTION

CHEMOTHERAPEUTIC AGENTS

Long-term hepatic damage from standard chemotherapy regimens is rare. Long-term methotrexate or high-dose chemotherapy alone or with radiation therapy, for example, in preparative regimens for bone marrow transplantation, may result in venoocclusive disease of the liver. This potentially lethal complication classically presents with anicteric ascites, elevated alkaline phosphatase, and hepatosplenomegaly. Pathologically, there is venous congestion, epithelial cell proliferation, and hepatocyte atrophy progressing to frank fibrosis. Frequent monitoring of liver function tests during any chemotherapy is necessary to avoid both idiosyncratic and expected toxicities.

Certain nucleoside drugs have been associated with hepatic dysfunction; however, this complication is rare in oncology.

RADIATION THERAPY

Hepatic radiation damage depends on dose, volume, fractionation, preexisting liver disease, and synchronous or metachronous chemotherapy. In general, radiation doses to the liver >1500 cGy can produce hepatic dysfunction with a steep dose-injury curve. Radiation-induced liver disease closely mimics hepatic venoocclusive disease.

RENAL/BLADDER DYSFUNCTION

Cisplatin produces reversible decrements in renal function, but may also produce severe irreversible toxicity in the presence of renal disease and may predispose to accentuated damage with subsequent renal insults. Cyclophosphamide and ifosfamide, as prodrugs primarily activated in the liver, have cleavage products (acrolein) that can produce hemorrhagic cystitis. This can be prevented with the free radical scavenger MESNA (mercaptoethane sulfonate), which is required for ifosfamide administration. Hemorrhagic cystitis caused by these agents may predispose to bladder cancer.

REPRODUCTIVE AND ENDOCRINE DYSFUNCTION

CHEMOTHERAPEUTIC AGENTS

Alkylating agents are associated with the highest rates of male and female infertility, which is directly dependent on age, dose, and duration of treatment. The age at treatment is an important determinant of fertility outcome, with prepubertal patients having the highest tolerance. Ovarian failure is age related, and females who resume menses after treatment are still at increased risk for premature menopause. Males generally have reversible azoospermia during lower intensity alkylator chemotherapy, and long-term infertility is associated with doses of cyclophosphamide >9 g/m^2 and with high-intensity therapy, such as that used in hematopoietic stem cell transplantation. Males undergoing potentially sterilizing chemotherapy should be offered sperm banking. Gonadotropin-releasing hormone (GnRH) analogs remain experimental to preserve ovarian function. Assisted reproductive technologies can be helpful to couples with chemotherapy-induced infertility.

RADIATION THERAPY

Testicles and ovaries in prepubertal patients are less sensitive to radiation damage; spermatogenesis is affected by low doses of radiation, and complete azoospermia occurs at 600–700 cGy. Leydig cell dysfunction, in contrast, occurs at <2000 cGy, and hence, endocrine function is lost at much higher radiation doses than spermatogenesis. Erectile dysfunction occurs in up to 80% of men treated with external-beam radiation therapy for prostate cancer. Sildenafil may be useful in reversing erectile dysfunction. Ovarian function damage with radiation is age related and occurs at doses of 150–500 cGy. Premature induction of menopause can have serious medical and psychological sequelae. Hormone replacement therapy is often contraindicated (as in estrogen receptor–positive breast cancer). Attention must be paid to maintenance of bone mass with calcium and vitamin D supplements and oral bisphosphonates, and bone mass should be monitored using bone density determinations. Paroxetine, clonidine, pregabalin, and other drugs may be useful in symptomatically controlling hot flashes.

Long-term survivors of childhood cancer (e.g., ALL) who have received cranial radiation may have altered leptin biology and growth hormone deficiency, leading to obesity and reduced strength, exercise tolerance, and bone density.

Radiation therapy to the neck (e.g., in Hodgkin's lymphoma) may lead to hypothyroidism, Graves' disease, thyroiditis, and thyroid malignancies. Thyroid-stimulating hormone (TSH) is followed routinely in such patients to prevent hypothyroidism, and to suppress persistently elevated levels of TSH, which may cause or drive thyroid cancer.

IMMUNOTHERAPY

The development of treatments that inhibit immune checkpoints like CTLA-4 and PD-1 has led to significant advances in treating a number of malignancies. However, late side effects from these agents may occur. The most serious chronic toxicities include the breaking of self-tolerance and the autoimmune destruction of certain endocrine organs, particularly the thyroid and the adenohypophysis (anterior pituitary). Patients with autoimmune thyroiditis or hypophysitis require life-long hormone replacement. Early recognition is important.

OCULAR COMPLICATIONS

Cataracts may be caused by glucocorticoids, depending on duration and dose; radiation therapy; and uncommonly, tamoxifen. Orbital radiation therapy may cause blindness.

ORAL COMPLICATIONS

Radiation therapy can produce xerostomia (dry mouth), with an attendant increase in caries and poor dentition. Taste and appetite may be suppressed. Bisphosphonate use may result in osteonecrosis of the jaw.

RAYNAUD'S PHENOMENON

Up to 40% of patients treated with bleomycin may develop Raynaud's phenomenon as a result of an unknown mechanism.

SECOND MALIGNANCIES

Second malignancies in patients cured of cancer are a major cause of death, and treated cancer patients must be monitored for their occurrence. The induction of second malignancies is governed by the complex interplay of a number of factors including age, gender, environmental exposures, genetic susceptibility, and cancer treatment itself. In a number of settings, the events leading to the primary cancer themselves increase the risk of second malignancies. Patients with lung cancer are at increased risk of esophageal and head and neck cancers, and vice versa, due to shared risk factors including alcohol and tobacco abuse. Indeed, the risk of developing a second primary head and neck, esophageal, or lung cancer is also increased in these patients. Patients with breast cancer are at increased risk of breast cancer in the opposite breast. Patients with Hodgkin's lymphoma are at risk for non-Hodgkin's lymphomas. Genetic cancer syndromes (e.g., multiple endocrine neoplasia or Li-Fraumeni, Lynch's, Cowden's, and Gardner's syndromes) are examples of genetically based second malignancies of specific types. Cancer treatment itself does not appear to be responsible for the risk of these secondary malignancies. Deficient DNA repair can greatly increase the risk of cancers from DNA-damaging agents, as in ataxia-telangiectasia. Importantly, the risk of treatment-related second malignancies is at least additive and often synergistic with combined chemotherapy and radiation therapy, and hence for such combined-therapy treatment approaches, it is important to establish the necessity of each in the treatment program. All of these patients require special surveillance or, in some cases, prophylactic surgery as part of appropriate treatment and follow-up.

CHEMOTHERAPEUTIC AGENTS

Chemotherapy is significantly associated with two fatal second malignancies: acute leukemia and myelodysplastic syndromes. Two types

of leukemia have been described; in patients treated with alkylating agents, acute myeloid leukemia is associated with deletions in chromosome 5 or 7. The lifetime risk is about 1–5%, is increased by radiation therapy, and increases with age. The incidence of these leukemias peaks at 4–6 years, with risk returning close to baseline at 10 years. The other type of acute myeloid leukemia is related to therapy with topoisomerase inhibitors, is associated with chromosome 10q23 translocations, has an incidence of <1%, and generally occurs 1.5–3 years after treatment. Both of these acute myeloid leukemias are refractory to treatment and have a high mortality. The development of myelodysplastic syndromes is increased following chemotherapy, and these are often associated with leukemic progression and a dismal prognosis. A fraction of the population (those with or without cancer) develops clonal hematopoiesis and the percentage increases with age. In such patients, the hematopoietic stem cells carry mutations that are associated with myeloid malignancy despite normal blood counts. It is thought that the presence of these genetic lesions may predispose patients to develop myeloid malignancies.

RADIATION THERAPY

Patients receiving radiation have an increasing and lifelong risk of second malignancies that is 1–2% in the second decade following treatment but increases to >25% after 25 years. These malignancies include cancers of the thyroid and breast, sarcomas, gastric cancer, and CNS cancers, which often tend to be aggressive, occur in or adjacent to a radiation field, and have a poor prognosis. An example of organ-, age-, and sex-dependent radiation-induced secondary malignancy is breast cancer, in which the risk is small with radiation in women aged <30 years but increases about twentyfold over baseline in women aged >30 years. A 25-year-old woman treated with mantle radiation for Hodgkin's lymphoma has a 29% actuarial risk of developing breast cancer by age 55.

HORMONAL THERAPY

Treatment of breast cancer with tamoxifen for 5 years or longer is associated with a 1–2% risk of endometrial cancer. Surveillance is generally effective at finding these cancers at an early stage. The risk of mortality from tamoxifen-induced endometrial cancer is low compared to the benefit of tamoxifen as adjuvant therapy for breast cancer.

IMMUNOSUPPRESSIVE THERAPY

Immunosuppressive therapy, as used in allogeneic bone marrow transplantation, particularly with T-cell depletion using antithymocyte globulin or other means, increases the risk of Epstein Barr virus–associated B-cell lymphoproliferative disorder. The incidence at 10 years after T-cell depletion is 9–12%. Discontinuing immunosuppressive therapy, if possible, is often associated with complete disease regression.

RECOMMENDATIONS FOR FOLLOW-UP

All former cancer patients should be followed indefinitely. This is most often done by oncologists, but demographic changes suggest that more primary care physicians will need to be trained in the follow-up of treated cancer patients in remission. Cancer patients need to be educated about signs and symptoms of recurrence and potentially adverse effects related to therapy. Localized pain or palpable abnormality in a previously radiated field should prompt radiographic evaluation. Screening tests, when available and validated, should be used on a routine and regular basis (e.g., mammography and Pap smear), particularly in patients receiving radiation to specific organs. Annual mammography should start no later than 10 years after breast radiation. Patients receiving radiation fields encompassing thyroid tissue should have regular thyroid examinations and TSH testing. Patients treated with alkylating agents or topoisomerase inhibitors should have a complete blood count every 6–12 months, and cytopenias, abnormal cells on peripheral smear, or macrocytosis should be evaluated with bone marrow biopsy and aspirate, to include cytogenetics, flow cytometry, or fluorescence in situ hybridization (FISH) studies as appropriate.

As the population of cancer survivors lives longer and grows, cancer survivorship has become an increasingly recognized subject, and the Institute of Medicine and National Research Council have published a monograph entitled *From Cancer Patient to Cancer Survivor: Lost in Transition.* The monograph proposes a plan that would inform clinicians caring for cancer survivors in complete detail of their previous treatments, complications thereof, signs and symptoms of late effects, and recommended screening and follow-up procedures. **Table 91-2** lists long-term treatment effects by cancer type.

TABLE 91-2 Long-Term Treatment Effects by Cancer Type

CANCER TYPE	LATE EFFECTS
Pediatric cancers	Majority have at least one late effect 30% with moderate/severe problems Cardiovascular: radiation, anthracyclines Lungs: radiation Skeletal abnormalities: radiation Psychological, cognitive, and sexual problems Second neoplasms significant cause of death
Hodgkin's lymphoma	Thyroid dysfunction: radiation Premature coronary artery disease: radiation Gonadal dysfunction: chemotherapy Postsplenectomy sepsis Myelodysplasia Acute myeloid leukemia Non-Hodgkin's lymphomas Breast cancer, lung cancer, and melanoma Fatigue, psychological and sexual problems Peripheral neuropathy
Non-Hodgkin's lymphoma	Myelodysplasia Acute leukemia Bladder cancer Peripheral neuropathy
Acute leukemia	Second malignancies: hematologic, solid tumors Neuropsychiatric dysfunction Subnormal growth Thyroid abnormalities Infertility
Bone marrow stem cell transplantation	Infertility Graft-versus-host disease (allogeneic transplant) Psychosexual dysfunction
Head and neck cancer	Poor dentition, dry mouth, poor nutrition: radiation
Breast cancer	Tamoxifen: endometrial cancer, blood clots Aromatase inhibitors: osteoporosis, arthritis Cardiomyopathy: anthracycline ± radiation, trastuzumab Acute leukemia Hormone deficiency symptoms: hot flashes, vaginal dryness, dyspareunia Psychosocial dysfunction "Chemo brain"
Testicular cancer	Raynaud's phenomenon Renal dysfunction Pulmonary dysfunction Retrograde ejaculation: surgery 15% sexual dysfunction
Colon cancer	Major risk is second colon cancer Quality of life high in survivors
Prostate cancer	Impotence Urinary incontinence (0–15%) Chronic proctitis, prostatitis/cystitis: radiation

OUTLOOK

Clearly, the challenge for the future is to combine chemotherapy, targeted agents, biologic therapies, radiation, and surgery to produce better outcomes with less toxicity, including late effects of therapy. This

is easily said but less easily accomplished. As treatment becomes more effective in new patient populations (ovarian, bladder, anal, and laryngeal cancers, for example), we will expect to discover new populations at risk for late effects. These populations will need to be followed carefully, so that such effects are recognized and treated. Cancer survivors represent an underused resource for prevention studies. Childhood cancer survivors, especially, suffer multiple chronic health impairments. The incidence of these late treatment consequences appears to have no plateau with age, throwing in stark relief the necessity of close monitoring and therapies with fewer late consequences of treatment.

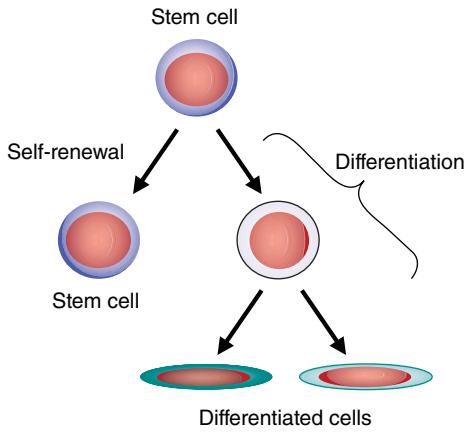

FIGURE 92-1 Signature characteristics of the stem cell. Stem cells have two essential features: the capacity to differentiate into a variety of mature cell types and the capacity for self-renewal. Intrinsic factors associated with self-renewal include expression of *Bmi-1*, *Gfi-1*, *PTEN*, *STAT5*, *Tel/Atv6*, *p21*, *p18*, *MCL-1*, *Mel-18*, *RAE28*, and *HoxB4*. Extrinsic signals for self-renewal include Notch, Wnt, SHH, angiogenin, and Tie2/Ang-1. Based mainly on murine studies, hematopoietic stem cells express the following cell surface molecules: CD34, Thy-1 (CD90), c-Kit receptor (CD117), CD133, CD164, and c-Mpl (CD110, also known as the thrombopoietin receptor).

Section 2 Hematopoietic Disorders

92 Hematopoietic Stem Cells

David T. Scadden, Dan L. Longo

All of the cell types in the peripheral blood and some cells in every tissue of the body are derived from hematopoietic (*hemo*: blood; *poiesis*: creation) stem cells. If the hematopoietic stem cell is damaged and can no longer function (e.g., due to a nuclear accident), a person would survive 2–4 weeks in the absence of extraordinary support measures. With the clinical use of hematopoietic stem cells, tens of thousands of lives are saved each year **(Chap. 110)**. Stem cells produce hundreds of billions of blood cells daily from a stem cell pool that is estimated to be only in the tens of thousands. How stem cells do this, how they persist for many decades despite the production demands, and how they may be better used in clinical care are important issues in medicine.

The study of blood cell production has become a paradigm for how other tissues may be organized and regulated. Basic research in hematopoiesis includes defining stepwise molecular changes accompanying functional changes in maturing cells, aggregating cells into functional subgroups, and demonstrating hematopoietic stem cell regulation by a specialized microenvironment; these concepts are worked out in hematology, but they offer models for other tissues. Moreover, these concepts may not be restricted to normal tissue function but extend to malignancy. Stem cells are rare cells among a heterogeneous population of cell types, and their behavior is assessed mainly in experimental animal models involving reconstitution of hematopoiesis. Thus, much of what we know about stem cells is imprecise and based on inferences from genetically manipulated animals.

CARDINAL FUNCTIONS OF HEMATOPOIETIC STEM CELLS

All stem cell types have two cardinal functions: self-renewal and differentiation **(Fig. 92-1)**. Stem cells exist to generate, maintain, and repair tissues. They function successfully if they can replace a wide variety of shorter-lived mature cells over prolonged periods. The process of self-renewal (see below) assures that a stem cell population can be sustained over time. Without self-renewal, the stem cell pool would become exhausted and tissue maintenance would not be possible. The process of differentiation leads to production of the effectors of tissue function: mature cells. Without proper differentiation, the integrity of tissue function would be compromised and organ failure or neoplasia would ensue.

In the blood, mature cells have variable average life spans, ranging from hours for mature neutrophils to a few months for red blood cells to many years for memory lymphocytes. However, the stem cell pool is the central, durable source of all blood and immune cells, maintaining a capacity to produce a broad range of cells from a single cell source, yet keeping itself vigorous over decades of life. As an individual stem cell divides, it has the capacity to accomplish one of three division outcomes: two stem cells, two cells destined for differentiation, or one stem cell and one differentiating cell. The former two outcomes are the result of symmetric cell division, whereas the latter indicates a different outcome for the two daughter cells—an event termed *asymmetric cell division*. The relative balance for these types of outcomes may change during development and under particular kinds of demands on the stem cell pool.

DEVELOPMENTAL BIOLOGY OF HEMATOPOIETIC STEM CELLS

During development, blood cells are produced at different sites. Initially, the yolk sac provides oxygen-carrying red blood cells and many of the macrophage-like cells that are resident in tissues: cells like microglia in the brain. The placenta and several sites of intraembryonic blood cell production then become involved in sequential order. These move from the genital ridge at a site where the aorta, gonadal tissue, and mesonephros are emerging to the fetal liver and then, in the second trimester, to the bone marrow and spleen. As the location of stem cells changes, the cells they produce also change. The yolk sac provides red cells expressing embryonic hemoglobins and tissue-resident macrophages. Intraembryonic sites of hematopoiesis generate stem cells, red cells, platelets, and the circulating cells of innate immunity. The production of the cells of adaptive immunity occurs when the bone marrow is colonized and the thymus forms. Stem cell proliferation remains high, even in the bone marrow, until shortly after birth, when it appears to dramatically decline. The cells in the bone marrow are thought to arrive by the bloodborne transit of cells from the fetal liver after calcification of the long bones has begun. The presence of stem cells in the circulation is not unique to a time window in development, however, as hematopoietic stem cells circulate throughout life. The time that stem cells spend freely circulating appears to be brief (measured in minutes

in the mouse), but the stem cells that do circulate are functional and can be used for transplantation. The number of stem cells that circulate can be increased in a number of ways to facilitate harvest and transfer to the same or a different host.

MOBILITY OF HEMATOPOIETIC STEM CELLS

Cells entering and exiting the bone marrow do so through a series of molecular interactions. Circulating stem cells (through CD162 and CD44) engage the lectins (carbohydrate binding proteins) P- and E-selectin on the endothelial surface to slow the movement of the cells to a rolling phenotype. Stem cell integrins are then activated and accomplish firm adhesion between the stem cell and vessel wall, with a particularly important role for stem cell VCAM-1 engaging endothelial VLA-4. The chemokine CXCL12 (SDF1) interacting with stem cell CXCR4 receptors and ionic calcium interacting with the calcium sensing receptor appear to be important in the process of stem cells getting from the circulation to where they engraft in the bone marrow. This is particularly true in the developmental move from fetal liver to bone marrow.

However, the role for CXCR4 in adults appears to be more related to retention of stem cells in the bone marrow rather than the process of getting them there. Interrupting that retention process through either specific molecular blockers of the CXCR4/CXCL12 interaction, cleavage of CXCL12, or downregulation of the CXCR4 receptor can all result in the release of stem cells into the circulation. This process is an increasingly important aspect of recovering stem cells for therapeutic use as it has permitted the harvesting process to be done by leukapheresis rather than bone marrow punctures in the operating room. Granulocyte colony-stimulating factor and plerixafor, a macrocyclic compound that can block CXCR4, are both used clinically to mobilize marrow hematopoietic stem cells for transplant. Refining our knowledge of how stem cells get into and out of the bone marrow may improve our ability to obtain stem cells and make them more efficient at finding their way to the specific sites for blood cell production, the so-called stem cell niche.

HEMATOPOIETIC STEM CELL MICROENVIRONMENT

The concept of a specialized microenvironment, or stem cell niche, was first proposed to explain why cells derived from the bone marrow of one animal could be used in transplantation and again be found in the bone marrow of the recipient. This niche is more than just a housing site for stem cells, however. It is an anatomic location where regulatory signals are provided that allow the stem cells to thrive, to expand if needed, and to provide varying amounts of descendant daughter cells. In addition, unregulated growth of stem cells may be problematic based on their undifferentiated state and self-renewal capacity. Thus, the niche must also regulate the number of stem cells produced. In this manner, the niche has the dual function of serving as a site of nurture but imposing limits for stem cells: in effect, acting as both a nutritive and constraining home.

The niche for blood stem cells changes with each of the sites of blood production during development, but for most of human life it is located in the bone marrow. Within the bone marrow, the perivascular space particularly in regions of trabecular bone serves as a niche. The mesenchymal and endothelial cells of the marrow microvessels produce kit ligand and CXCL12, both known to be important for hematopoietic stem cells. Other cell types, such as sympathetic neurons, nonmyelinating Schwann cells, macrophages, megakaryocytes, osteoclasts, and osteoblasts, have been shown to regulate stem cells, some by direct and others by indirect effects. Extracellular matrix proteins like osteopontin and heparan sulfates also affect stem cell function. The endosteal region appears to be particularly important for transplanted cells, in part because many of the mesenchymal cells and sinusoidal blood vessels of the central marrow are disrupted by the conditioning regimens used to prepare a patient for transplantation. The functioning of the niche as a supportive context for stem cells is of obvious importance for maintaining hematopoiesis and in transplantation. An active area of study involves determining whether the niche is altered in disease and whether drugs can modify niche function to improve transplantation or normal stem cell function in hematologic disease.

EXCESS CAPACITY OF HEMATOPOIETIC STEM CELLS

In the absence of disease, one never runs out of hematopoietic stem cells. Indeed, serial transplantation studies in mice suggest that sufficient stem cells are present to reconstitute several animals in succession, with each animal having normal blood cell production. The fact that allogeneic stem cell transplant recipients also never run out of blood cells in their life span, which can extend for decades, argues that even the limiting numbers of stem cells provided to them are sufficient. How stem cells respond to different conditions to increase or decrease their mature cell production remains poorly understood. Clearly, negative feedback mechanisms affect the level of production of most of the cells, leading to the normal tightly regulated blood cell counts. However, many of the regulatory mechanisms that govern production of more mature progenitor cells do not apply or apply differently to stem cells. Similarly, most of the molecules shown to be able to change the size of the stem cell pool have little effect on more mature blood cells. For example, the growth factor erythropoietin, which stimulates red blood cell production from more mature precursor cells, has no effect on stem cells. Similarly, granulocyte colony-stimulating factor drives the rapid proliferation of granulocyte precursors but has little or no effect on the cell cycling of stem cells. Rather, it changes the location of stem cells by indirect means, altering molecules such as CXCL12 that tether stem cells to their niche. Molecules shown to be important for altering the proliferation, self-renewal, or survival of stem cells, such as cyclin-dependent kinase inhibitors, transcription factors like *Bmi-1*, microRNA-processing enzymes like Dicer, or even metabolic regulators like pyruvate kinase isoforms have little or different effects on progenitor cells. Hematopoietic stem cells have governing mechanisms that are distinct from the cells they generate.

HEMATOPOIETIC STEM CELL DIFFERENTIATION

Hematopoietic stem cells sit at the base of a branching hierarchy of cells culminating in the many mature cell types that compose the blood and immune system **(Fig. 92-2)**. The maturation steps leading to terminally differentiated and functional blood cells take place both as a consequence of intrinsic changes in gene expression and niche-directed and cytokine-directed changes in the cells. Our knowledge of the details remains incomplete. As stem cells mature to progenitors, precursors, and, finally, mature effector cells, they undergo a series of functional changes. These include the obvious acquisition of functions defining mature blood cells, such as phagocytic capacity or hemoglobin synthesis. They also include the progressive loss of plasticity (i.e., the ability to become other cell types). For example, the myeloid progenitor can make all cells in the myeloid series but none in the lymphoid series. As common myeloid progenitors mature, they become precursors for either monocytes and granulocytes or erythrocytes and megakaryocytes, but not both. Some amount of reversibility of this process may exist early in the differentiation cascade, but that is lost beyond a distinct stage in normal physiologic conditions. With genetic interventions, however, blood cells, like other somatic cells, can be reprogrammed to become a variety of cell types.

As cells differentiate, they may also lose proliferative capacity **(Fig. 92-3)**. Mature granulocytes are incapable of proliferation and only increase in number by increased production from precursors. The exceptions to the rule are some tissue-resident macrophages, which appear capable of proliferation, and lymphoid cells. Lymphoid cells retain the capacity to proliferate but have linked their proliferation to the recognition of particular proteins or peptides by specific antigen receptors on their surface. Like many tissues with short-lived mature cells such as the skin and intestine, blood cell proliferation is largely accomplished by a more immature progenitor population. In general, cells within the highly proliferative progenitor cell compartment are also relatively short-lived, making their way through the differentiation process in a defined molecular program involving the sequential activation of particular sets of genes. For any particular cell type, the

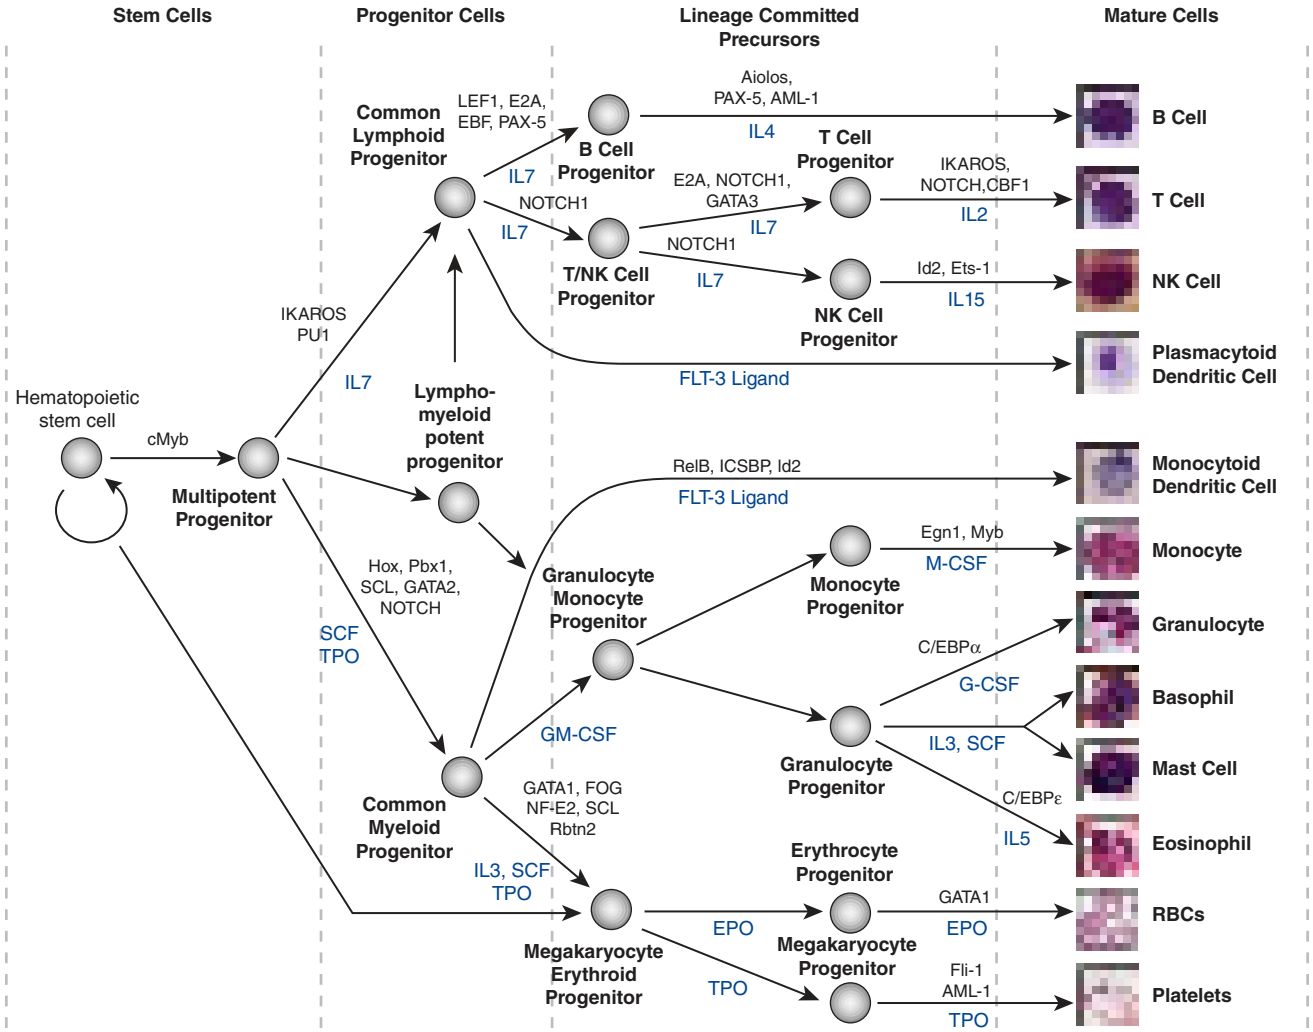

FIGURE 92-2 Hierarchy of hematopoietic differentiation. *Stem cells* are multipotent cells that are the source of all descendant cells and have the capacity to provide either long-term (measured in years) or short-term (measured in months) cell production. *Progenitor cells* have a more limited spectrum of cells they can produce and are generally a shorter-lived, highly proliferative population also known as transient amplifying cells. *Precursor cells* are cells committed to a single blood cell lineage but with a continued ability to proliferate; they do not have all the features of a fully mature cell. *Mature cells* are the terminally differentiated product of the differentiation process and are the effector cells of specific activities of the blood and immune system. Progress through the pathways is mediated by alterations in gene expression. The regulation of the differentiation by soluble factors and cell-cell communications within the bone marrow niche are still being defined. The transcription factors that characterize particular cell transitions are illustrated on the *arrows*; the soluble factors that contribute to the differentiation process are in *blue*. This picture is a simplification of the process. Active research is revealing multiple discrete cell types in the maturation of B cells and T cells and has identified cells that are biased toward one lineage or another (rather than uncommitted) in their differentiation. EPO, erythropoietin; RBC, red blood cell; SCF, stem cell factor; TPO, thrombopoietin.

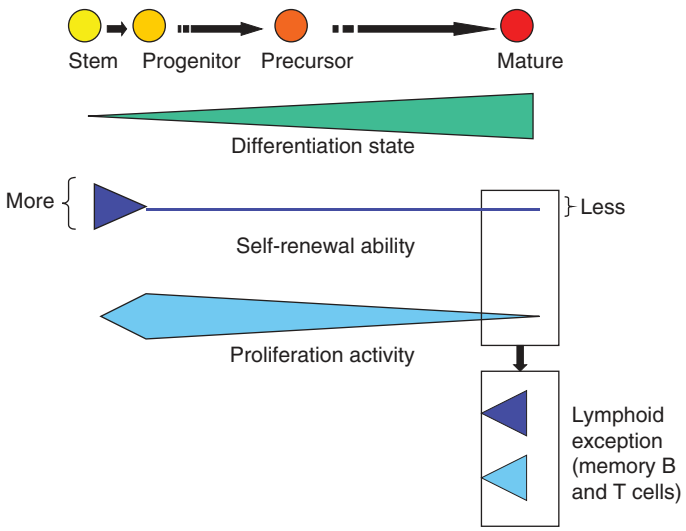

FIGURE 92-3 Relative function of cells in the hematopoietic hierarchy. The boxes represent distinct functional features of cells in the myeloid (*upper box*) versus lymphoid (*lower box*) lineages.

differentiation program is difficult to speed up. The time it takes for hematopoietic progenitors to become mature cells is ~10–14 days in humans, evident clinically by the interval between cytotoxic chemotherapy and blood count recovery in patients.

Although hematopoietic stem cells are generally thought to have the capacity to form all cells of the blood, it is becoming clear that individual stem cells may not be equal in their differentiation potential. That is, some stem cells are "biased" to become mature cells of a particular type. In addition, the general concept of cells having a binary choice of lymphoid or myeloid differentiation is not entirely accurate. A cell population with limited megakaryocytic and erythroid or myeloid (monocyte and granulocyte) and lymphoid potential is now added to the commitment steps stem cells may undergo.

SELF-RENEWAL

The hematopoietic stem cell must balance its three potential fates: apoptosis, self-renewal, and differentiation. The proliferation of cells is generally not associated with the ability to undergo a self-renewing division except among memory T and B cells and among stem cells. Self-renewal capacity has generally been regarded as giving way to differentiation as the only option after cell division when cells leave the stem cell compartment, unless they become memory lymphocytes.

However, emerging data suggest that some myeloid committed progenitors may have self-renewing potential in vivo, providing long-term production of cells. Stem cells all have self-renewing capacity by definition, and they have an additional feature characterizing their proliferation machinery. Stem cells in many mature adult tissues are heterogeneous with some being deeply quiescent, serving as a deep reserve, whereas others are more proliferative and replenish the short-lived progenitor population. In the hematopoietic system, stem cells are generally cytokine-resistant, remaining dormant even when cytokines drive bone marrow progenitors to proliferation rates measured in hours. Stem cells, in contrast, are thought to divide at far longer intervals, measured in months to years, for the most quiescent cells. This quiescence is difficult to overcome in vitro, limiting the ability to effectively expand human hematopoietic stem cells. The process may be controlled by particularly high levels of cyclin-dependent kinase inhibitors like p57 or CDKN1c that restrict entry of stem cells into the cell cycle, blocking the G_1-S transition. Exogenous signals from the niche also appear to enforce quiescence, including angiogenin, interleukin-18, and perhaps angiopoietin 1.

The regulation of stem cell proliferation also appears to change with age. In mice, the cyclin-dependent kinase inhibitor p16INK4a accumulates in stem cells in older animals and is associated with a change in stem cell functions, including cell cycling. Lowering expression of p16INK4a in older animals improves stem cell cycling and capacity to reconstitute hematopoiesis in adoptive hosts, making them similar to younger animals. Mature cell numbers are unaffected. Therefore, molecular events governing the specific functions of stem cells are being gradually made clear and offer the potential of new approaches to changing stem cell function for therapy. One critical stem cell function that remains poorly defined is the molecular regulation of self-renewal.

For medicine, self-renewal is perhaps the most important function of stem cells because it is critical in regulating the number of stem cells. Stem cell number is a key limiting parameter for both autologous and allogeneic stem cell transplantation. Were we to have the ability to use fewer stem cells or expand limited numbers of stem cells ex vivo, it might be possible to reduce the morbidity and expense of stem cell harvests and enable use of other stem cell sources. Specifically, umbilical cord blood is a rich source of stem cells. However, the volume of cord blood units is extremely small, and therefore, the total number of hematopoietic stem cells that can be obtained in any single cord blood unit is generally only sufficient to transplant an individual of <40 kg. This limitation restricts what would otherwise be an extremely promising source of stem cells. Two features of cord blood stem cells are particularly important: (1) They are derived from a diversity of individuals that far exceeds the adult donor pool and therefore can overcome the majority of immunologic cross-matching obstacles. (2) Cord blood stem cells have a large number of T cells associated with them, but (paradoxically) they appear to be associated with a lower incidence of graft-versus-host disease when compared with similarly mismatched stem cells from other sources. If stem cell expansion by self-renewal could be achieved, the number of cells available might be sufficient for use in larger adults. An alternative approach to this problem is to improve the efficiency of engraftment of donor stem cells. Graft engineering is exploring methods of adding cell components that may enhance engraftment. Furthermore, at least some data suggest that depletion of host NK (natural killer) cells may lower the number of stem cells necessary to reconstitute hematopoiesis.

Some limited understanding of self-renewal exists and, intriguingly, implicates gene products that are associated with the chromatin state, a high-order organization of chromosomal DNA that influences transcription. These include members of the polycomb family, a group of zinc finger–containing transcriptional regulators that interact with the chromatin structure, contributing to the accessibility of groups of genes for transcription. One member, *Bmi-1*, is important in enabling hematopoietic stem cell self-renewal through modification of cell cycle regulators such as the cyclin-dependent kinase inhibitors. In the absence of *Bmi-1* or of the transcriptional regulator, Gfi-1, hematopoietic stem cells decline in number and function. In contrast, dysregulation of *Bmi-1* has been associated with leukemia; it may promote leukemic stem cell self-renewal when it is overexpressed. Other transcription regulators have also been associated with self-renewal, particularly homeobox, or "hox," genes. These transcription factors are named for their ability to govern large numbers of genes, including those determining body patterning in invertebrates. HoxB4 is capable of inducing extensive self-renewal of stem cells through its DNA-binding motif. Other members of the hox family of genes have been noted to affect normal stem cells, but they are also associated with leukemia. External signals that may influence the relative self-renewal versus differentiation outcomes of stem cell cycling include specific Wnt ligands. Intracellular signal transducing intermediates are also implicated in regulating self-renewal. They include PTEN, an inhibitor of the AKT pathway, and STAT5, both of which are downstream of activated growth factor receptors and necessary for normal stem cell functions including self-renewal, at least in mouse models. The connections between these molecules remain to be defined, and their role in physiologic regulation of stem cell self-renewal is still poorly understood.

CANCER IS SIMILAR TO AN ORGAN WITH SELF-RENEWING CAPACITY

The relationship of stem cells to cancer is an important evolving dimension of adult stem cell biology. Cancer may share principles of organization with normal tissues. Cancer cells are heterogeneous even within a given patient and may have a hierarchical organization of cells with a base of stem-like cells capable of the signature stem cell features: self-renewal and differentiation. These stem-like cells might be the basis for perpetuation of the tumor and represent a slowly dividing, rare population with distinct regulatory mechanisms, including a relationship with a specialized microenvironment. A subpopulation of self-renewing cells has been defined for some, but not all, cancers. A more sophisticated understanding of the stem cell organization of cancers may lead to improved strategies for developing new therapies for the many common and difficult-to-treat types of malignancies that have been relatively refractory to interventions aimed at dividing cells.

Does the concept of cancer stem cells provide insight into the cellular origin of cancer? The fact that some cells within a cancer have stem cell–like properties does not necessarily mean that the cancer arose in the stem cell itself. Rather, more mature cells could have acquired the self-renewal characteristics of stem cells. Any single genetic event is unlikely to be sufficient to enable full transformation of a normal cell to a frankly malignant one. Rather, cancer is a multistep process, and for the multiple steps to accumulate, the cell of origin must be able to persist for prolonged periods. It must also be able to generate large numbers of daughter cells. The normal stem cell has these properties and, by virtue of its having intrinsic self-renewal capability, may be more readily converted to a malignant phenotype. This hypothesis has been tested experimentally in the hematopoietic system. Taking advantage of the cell-surface markers that distinguish hematopoietic cells of varying maturity, stem cells, progenitors, precursors, and mature cells can be isolated. Powerful transforming gene constructs were placed in these cells, and it was found that the cell with the greatest potential to produce a malignancy was dependent on the transforming gene. In some cases, it was the stem cell, but in others, the progenitor cell functioned to initiate and perpetuate the cancer. This shows that cells can acquire stem cell–like properties in malignancy.

WHAT ELSE CAN HEMATOPOIETIC STEM CELLS DO?

Some experimental data have suggested that hematopoietic stem cells or other cells mobilized into the circulation by the same factors that mobilize hematopoietic stem cells are capable of playing a role in healing the vascular and tissue damage associated with stroke and myocardial infarction. These data are controversial, and the applicability of a stem cell approach to nonhematopoietic conditions remains experimental. However, reprogramming technology offers the potential for using the readily obtained hematopoietic stem cell as a source for cells with other capabilities.

The stem cell, therefore, represents a true dual-edged sword. It has tremendous healing capacity and is essential for life. Uncontrolled, it can threaten the life it maintains. Understanding how stem cells function, the signals that modify their behavior, and the tissue niches that modulate stem cell responses to injury and disease are critical for more effectively developing stem cell–based medicine. That aspect of medicine will include the use of the stem cells and the use of drugs to target stem cells to enhance repair of damaged tissues. It will also include the careful balance of interventions to control stem cells where they may be dysfunctional or malignant.

93 Iron Deficiency and Other Hypoproliferative Anemias

John W. Adamson

Anemias associated with normocytic and normochromic red cells and an inappropriately low reticulocyte response (reticulocyte index <2–2.5) are *hypoproliferative anemias*. This category includes early iron deficiency (before hypochromic microcytic red cells develop), acute and chronic inflammation (including many malignancies), renal disease, hypometabolic states such as protein malnutrition and endocrine deficiencies, and anemias from marrow damage. **Marrow damage states are discussed in Chap. 98.**

Hypoproliferative anemias are the most common anemias, and in the clinic, iron deficiency anemia is the most common of these followed by the anemia of inflammation. The anemia of inflammation, similar to iron deficiency, is related in part to abnormal iron metabolism. The anemias associated with renal disease, inflammation, cancer, and hypometabolic states are characterized by a suboptimal erythropoietin response to the anemia.

IRON METABOLISM

Iron is a critical element in the function of all cells, although the amount of iron required by individual tissues varies during development. At the same time, the body must protect itself from free iron, which is highly toxic in that it participates in chemical reactions that generate free radicals such as singlet O_2 or OH^-. Consequently, elaborate mechanisms have evolved that allow iron to be made available for physiologic functions while at the same time conserving this element and handling it in such a way that toxicity is avoided.

The major role of iron in mammals is to carry O_2 as part of hemoglobin. O_2 is also bound by myoglobin in muscle. Iron is a critical element in iron-containing enzymes, including the cytochrome system in mitochondria. Iron distribution in the body is shown in Table 93-1. Without iron, cells lose their capacity for electron transport and energy metabolism. In erythroid cells, hemoglobin synthesis is impaired, resulting in anemia and reduced O_2 delivery to tissue.

THE IRON CYCLE IN HUMANS

Figure 93-1 outlines the major pathways of internal iron exchange in humans. Iron absorbed from the diet or released from stores circulates in the plasma bound to *transferrin*, the iron transport protein. Transferrin is a bilobed glycoprotein with two iron-binding sites. Transferrin that carries iron exists in two forms—*monoferric* (one iron atom) or *diferric* (two iron atoms). The turnover (half-clearance time) of transferrin-bound iron is very rapid—typically 60–90 min. Because almost all of the iron transported by transferrin is delivered to the erythroid marrow, the clearance time of transferrin-bound iron from the circulation is affected most by the plasma iron level and the erythroid marrow activity. When erythropoiesis is markedly stimulated, the pool of erythroid cells requiring iron increases, and the clearance time of iron from the circulation decreases. The half-clearance time of iron in the presence of iron deficiency is as short as 10–15 min. With suppression of erythropoiesis, the plasma iron level typically increases, and the half-clearance time may be prolonged to several hours. Normally, the iron bound to transferrin turns over 6–8 times per day. Assuming a normal plasma iron level of 80–100 μg/dL, the amount of iron passing through the transferrin pool is 20–24 mg/d.

The iron-transferrin complex circulates in the plasma until it interacts with specific *transferrin receptors* on the surface of marrow erythroid cells. Diferric transferrin has the highest affinity for transferrin receptors; apotransferrin (not carrying iron) has very little affinity. Although transferrin receptors are found on cells in many tissues within the body—and all cells at some time during development will display transferrin receptors—the cell having the greatest number of receptors (300,000–400,000/cell) is the developing erythroblast.

Once the iron-bearing transferrin interacts with its receptor, the complex is internalized via clathrin-coated pits and transported to an acidic endosome, where the iron is released at the low pH. The iron is then made available for heme synthesis while the transferrin-receptor complex is recycled to the surface of the cell, where the bulk of the

TABLE 93-1 Body Iron Distribution

	IRON CONTENT, mg	
	ADULT MALE, 80 kg	ADULT FEMALE, 60 kg
Hemoglobin	2500	1700
Myoglobin/enzymes	500	300
Transferrin iron	3	3
Iron stores	600–1000	0–300

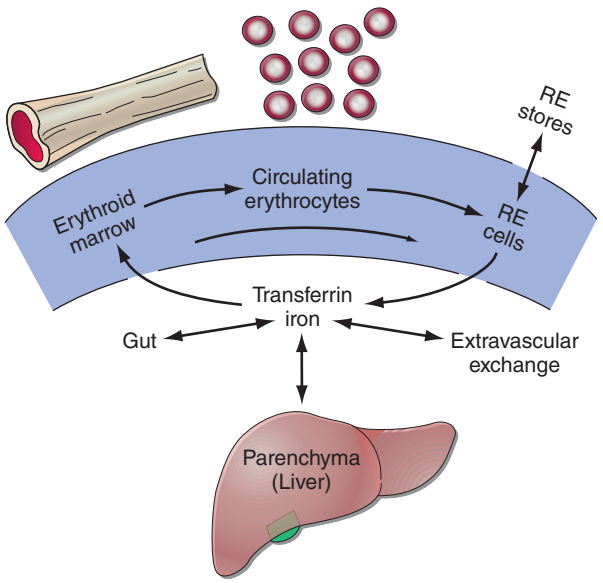

FIGURE 93-1 Internal iron exchange. Normally 80% of iron passing through the plasma transferrin pool is recycled from senescent red cells. Absorption of ~1 mg/d is required from the diet in men, and 1.4 mg/d in women to maintain homeostasis. As long as transferrin saturation is maintained between 20 and 60% and erythropoiesis is not increased, use of iron stores is not required. However, in the event of blood loss, dietary iron deficiency, or inadequate iron absorption, up to 40 mg/d of iron can be mobilized from stores. RE, reticuloendothelial.

transferrin is released back into circulation and the transferrin receptor re-anchors into the cell membrane. At this point a certain amount of the transferrin receptor protein may be released into circulation and can be measured as soluble transferrin receptor protein. Within the erythroid cell, iron in excess of the amount needed for hemoglobin synthesis binds to a storage protein, *apoferritin*, forming *ferritin*. This mechanism of iron exchange also takes place in other cells of the body expressing transferrin receptors, especially liver parenchymal cells where the iron can be incorporated into heme-containing enzymes or stored. The iron incorporated into hemoglobin subsequently enters the circulation as new red cells are released from the bone marrow. The iron is then part of the red cell mass and will not become available for reutilization until the red cell dies.

In a normal individual, the average red cell life span is 120 days. Thus, 0.8–1% of red cells is replaced each day. At the end of its life span, the red cell is recognized as senescent by the cells of the *reticuloendothelial (RE) system*, and the red cell undergoes phagocytosis. Once within the RE cell, the ingested hemoglobin is broken down, the globin and other proteins are returned to the amino acid pool, and the iron is shuttled back to the surface of the RE cell, where it is presented to circulating transferrin. It is the efficient and highly conserved recycling of iron from senescent red cells that supports steady-state (and even mildly accelerated) erythropoiesis.

Because each milliliter of red cells contains 1 mg of elemental iron, the amount of iron needed to replace those red cells lost through senescence amounts to 20 mg/d (assuming an adult with a red cell mass of 2 L). Any additional iron required for daily red cell production comes from the diet. Normally, an adult male will need to absorb at least 1 mg of elemental iron daily to meet needs, while females in the childbearing years will need to absorb an average of 1.4 mg/d. However, to achieve a maximum proliferative erythroid marrow response to anemia, additional iron must be available. With markedly stimulated erythropoiesis, demands for iron are increased by as much as six- to eightfold. With extravascular hemolytic anemia, the rate of red cell destruction is increased, but the iron recovered from the red cells is efficiently reutilized for hemoglobin synthesis. In contrast, with intravascular hemolysis or blood loss anemia, the rate of red cell production is limited by the amount of iron that can be mobilized from stores. Typically, the rate of mobilization under these circumstances will not support red cell production more than 2.5 times normal. If the delivery of iron to the stimulated marrow is suboptimal, the marrow's proliferative response is blunted, and hemoglobin synthesis is impaired. The result is a hypoproliferative marrow accompanied by microcytic, hypochromic anemia.

Whereas blood loss or hemolysis places a demand on the iron supply, inflammatory conditions interfere with iron release from stores and can result in a rapid decrease in the serum iron (see below).

NUTRITIONAL IRON BALANCE

The balance of iron in humans is tightly controlled and designed to conserve iron for reutilization. There is no regulated excretory pathway for iron, and the only mechanisms by which iron is lost are blood loss (via gastrointestinal bleeding, menses, or other forms of bleeding) and the loss of epithelial cells from the skin, gut, and genitourinary tract. Normally, the only route by which iron comes into the body is via absorption from food or from medicinal iron taken orally. Iron may also enter the body through red cell transfusions or injection of iron complexes. The margin between the amount of iron available for absorption and the requirement for iron in growing infants and the adult female is narrow; this accounts for the great prevalence of iron deficiency worldwide—currently estimated at more than one billion people.

The amount of iron required from the diet to replace losses averages ~10% of body iron content a year in men and 15% in women of childbearing age. Dietary iron content is closely related to total caloric intake (~6 mg of elemental iron per 1000 calories). Iron bioavailability is affected by the nature of the foodstuff, with heme iron (e.g., red meat) being most readily absorbed. In the United States, the average iron intake in an adult male is 15 mg/d with 6% absorption; for the average female, the intake is 11 mg/d with 12% absorption. An individual with iron deficiency can increase iron absorption to ~20% of the iron present in a meat-containing diet but only 5–10% of the iron in a vegetarian diet. As a result, one-third of the female population in the United States has virtually no iron stores. Vegetarians are at an additional disadvantage because certain foodstuffs that include phytates and phosphates reduce iron absorption by ~50%. When ionizable iron salts are given together with food, the amount of iron absorbed is reduced. When the percentage of iron absorbed from individual food items is compared with the percentage for an equivalent amount of ferrous salt, iron in vegetables is only about one-twentieth as available, egg iron one-eighth, liver iron one-half, and heme iron one-half to two-thirds.

Infants, children, and adolescents may be unable to maintain normal iron balance because of the demands of body growth and lower dietary intake of iron. During the last two trimesters of pregnancy, daily iron requirements increase to 5–6 mg, and iron supplements are strongly recommended for pregnant women in developed countries.

Iron absorption takes place largely in the duodenum and proximal small intestine and is a carefully regulated process. For absorption, iron must be taken up by the luminal cell. That process is facilitated by the acidic contents of the stomach, which maintains the iron in solution. At the brush border of the absorptive cell, the ferric iron is converted to the ferrous form by a ferrireductase. Transport across the membrane is accomplished by divalent metal transporter type 1 (DMT-1, also known as natural resistance macrophage-associated protein type 2 [Nramp 2] or DCT-1). DMT-1 is a general cation transporter. Once inside the gut cell, iron may be stored as ferritin or transported through the cell to be released at the basolateral surface to plasma transferrin through the membrane-embedded iron exporter, ferroportin. The function of ferroportin is negatively regulated by hepcidin, the principal iron regulatory hormone. In the process of release, iron interacts with another ferroxidase, hephaestin, which oxidizes the iron to the ferric form for transferrin binding. Hephaestin is similar to ceruloplasmin, the copper-carrying protein.

Iron absorption is influenced by a number of physiologic states. Erythroid hyperplasia stimulates iron absorption even in the face of normal or increased iron stores, and hepcidin levels are inappropriately low. Thus, patients with anemias associated with high levels of ineffective erythropoiesis absorb excess amounts of dietary iron. The molecular mechanism underlying this is the production of erythroferrone *(ERFE)* by developing erythroblasts. ERFE suppresses hepcidin production and, over time, this may lead to iron overload and tissue damage. In iron deficiency, hepcidin levels are also low and iron is much more efficiently absorbed; the contrary is true in states of secondary iron overload. The normal individual can reduce iron absorption in situations of excessive intake or medicinal iron intake; however, while the percentage of iron absorbed goes down, the absolute amount goes up. This accounts for the acute iron toxicity occasionally seen when children ingest large numbers of iron tablets. Under these circumstances, the amount of iron absorbed exceeds the transferrin binding capacity of the plasma, resulting in free iron that affects critical organs such as cardiac muscle cells.

IRON-DEFICIENCY ANEMIA

Iron deficiency is one of the most prevalent forms of malnutrition. Globally, 50% of anemia is attributable to iron deficiency and accounts for approximately nearly a million deaths annually worldwide. Africa and parts of Asia bear 71% of the global mortality burden; North America represents only 1.4% of the total morbidity and mortality associated with iron deficiency.

STAGES OF IRON DEFICIENCY

The progression to iron deficiency can be divided into three stages **(Fig. 93-2)**. The first stage is *negative iron balance*, in which the demands for (or losses of) iron exceed the body's ability to absorb iron from the diet. This stage results from a number of physiologic mechanisms, including blood loss, pregnancy (in which the demands for red cell production by the fetus outstrip the mother's ability to provide iron), rapid growth spurts in the adolescent, or inadequate dietary iron intake. Blood loss in excess of 10–20 mL of red cells per day is greater than

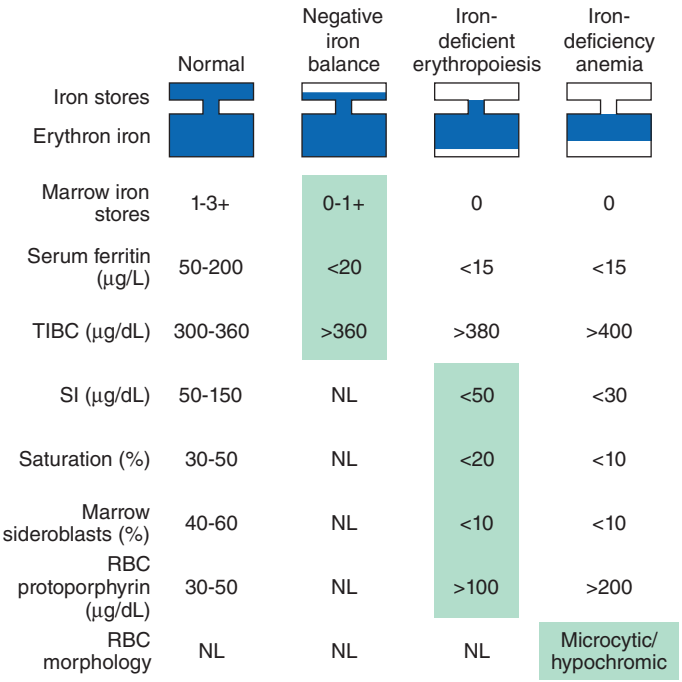

FIGURE 93-2 Laboratory studies in the evolution of iron deficiency. Measurements of marrow iron stores, serum ferritin, and total iron-binding capacity (TIBC) are sensitive to early iron-store depletion. Iron-deficient erythropoiesis is recognized from additional abnormalities in the serum iron (SI), percent transferrin saturation, the pattern of marrow sideroblasts, and the red blood cell (RBC) protoporphyrin level. Patients with iron-deficiency anemia demonstrate all the same abnormalities plus hypochromic microcytic anemia. *(From RS Hillman, CA Finch: The Red Cell Manual, 7th ed. Philadelphia, F.A. Davis and Co, 1996, with permission.)*

the amount of iron that the gut can absorb from a normal diet. Under these circumstances, the iron deficit must be made up by mobilization of iron from RE storage sites. During this period, iron stores—reflected by the serum ferritin level or the appearance of stainable iron on bone marrow aspirations—decrease. As long as iron stores are present and can be mobilized, the serum iron, total iron-binding capacity (TIBC), and red cell protoporphyrin levels remain within normal limits. At this stage, red cell morphology and indices are normal.

When iron stores become depleted, the serum iron begins to fall. Gradually, the TIBC increases, as do red cell protoporphyrin levels. By definition, marrow iron stores are absent when the serum ferritin level is <15 μg/L. As long as the serum iron remains within the normal range, hemoglobin synthesis is unaffected despite the dwindling iron stores. Once the transferrin saturation falls to 15–20%, hemoglobin synthesis becomes impaired. This is a period of *iron-deficient erythropoiesis*. Careful evaluation of the peripheral blood smear reveals the first appearance of microcytic cells, and if the laboratory technology is available, one finds hypochromic reticulocytes in circulation. Gradually, the hemoglobin begins to fall, reflecting *iron-deficiency anemia*. The transferrin saturation at this point is <10–15%.

When moderate anemia is present (hemoglobin 10–13 g/dL), the bone marrow remains hypoproliferative. With more severe anemia (hemoglobin 7–8 g/dL), hypochromia and microcytosis become more prominent, target cells and misshapen red cells (poikilocytes) appear on the blood smear as cigar- or pencil-shaped forms, and the erythroid marrow becomes increasingly ineffective. Consequently, with severe prolonged iron-deficiency anemia, erythroid hyperplasia of the marrow develops, rather than hypoproliferation.

CAUSES OF IRON DEFICIENCY

Conditions that increase demand for iron, increase iron loss, or decrease iron intake or absorption can produce iron deficiency **(Table 93-2)**.

CLINICAL PRESENTATION OF IRON DEFICIENCY

Certain clinical conditions carry an increased likelihood of iron deficiency. Pregnancy, adolescence, periods of rapid growth, and an intermittent history of blood loss of any kind should alert the clinician to possible iron deficiency. A cardinal rule is that the appearance of iron deficiency in an adult male or post-menopausal female means gastrointestinal blood loss until proven otherwise. Signs related to iron deficiency depend on the severity and chronicity of the anemia in addition to the usual signs of anemia—fatigue, pallor, and reduced exercise capacity. *Cheilosis* (fissures at the corners of the mouth) and *koilonychia* (spooning of the fingernails) are signs of advanced tissue iron deficiency. The diagnosis of iron deficiency is typically based on laboratory results.

TABLE 93-2 Causes of Iron Deficiency

Increased Demand for Iron
Rapid growth in infancy or adolescence
Pregnancy
Erythropoietin therapy
Increased Iron Loss
Chronic blood loss
Menses
Acute blood loss
Blood donation
Phlebotomy as treatment for polycythemia vera
Decreased Iron Intake or Absorption
Inadequate diet
Malabsorption from disease (sprue, Crohn's disease)
Malabsorption from surgery (gastrectomy and some forms of bariatric surgery)
Acute or chronic inflammation

LABORATORY IRON STUDIES

Serum Iron and Total Iron-Binding Capacity The serum iron level represents the amount of circulating iron bound to transferrin. The TIBC is an indirect measure of the circulating transferrin. The normal range for the serum iron is 50–150 μg/dL; the normal range for TIBC is 300–360 μg/dL. Transferrin saturation, which is normally 25–50%, is obtained by the following formula: serum iron × 100 ÷ TIBC. Iron-deficiency states are associated with saturation levels <20%. There is a diurnal variation in the serum iron. A transferrin saturation >50% indicates that a disproportionate amount of the iron bound to transferrin is being delivered to nonerythroid tissues. If this persists for an extended time, tissue iron overload may occur.

Serum Ferritin Free iron is toxic to cells, and the body has established an elaborate set of protective mechanisms to bind iron in various tissue compartments. Within cells, iron is stored complexed to protein as ferritin or hemosiderin. Apoferritin binds to free ferrous iron and stores it in the ferric state. As ferritin accumulates within cells of the RE system, protein aggregates are formed as hemosiderin. Iron in ferritin or hemosiderin can be extracted for release by the RE cells, although hemosiderin is less readily available. Under steady-state conditions, the serum ferritin level correlates with total body iron stores; thus, the serum ferritin level is the most convenient laboratory test to estimate iron stores. The normal value for ferritin varies according to the age and gender of the individual **(Fig. 93-3)**. Adult males have serum ferritin values averaging 100 μg/L, while adult females have levels averaging 30 μg/L. As iron stores are depleted, the serum ferritin falls to <15 μg/L. Such levels are diagnostic of absent body iron stores.

Evaluation of Bone Marrow Iron Stores Although RE iron stores can be estimated from the iron stain of a bone marrow aspirate or biopsy, the measurement of serum ferritin has largely supplanted these procedures for determination of storage iron **(Table 93-3)**. The serum ferritin level is a better indicator of iron overload than the marrow iron stain. However, in addition to storage iron, the marrow iron stain provides information about the effective delivery of iron to developing erythroblasts. Normally, when the marrow smear is stained for iron, 20–40% of developing erythroblasts—called *sideroblasts*—will

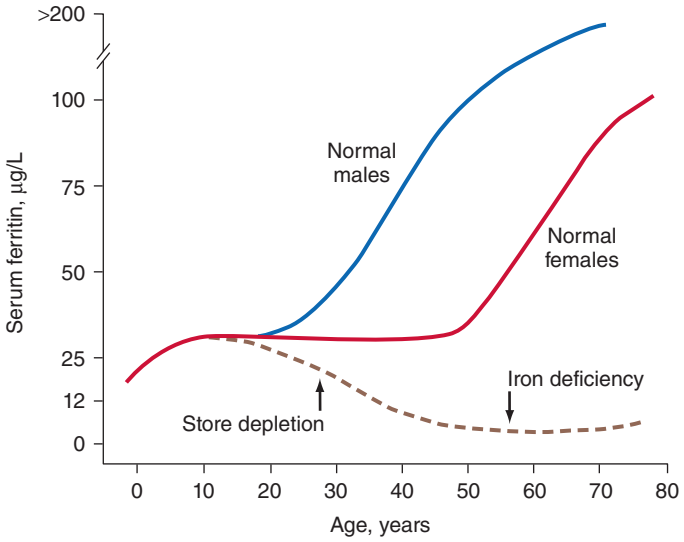

FIGURE 93-3 Serum ferritin levels as a function of sex and age. Iron store depletion and iron deficiency are accompanied by a decrease in serum ferritin level below 20 µg/L. *(From RS Hillman et al: Hematology in Clinical Practice, 5th ed. New York, McGraw-Hill, 2011, with permission.)*

have visible ferritin granules in their cytoplasm. This represents iron in excess of that needed for hemoglobin synthesis. In states in which release of iron from storage sites is blocked, RE iron will be detectable, and there will be few or no sideroblasts. In the myelodysplastic syndromes, mitochondrial dysfunction can occur, and accumulation of iron in mitochondria appears in a necklace fashion around the nucleus of the erythroblast. Such cells are referred to as *ring sideroblasts*.

Red Cell Protoporphyrin Levels Protoporphyrin is an intermediate in the pathway to heme synthesis. Under conditions in which heme synthesis is impaired, protoporphyrin accumulates within the red cell. This reflects an inadequate iron supply to erythroid precursors to support hemoglobin synthesis. Normal values are <30 µg/dL of red cells. In iron deficiency, values >100 µg/dL are seen. The most common causes of increased red cell protoporphyrin levels are absolute or relative iron deficiency and lead poisoning.

Serum Levels of Transferrin Receptor Protein Because erythroid cells have the highest numbers of transferrin receptors of any cell in the body, and because transferrin receptor protein (TRP) is released by cells into the circulation, serum levels of TRP reflect the total erythroid marrow mass. Another condition in which TRP levels are elevated is absolute iron deficiency. Normal values are 4–9 µg/L determined by immunoassay. This laboratory test is becoming increasingly available and, along with the serum ferritin, has been proposed to distinguish between iron deficiency and the anemia of inflammation (see below).

DIFFERENTIAL DIAGNOSIS

Other than iron deficiency, only three conditions need to be considered in the differential diagnosis of a hypochromic microcytic anemia **(Table 93-4)**. The first is an inherited defect in globin chain synthesis: the thalassemias. These are differentiated from iron deficiency most readily by serum iron values; normal or increased serum iron levels and transferrin saturation are characteristic of the thalassemias. In addition, the red blood cell distribution width (RDW) index is generally normal in thalassemia and elevated in iron deficiency.

The second condition is the anemia of inflammation (AI; also referred to as the anemia of chronic disease) with inadequate iron supply to the erythroid marrow. The distinction between true iron-deficiency anemia and AI is among the most common diagnostic problems encountered by clinicians (see below). Usually, AI is normocytic and normochromic. The iron values usually make the differential diagnosis clear, as the ferritin level is normal or increased and the percent transferrin saturation and TIBC are typically below normal.

Finally, the myelodysplastic syndromes represent the third and least common condition. Occasionally, patients with myelodysplasia have impaired hemoglobin synthesis with mitochondrial dysfunction, resulting in impaired iron incorporation into heme. The iron values again reveal normal stores and more than an adequate supply to the marrow, despite the microcytosis and hypochromia.

TABLE 93-3 Iron Store Measurements

IRON STORES	MARROW IRON STAIN, 0–4+	SERUM FERRITIN, µg/L
0	0	<15
1–300 mg	Trace to 1+	15–30
300–800 mg	2+	30–60
800–1000 mg	3+	60–150
1–2 g	4+	>150
Iron overload	—	>500–1000

TREATMENT

Iron-Deficiency Anemia

The severity and cause of iron-deficiency anemia will determine the appropriate approach to treatment. As an example, symptomatic elderly patients with severe iron-deficiency anemia and cardiovascular instability may require red cell transfusions. Younger individuals who have compensated for their anemia can be treated more conservatively with iron replacement. The foremost issue for the latter patient is the precise identification of the cause of the iron deficiency.

For the majority of cases of iron deficiency (pregnant women, growing children and adolescents, patients with infrequent episodes of bleeding, and those with inadequate dietary intake of iron), oral iron therapy will suffice. For patients with unusual blood loss or malabsorption, specific diagnostic tests and appropriate therapy take priority. Once the diagnosis of iron-deficiency anemia and its cause is made, there are three major therapeutic approaches.

RED CELL TRANSFUSION

Transfusion therapy is reserved for individuals who have symptoms of anemia, cardiovascular instability, and continued and excessive blood loss from whatever source and who require immediate intervention. The management of these patients is less related to the iron deficiency than it is to the consequences of the severe anemia. Not only do transfusions correct the anemia acutely, but the transfused red cells provide a source of iron for reutilization, assuming they are not lost through continued bleeding. Transfusion therapy will stabilize the patient while other options are reviewed.

ORAL IRON THERAPY

In the asymptomatic patient with established iron-deficiency anemia and an intact gastrointestinal tract, treatment with oral iron is usually adequate. Multiple preparations are available, ranging from simple iron salts to complex iron compounds designed for sustained release throughout the small intestine **(Table 93-5)**. Although the various preparations contain different amounts of iron, they are generally all absorbed well and are effective in treatment. Some come with other compounds designed to enhance iron absorption, such as ascorbic acid. It is not clear whether the benefits of such compounds justify their costs. Typically, for iron replacement therapy, up to 200 mg of elemental iron per day is given, usually as three or four iron tablets (each containing 50–65 mg elemental iron) given over the course of the day. Ideally, oral iron preparations should be taken on an empty stomach, since food may inhibit iron absorption. Some patients with gastric disease or prior gastric surgery require special treatment with iron solutions because the retention capacity of the stomach may be reduced. The retention capacity is necessary for dissolving the shell of the iron tablet before the release of iron. A dose of 200 mg of elemental iron per day should result in the absorption of iron up to 50 mg/d. This supports a red cell production level of

TABLE 93-4 Diagnosis of Microcytic Anemia

TESTS	IRON DEFICIENCY	INFLAMMATION	THALASSEMIA	SIDEROBLASTIC ANEMIA
Smear	Micro/hypo	Normal micro/hypo	Micro/hypo with targeting	Variable
Serum iron (μg/dL)	<30	<50	Normal to high	Normal to high
TIBC (μg/dL)	>360	<300	Normal	Normal
Percent saturation	<10	10–20	30–80	30–80
Ferritin (μg/L)	<15	30–200	50–300	50–300
Hemoglobin pattern on electrophoresis	Normal	Normal	Abnormal with β thalassemia; can be normal with α thalassemia	Normal

Abbreviation: TIBC, total iron-binding capacity.

two to three times normal in an individual with a normally functioning marrow and appropriate erythropoietin stimulus. However, as the hemoglobin level rises, erythropoietin stimulation decreases, and the amount of iron absorbed is reduced. The goal of therapy in individuals with iron-deficiency anemia is not only to repair the anemia, but also to provide stores of at least 0.5–1 g of iron. Sustained treatment for a period of 6–12 months after correction of the anemia will be necessary to achieve this.

Of the complications of oral iron therapy, gastrointestinal distress is the most prominent and is seen in at least 15–20% of patients. Abdominal pain, nausea, vomiting, or constipation may lead to noncompliance. Although small doses of iron or iron preparations with delayed release may help somewhat, the gastrointestinal side effects are a major impediment to the effective treatment of a number of patients.

The response to iron therapy varies, depending on the erythropoietin stimulus and the rate of absorption. Typically, the reticulocyte count should begin to increase within 4–7 days after initiation of therapy and peak at 1–1½ weeks. The absence of a response may be due to poor absorption, noncompliance (which is common), or a confounding diagnosis. A useful test in the clinic to determine the patient's ability to absorb iron is the *iron tolerance test*. Two iron tablets are given to the patient on an empty stomach, and the serum iron is measured serially over the subsequent 2–3 h. Normal absorption will result in an increase in the serum iron of at least 100 μg/dL. If iron deficiency persists despite adequate treatment, it may be necessary to switch to parenteral iron therapy.

PARENTERAL IRON THERAPY

Intravenous iron can be given to patients who are unable to tolerate oral iron; whose needs are relatively acute; or who need iron on an ongoing basis, usually due to persistent gastrointestinal or menstrual blood loss. Parenteral iron use has been increasing rapidly in the last several years with the recognition that recombinant erythropoietin (EPO) therapy induces a large demand for iron—a demand that frequently cannot be met through the physiologic release of iron from RE sources or oral iron absorption. The safety of parenteral iron has been a concern largely driven by the high adverse reaction rate to high-molecular-weight iron dextran. The newer iron complexes that are available, such as ferumoxytol (Feraheme), sodium ferric gluconate (Ferrlecit), iron sucrose (Venofer), low-molecular-weight (LMW) iron dextran (InFed), and ferric carboxymaltose (Injectafer), have much lower rates of adverse effects. Ferumoxytol delivers 510 mg of iron per injection; ferric gluconate 125 mg per injection; LMW iron dextran up to 1500 mg; ferric carboxymaltose 750 mg per injection and iron sucrose 200 mg per injection.

Parenteral iron is used in two ways: one is to administer the total dose of iron required to correct the hemoglobin deficit and provide the patient with at least 500 mg of iron stores; the second is to give repeated small doses of parenteral iron over a protracted period. The latter approach is common in dialysis centers, where it is not unusual for 100 mg of elemental iron to be given weekly for 10 weeks to augment the response to recombinant EPO therapy. The amount of iron needed by an individual patient is calculated by the following formula:

$$\text{Body weight (kg)} \times 2.3 \times (15 - \text{patient's hemoglobin, g/dL}) + 500 \text{ or } 1000 \text{ mg (for stores)}.$$

In administering any intravenous iron preparation, anaphylaxis is a concern. Anaphylaxis is much rarer with the newer preparations. The factors that have correlated with an anaphylactic-like reaction include a history of multiple allergies or a prior allergic reaction to an iron preparation. Generalized symptoms appearing several days after the infusion of a large dose of iron can include arthralgias, skin rash, and low-grade fever. These may be dose-related, but they do not preclude the further use of parenteral iron in the patient. To date, patients with sensitivity to one iron preparation have been safely treated with other parenteral iron preparations. If a large dose of LMW iron dextran is to be given (>100 mg), the iron preparation should be diluted in 5% dextrose in water or 0.9% NaCl solution. The iron solution can then be infused over a 60- to 90-min period (for larger doses) or at a rate convenient for the attending nurse or physician. Although a test dose (25 mg) of parenteral LMW iron dextran is recommended, in reality a slow infusion of a larger dose of parenteral iron solution will afford the same kind of early warning as a separately injected test dose. Early in the infusion of iron, if chest pain, wheezing, a fall in blood pressure, or other systemic symptoms occur, the infusion of iron should be stopped immediately.

TABLE 93-5 Oral Iron Preparations

GENERIC NAME	TABLET (IRON CONTENT), mg	ELIXIR (IRON CONTENT), mg in 5 mL
Ferrous sulfate	325 (65) 195 (39)	300 (60) 90 (18)
Extended release	525 (105)	
Ferrous fumarate	325 (107) 195 (64)	 100 (33)
Ferrous gluconate	325 (39)	300 (35)
Polysaccharide iron	150 (150) 50 (50)	100 (100)

OTHER HYPOPROLIFERATIVE ANEMIAS

In addition to mild to moderate iron-deficiency anemia, the hypoproliferative anemias can be divided into four categories: (1) chronic inflammation, (2) renal disease, (3) endocrine and nutritional deficiencies (hypometabolic states), and (4) marrow damage (Chap. 98). With chronic inflammation, renal disease, or hypometabolism, endogenous EPO production is inadequate for the degree of anemia observed. For the anemia of chronic inflammation, the erythroid marrow also responds inadequately to stimulation, due in part to defective *iron reutilization*. As a result of the lack of adequate EPO stimulation, an examination of the peripheral blood smear will disclose only an occasional polychromatophilic ("shift") reticulocyte. In cases of iron deficiency or marrow damage, appropriate elevations in endogenous EPO levels are typically found, and shift reticulocytes will be present on the blood smear.

ANEMIA OF ACUTE AND CHRONIC INFLAMMATION/INFECTION (AI)

AI—which encompasses inflammation, infection, tissue injury, and conditions (such as cancer) associated with the release of proinflammatory

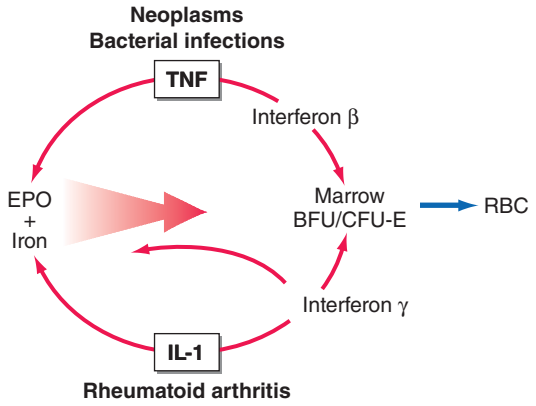

FIGURE 93-4 Suppression of erythropoiesis by inflammatory cytokines. Through the release of tumor necrosis factor (TNF) and interferon β (IFN-β), neoplasms and bacterial infections suppress erythropoietin (EPO) production and the proliferation of erythroid progenitors (erythroid burst-forming units and erythroid colony-forming units [BFU/CFU-E]). The mediators in patients with vasculitis and rheumatoid arthritis include interleukin 1 (IL-1) and IFN-γ. The *red arrows* indicate sites of inflammatory cytokine inhibitory effects. RBC, red blood cell.

cytokines—is one of the most common forms of anemia seen clinically. It is the most important anemia in the differential diagnosis of iron deficiency because many of the features of the anemia are brought about by inadequate iron delivery to the marrow, despite the presence of normal or increased iron stores. This is reflected by a low serum iron, increased red cell protoporphyrin, a hypoproliferative marrow, transferrin saturation in the range of 15–20%, and a normal or increased serum ferritin. The serum ferritin values are often the most distinguishing features between true iron-deficiency anemia and the iron-restricted erythropoiesis associated with inflammation. Typically, serum ferritin values increase threefold over basal levels in the face of inflammation. These changes are due to the effects of inflammatory cytokines and hepcidin, the key iron regulatory hormone, acting at several levels of erythropoiesis **(Fig. 93-4)**.

Interleukin 1 (IL-1) directly decreases EPO production in response to anemia. IL-1, acting through accessory cell release of interferon γ (IFN-γ), suppresses the response of the erythroid marrow to EPO—an effect that can be overcome by EPO administration in vitro and in vivo. In addition, tumor necrosis factor (TNF), acting through the release of IFN-β by marrow stromal cells, also suppresses the response to EPO. Hepcidin, made by the liver, is increased in inflammation via an IL-6 mediated pathway, and acts to suppress iron absorption and iron release from storage sites. The overall result is a chronic hypoproliferative anemia with classic changes in iron metabolism. The anemia is further compounded by a mild to moderate shortening in red cell survival.

With chronic inflammation, the primary disease will determine the severity and characteristics of the anemia. For example, many patients with cancer also have anemia that is typically normocytic and normochromic. In contrast, patients with long-standing active rheumatoid arthritis or chronic infections such as tuberculosis will have a microcytic, hypochromic anemia. In both cases, the bone marrow is hypoproliferative, but the differences in red cell indices reflect differences in the availability of iron for hemoglobin synthesis. Occasionally, conditions associated with chronic inflammation are also associated with chronic blood loss. Under these circumstances, the measurement of soluble transferrin protein may be necessary to rule out absolute iron deficiency. However, the administration of iron in this case will correct the iron deficiency component of the anemia and leave the inflammatory component unaffected.

The anemia associated with acute infection or inflammation is typically mild but becomes more pronounced over time. Acute infection can produce a decrease in hemoglobin levels of 2–3 g/dL within 1 or 2 days; this is largely related to the hemolysis of red cells near the end of their natural life span. The fever and cytokines released exert a selective pressure against cells with more limited capacity to maintain the red cell membrane. In most individuals, the mild anemia is reasonably well tolerated, and symptoms, if present, are associated with the underlying disease. Occasionally, in patients with preexisting cardiac disease, moderate anemia (hemoglobin 10–11 g/dL) may be associated with angina, exercise intolerance, and shortness of breath. The erythropoietic profile that distinguishes the anemia of inflammation from the other causes of hypoproliferative anemias is shown in **Table 93-6**.

ANEMIA OF CHRONIC KIDNEY DISEASE (CKD)

Progressive CKD is usually associated with a moderate to severe hypoproliferative anemia; the level of the anemia correlates with the stage of CKD. Red cells are typically normocytic and normochromic, and reticulocytes are decreased. The anemia is primarily due to a failure of EPO production by the diseased kidney and a reduction in red cell survival. In certain forms of acute renal failure, the correlation between the anemia and renal function is weaker. Patients with the hemolytic-uremic syndrome increase erythropoiesis in response to the hemolysis, despite renal failure. Polycystic kidney disease also shows a smaller degree of EPO deficiency for a given level of renal failure. By contrast, patients with diabetes or myeloma have more severe EPO deficiency for a given level of renal failure.

Assessment of iron status provides information to distinguish the anemia of CKD from the other forms of hypoproliferative anemia (Table 93-6) and to guide management. Patients with the anemia of CKD usually present with normal serum iron, TIBC, and ferritin levels. However, those maintained on chronic hemodialysis may develop iron deficiency from blood loss through the dialysis procedure. Iron must be replenished in these patients to ensure an adequate response to EPO therapy (see below).

ANEMIA IN HYPOMETABOLIC STATES

Patients who are starving, particularly for protein, and those with a variety of endocrine disorders that produce lower metabolic rates, may develop a mild to moderate hypoproliferative anemia. The release of EPO from the kidney is sensitive to the need for O_2, not just O_2 levels. Thus, EPO production is triggered at lower levels of blood O_2 content in disease states (such as hypothyroidism and starvation) where metabolic activity, and thus O_2 demand, is decreased.

Endocrine Deficiency States The difference in the levels of hemoglobin between men and women is related to the effects of androgen and estrogen on erythropoiesis. Testosterone and anabolic steroids augment erythropoiesis; castration and estrogen administration to males decrease erythropoiesis. Patients who are hypothyroid or have deficits in pituitary hormones also may develop a mild anemia. Pathogenesis may be complicated by other nutritional deficiencies because iron and folic acid absorption can be affected by these disorders. Usually, correction of the hormone deficiency reverses the anemia.

Anemia may be more severe in Addison's disease, depending on the level of thyroid and androgen hormone dysfunction; however, anemia

TABLE 93-6 Diagnosis of Hypoproliferative Anemias

TESTS	IRON DEFICIENCY	INFLAMMATION	RENAL DISEASE	HYPOMETABOLIC STATES
Anemia	Mild to severe	Mild	Mild to severe	Mild
MCV (fL)	60–90	80–90	90	90
Morphology	Normo-microcytic	Normocytic	Normocytic	Normocytic
SI (μg/dL)	<30	<50	Normal	Normal
TIBC (μg/dL)	>360	<300	Normal	Normal
Saturation (%)	<10	10–20	Normal	Normal
Serum ferritin (μg/L)	<15	30–200	115–150	Normal
Iron stores	0	2–4+	1–4+	Normal

Abbreviations: MCV, mean corpuscular volume; SI, serum iron; TIBC, total iron-binding capacity.

may be masked by decreases in plasma volume. Once such patients are given cortisol and volume replacement, the hemoglobin level may fall rapidly. Mild anemia complicating hyperparathyroidism may be due to decreased EPO production as a consequence of the renal effects of hypercalcemia or to impaired proliferation of erythroid progenitors.

Protein Starvation Decreased dietary intake of protein may lead to mild to moderate hypoproliferative anemia; this form of anemia may be prevalent in the elderly. The anemia can be more severe in patients with a greater degree of starvation. In marasmus, where patients are both protein- and calorie-deficient, the release of EPO is impaired in proportion to the reduction in metabolic rate; however, the degree of anemia may be masked by volume depletion and becomes apparent after refeeding. Deficiencies in other nutrients (iron, folate) may also complicate the clinical picture but may not be apparent at diagnosis. Changes in the erythrocyte indices on refeeding should prompt evaluation of iron, folate, and B_{12} status.

Anemia in Liver Disease A mild hypoproliferative anemia may develop in patients with chronic liver disease from nearly any cause. The peripheral blood smear may show spur cells and stomatocytes from the accumulation of excess cholesterol in the membrane from a deficiency of lecithin-cholesterol acyltransferase. Red cell survival is shortened, and the production of EPO is inadequate to compensate. In alcoholic liver disease, nutritional deficiencies are common and complicate the management. Folate deficiency from inadequate intake, as well as iron deficiency from blood loss and inadequate intake, can alter the red cell indices.

ANEMIA IN AGING

Anemia is common in people over age 65 years. It has been estimated to affect about 11% of community living older adults and up to 40% of nursing home residents. In at least one-third of these anemic people, a cause for the anemia is not found. Patients with the unexplained anemia of aging do not have nutrient deficiency or renal dysfunction and while older people can have an increase in systemic inflammatory cytokines (the inflammation of aging), the levels are not high enough to mimic the anemia of chronic inflammation. If hepcidin levels are elevated at all, they are minimally so.

Investigations into the cause(s) of this form of anemia have noted that erythropoietin levels are generally in the normal range, that is, they are inappropriately low for the hemoglobin level. In general, in older people who maintain a normal hemoglobin level, erythropoietin levels increase with age. This compensatory increase to maintain normal oxygen delivery seems to be due to a relative resistance to erythropoietin stimulation; studies of red cell life span in older people have not noted a decrease in red cell survival. More data on mechanism are needed.

The importance of this unexplained anemia of aging is that low hemoglobin levels are associated with increases in falls, hospitalizations, development of frailty, and mortality. It is not clear whether reversing the anemia would influence these increased risks.

TREATMENT

Hypoproliferative Anemias

Many patients with hypoproliferative anemias experience recovery of normal hemoglobin levels when the underlying disease is appropriately treated. For those in whom such reversals are not possible—such as patients with end-stage kidney disease, cancer, and chronic inflammatory diseases—symptomatic anemia requires treatment. The two major forms of treatment are transfusions and EPO.

TRANSFUSIONS

Thresholds for transfusion should be determined based on the patient's symptoms. In general, patients without serious underlying cardiovascular or pulmonary disease can tolerate hemoglobin levels above 7–8 g/dL and do not require intervention until the hemoglobin falls below that level. Patients with more physiologic compromise may need to have their hemoglobin levels kept above 11 g/dL. Usually, a unit of packed red cells increases the hemoglobin level by 1 g/dL. Transfusions are associated with certain infectious risks **(Chap. 109)**, and chronic transfusions can produce iron overload. Importantly, the liberal use of blood has been associated with increased morbidity and mortality, particularly in the intensive care setting. Therefore, in the absence of documented tissue hypoxia, a conservative approach to the use of red cell transfusions is preferable.

ERYTHROPOIETIN

EPO is particularly useful in anemias in which endogenous EPO levels are inappropriately low, such as CKD or AI. Iron status must be evaluated and iron replaced to obtain optimal effects from EPO. In patients with CKD, the usual dose of EPO is 50–150 U/kg three times a week intravenously. Hemoglobin levels of 10–12 g/dL are usually reached within 4–6 weeks if iron levels are adequate; 90% of these patients respond. Once a target hemoglobin level is achieved, the EPO dose can be decreased. A decrease in hemoglobin level occurring in the face of EPO therapy usually signifies the development of an infection or iron depletion. Aluminum toxicity and hyperparathyroidism can also compromise the response to EPO. When an infection intervenes, it is best to interrupt the EPO therapy and rely on transfusions to correct the anemia until the infection is adequately treated. The dose of EPO needed to correct chemotherapy-induced anemia in patients with cancer is higher, up to 300 U/kg three times a week, and only ~60% of patients respond. Because of evidence that there is an increased risk of thromboembolic complications and tumor progression with EPO administration, the risks and benefits of using EPO in such patients must be weighed carefully, and the target hemoglobin should be that necessary to avoid transfusions.

Longer-acting preparations of EPO can reduce the frequency of injections. Darbepoetin alfa, a molecularly modified EPO with additional carbohydrate, has a half-life in the circulation that is three to four times longer than recombinant human EPO, permitting weekly or every other week dosing.

Orally bioavailable EPO mimetics that act to increase the biological half-life of active hypoxia-induced factor (HIF) are demonstrating activity to increase hemoglobin levels in patients with chronic renal disease and other settings.

94 Disorders of Hemoglobin

Edward J. Benz, Jr.

Hemoglobin is critical for normal oxygen delivery to tissues; it is also present in erythrocytes in such high concentrations that it can alter red cell shape, deformability, and viscosity. Hemoglobinopathies are disorders affecting the structure, function, or production of hemoglobin. These conditions are usually inherited and range in severity from asymptomatic laboratory abnormalities to death in utero. Different forms may present as ineffective erythropoiesis, hemolytic anemia, erythrocytosis, cyanosis, or vasoocclusive stigmata.

PROPERTIES OF THE HUMAN HEMOGLOBINS

HEMOGLOBIN STRUCTURE

Different hemoglobins are produced during embryonic, fetal, and adult life **(Fig. 94-1)**. Each consists of a tetramer of globin polypeptide chains: a pair of α-like chains 141 amino acids long and a pair of β-like chains 146 amino acids long. The major adult hemoglobin, HbA, has the structure $\alpha_2\beta_2$. HbF ($\alpha_2\gamma_2$) predominates during most of gestation, and HbA_2 ($\alpha_2\delta_2$) is minor adult hemoglobin. Embryonic hemoglobins need not be considered here.

Each globin chain enfolds a single heme moiety, consisting of a protoporphyrin IX ring complexed with a single iron atom in the ferrous state (Fe^{2+}). Each heme moiety can bind a single oxygen molecule; a molecule of hemoglobin can transport up to four oxygen molecules.

Each globin chain has a highly helical *secondary structure*. Their globular *tertiary structures* cause the exterior surfaces to be rich in polar (hydrophilic) amino acids that enhance solubility, and the interior to be lined with nonpolar groups, forming a hydrophobic pocket into which heme is inserted. The tetrameric *quaternary structure* of HbA contains two αβ dimers. Numerous tight interactions (i.e., $\alpha_1\beta_1$ contacts) hold the α and β chains together. The complete tetramer is held together by interfaces (i.e., $\alpha_1\beta_2$ contacts) between the α-like chain of one dimer and the non-α chain of the other dimer.

The hemoglobin tetramer is highly soluble, but individual globin chains are insoluble. Unpaired globin precipitates, forming inclusions that damage the erythroblast and can trigger apoptosis. Normal globin chain synthesis is balanced so that each newly synthesized α or non-α globin chain will have an available partner with which to pair.

Solubility and reversible oxygen binding are the key properties deranged in hemoglobinopathies. Both depend most on the hydrophilic surface amino acids, the hydrophobic amino acids lining the heme pocket, a key histidine in the F helix, and the amino acids forming the $\alpha_1\beta_1$ and $\alpha_1\beta_2$ contact points. Mutations in these strategic regions tend to be the ones that alter oxygen affinity or solubility.

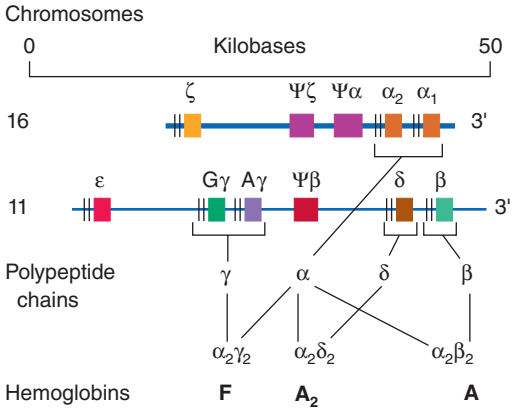

FIGURE 94-1 The globin genes. The α-like genes (α, ζ) are encoded on chromosome 16; the β-like genes (β, γ, δ, ε) are encoded on chromosome 11. The ζ and ε genes encode embryonic globins.

FUNCTION OF HEMOGLOBIN

To support oxygen transport, hemoglobin must bind O_2 efficiently at the partial pressure of oxygen (Po_2) of the alveolus, retain it in the circulation, and release it to tissues at the Po_2 of tissue capillary beds. Oxygen acquisition and delivery over a relatively narrow range of oxygen tensions depend on a property inherent in the tetrameric arrangement of heme and globin subunits within the hemoglobin molecule called *cooperativity* or *heme-heme interaction*.

At low oxygen tensions, the hemoglobin tetramer is fully deoxygenated **(Fig. 94-2)**. Oxygen binding begins slowly as O_2 tension rises. However, as soon as some oxygen has been bound by the tetramer, an abrupt increase occurs in the slope of the curve. Thus, hemoglobin molecules that have bound some oxygen develop a higher oxygen affinity, greatly accelerating their ability to combine with more oxygen. This S-shaped oxygen equilibrium curve (Fig. 94-2), along which substantial amounts of oxygen loading *and unloading* can occur over a narrow range of oxygen tensions, is physiologically more useful than the high-affinity hyperbolic curve of individual monomers.

Oxygen affinity is modulated by several factors. The Bohr effect is the ability of hemoglobin to deliver more oxygen to tissues at low pH. It arises from the stabilizing action of protons on deoxyhemoglobin, which binds protons more readily than oxyhemoglobin because the latter is a weaker acid (Fig. 94-2). Thus, hemoglobin has a lower oxygen affinity at low pH. The major small molecule that alters oxygen affinity in humans is 2,3-bisphosphoglycerate (2,3-BPG; formerly 2,3-DPG), which lowers oxygen affinity when bound to hemoglobin. HbA has a reasonably high affinity for 2,3-BPG. HbF does not bind 2,3-BPG, so it tends to have a higher oxygen affinity in vivo. Hemoglobin also binds nitric oxide reversibly; this interaction influences vascular tone, but its clinical relevance remains incompletely understood. Normal oxygen transport thus depends on the tetrameric structure of the proteins, the proper arrangement of hydrophilic and hydrophobic amino acids, and interaction with protons or 2,3-BPG.

DEVELOPMENTAL BIOLOGY OF HUMAN HEMOGLOBINS

Red cells, first appearing at about 6 weeks after conception, contain the embryonic hemoglobins Hb Portland ($\zeta_2\gamma_2$), Hb Gower I ($\zeta_2\varepsilon_2$), and Hb Gower II ($\alpha_2\varepsilon_2$). At 10–11 weeks, fetal hemoglobin (HbF; $\alpha_2\gamma_2$) becomes predominant. The switch to nearly exclusive synthesis of adult hemoglobin (HbA; $\alpha_2\beta_2$) occurs at about 38 weeks (Fig. 94-1). Fetuses and newborns therefore require α-globin but not β-globin for normal gestation. A major advance in understanding the HbF to HbA transition has been the demonstration that transcription factors such as Bcl11a play a pivotal role in its regulation, and that access to these factors depend on complex chromatin changes that render accessible binding sites for these factors. These "looping out" phenomena are in turn dependent on multiple protein factors.

Small amounts of HbF are produced during postnatal life. A few red cell clones called *F cells* are progeny of a small pool of immature committed erythroid precursors (BFU-e) that retain the ability to produce HbF. Profound erythroid stresses, such as severe hemolytic anemias, bone marrow transplantation, or cancer chemotherapy, cause more of the F-potent BFU-e to be recruited. HbF levels thus tend to rise in some patients with sickle cell anemia or thalassemia. This phenomenon probably explains the ability of hydroxyurea to increase levels of HbF in adults. Agents such as butyrate and histone deacetylase inhibitors can also activate fetal globin genes partially after birth.

GENETICS AND BIOSYNTHESIS OF HUMAN HEMOGLOBIN

The human hemoglobins are encoded in two tightly linked gene clusters; the α-like globin genes are clustered on chromosome 16 and the β-like genes on chromosome 11 (Fig. 94-1). The α-like cluster consists of two α-globin genes and a single copy of the ζ gene. The non-α gene cluster consists of a single ε gene, the Gγ and Aγ fetal globin genes, and the adult δ and β genes.

Important regulatory sequences flank each gene. Immediately upstream are typical promoter elements needed for the assembly of the

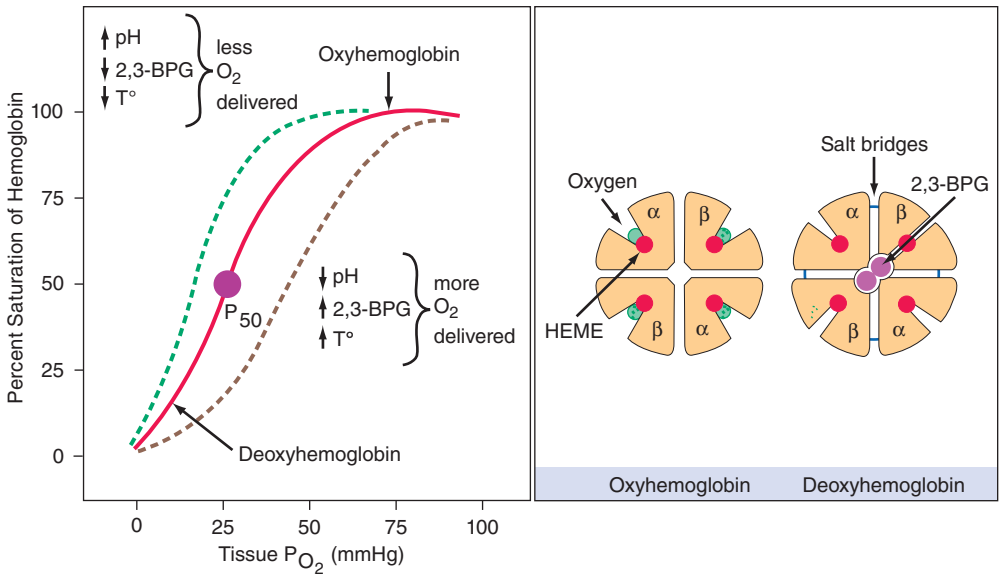

FIGURE 94-2 Hemoglobin-oxygen dissociation curve. The hemoglobin tetramer can bind up to four molecules of oxygen in the iron-containing sites of the heme molecules. As oxygen is bound, 2,3-bisphosphoglycerate (2,3-BPG) and carbon dioxide (CO_2) are expelled. Salt bridges are broken, and each of the globin molecules changes its conformation to facilitate oxygen binding. Oxygen release to the tissues is the reverse process, with salt bridges being formed and 2,3-BPG and CO_2 bound. Deoxyhemoglobin does not bind oxygen efficiently until the cell returns to conditions of higher pH, the most important modulator of O_2 affinity (Bohr effect). When acid is produced in the tissues, the dissociation curve shifts to the right, facilitating oxygen release and CO_2 binding. Alkalosis has the opposite effect, reducing oxygen delivery.

transcription initiation complex. Sequences in the 5′ flanking region of the γ and the β genes appear to be crucial for the correct developmental regulation of these genes, whereas elements that function like classic enhancers and silencers are in the 3′ flanking regions. The locus control region (LCR) elements located far upstream appear to control the overall level of expression of each cluster. These elements achieve their regulatory effects by interacting with *trans*-acting transcription factors. Some of these factors are ubiquitous (e.g., Sp1 and YY1), while others are more or less limited to erythroid cells or hematopoietic cells (e.g., GATA-1, NFE-2, and EKLF). The LCR controlling the α-globin gene cluster is modulated by a SWI/SNF-like protein called *ATRX*; this protein appears to influence chromatin remodeling and DNA methylation. The association of α thalassemia with mental retardation and myelodysplasia in some families appears to be related to mutations in the ATRX pathway. This pathway also modulates genes specifically expressed during erythropoiesis, such as those that encode the enzymes for heme biosynthesis. Normal red blood cell (RBC) differentiation requires the coordinated expression of the globin genes with the genes responsible for heme and iron metabolism. RBC precursors contain a protein, α-hemoglobin-stabilizing protein (AHSP), that enhances the folding and solubility of α globin, which is otherwise easily denatured, leading to insoluble precipitates. These precipitates play an important role in the thalassemia syndromes and certain unstable hemoglobin disorders.

CLASSIFICATION OF HEMOGLOBINOPATHIES

There are five major classes of hemoglobinopathies **(Table 94-1)**. *Structural hemoglobinopathies* occur when mutations alter the amino acid sequence of a globin chain, altering the physiologic properties of the variant hemoglobins and producing the characteristic clinical abnormalities. The most clinically relevant variant hemoglobins polymerize abnormally, as in sickle cell anemia, or exhibit altered solubility or oxygen-binding affinity. *Thalassemia syndromes* arise from mutations that impair production or translation of globin mRNA, leading to deficient globin chain biosynthesis. Clinical abnormalities are attributable to the inadequate supply of hemoglobin and the imbalances in the production of individual globin chains, leading to premature destruction of erythroblasts and RBC. *Thalassemic hemoglobin variants* combine features of thalassemia (i.e., abnormal globin biosynthesis) and of structural hemoglobinopathies (i.e., an abnormal amino acid sequence). *Hereditary persistence of fetal hemoglobin* (HPFH) is characterized by synthesis of high levels of fetal hemoglobin in adult life. *Acquired hemoglobinopathies* include modifications of the hemoglobin molecule by toxins (e.g., acquired methemoglobinemia) and clonal abnormalities of hemoglobin synthesis (e.g., high levels of HbF production in preleukemia and α thalassemia in myeloproliferative disorders).

EPIDEMIOLOGY

Hemoglobinopathies are especially common in areas in which malaria is endemic. This clustering of hemoglobinopathies is assumed to reflect a selective survival advantage for the abnormal RBC, which presumably provides a less hospitable environment

TABLE 94-1 Classification of Hemoglobinopathies

I. Structural hemoglobinopathies—hemoglobins with altered amino acid sequences that result in deranged function or altered physical or chemical properties
  A. Abnormal hemoglobin polymerization—HbS, hemoglobin sickling
  B. Altered O_2 affinity
    1. High affinity—polycythemia
    2. Low affinity—cyanosis, pseudoanemia
  C. Hemoglobins that oxidize readily
    1. Unstable hemoglobins—hemolytic anemia, jaundice
    2. M hemoglobins—methemoglobinemia, cyanosis
II. Thalassemias—defective biosynthesis of globin chains
  A. α thalassemias
  B. β thalassemias
  C. δβ, γδβ, αβ thalassemias
III. Thalassemic hemoglobin variants—structurally abnormal Hb associated with coinherited thalassemic phenotype
  A. HbE
  B. Hb Constant Spring
  C. Hb Lepore
IV. Hereditary persistence of fetal hemoglobin—persistence of high levels of HbF into adult life
V. Acquired hemoglobinopathies
  A. Methemoglobin due to toxic exposures
  B. Sulfhemoglobin due to toxic exposures
  C. Carboxyhemoglobin
  D. HbH in erythroleukemia
  E. Elevated HbF in states of erythroid stress and bone marrow dysplasia

during the obligate RBC stages of the parasitic life cycle. Very young children with α thalassemia are *more* susceptible to infection with the nonlethal *Plasmodium vivax*. Thalassemia might then favor a natural protection against infection with the more lethal *Plasmodium falciparum*.

Thalassemias are the most common genetic disorders in the world, affecting nearly 200 million people worldwide. About 15% of African Americans are silent carriers for α thalassemia; α thalassemia trait (minor) occurs in 3% of African American and in 1–15% of persons of Mediterranean origin. β thalassemia has a 10–15% incidence in individuals from the Mediterranean and Southeast Asia and 0.8% in African Americans. The number of severe cases of thalassemia in the United States is about 1000. Sickle cell disease is the most common structural hemoglobinopathy, occurring in heterozygous form in ~8% of African Americans and in homozygous form in 1 in 400. Between 2 and 3% of African Americans carry a hemoglobin C allele. The chronic nature of hemoglobinopathies and their requirement for complex, resource intensive care pose increasing major public health challenges in regions with emerging economies, as children increasingly survive the traditional causes of childhood mortality.

INHERITANCE AND ONTOGENY

Hemoglobinopathies are autosomal codominant traits—thus, compound heterozygotes who inherit a different abnormal mutant allele from each parent exhibit composite features of each. For example, patients inheriting sickle β thalassemia exhibit features of β thalassemia and sickle cell anemia. The α chain is present in HbA, HbA_2, and HbF; α-chain mutations thus cause abnormalities in all three. The α-globin hemoglobinopathies are symptomatic in utero and after birth because normal function of the α-globin gene is required throughout gestation and adult life. In contrast, infants with β-globin hemoglobinopathies tend to be asymptomatic until 3–9 months of age, when HbA has largely replaced HbF. Prevention or partial reversion of the switch should thus be an effective therapeutic strategy for β-chain hemoglobinopathies.

DETECTION AND CHARACTERIZATION OF HEMOGLOBINOPATHIES–GENERAL METHODS

While electrophoretic techniques are still used for hemoglobin analysis in some settings, high-performance liquid chromatography (HPLC) has largely supplanted electrophoresis in most reference laboratories. Some important variants can be missed by these methods because they co-migrate with normal hemoglobins. Complete characterization, including amino acid sequencing or genotyping by direct DNA analysis, is readily available from several reference laboratories and should be requested if clinical suspicion is high, or when HPLC fails to yield definitive answers.

Quantitation of the hemoglobin profile is often desirable. HbA_2 is frequently elevated in β thalassemia trait and depressed in iron deficiency. HbF is elevated in HPFH, some β thalassemia syndromes, and occasional periods of erythroid stress or marrow dysplasia. For characterization of sickle cell trait, sickle thalassemia syndromes, or HbSC disease, and for monitoring the progress of exchange transfusion therapy to lower the percentage of circulating HbS, quantitation of individual hemoglobins is also required. In most laboratories, quantitation is performed only if the test is specifically ordered.

Functional assays for hemoglobin sickling, solubility, or oxygen affinity should also be performed, as dictated by the clinical presentation. The best sickling assays involve measurement of the degree to which the hemoglobin sample becomes insoluble, or gelated, as it is deoxygenated (i.e., sickle solubility test). Unstable hemoglobins can be detected by their precipitation in isopropanol or after heating to 50°C. High-O_2 affinity and low-O_2 affinity variants can be detected by quantitating the P_{50}, the partial pressure of oxygen at which the hemoglobin sample becomes 50% saturated with oxygen. Direct tests for the percent carboxyhemoglobin and methemoglobin, using spectrophotometric techniques, can readily be obtained from most clinical laboratories on an urgent basis.

Laboratory evaluation remains an adjunct, rather than the sole diagnostic aid. Diagnosis is best established by recognition of a characteristic history, physical findings, peripheral blood smear morphology, and abnormalities of the complete blood cell count (e.g., profound microcytosis with minimal anemia in thalassemia trait).

STRUCTURALLY ABNORMAL HEMOGLOBINS

SICKLE CELL SYNDROMES

The sickle cell syndromes are caused by a mutation in the β-globin gene that changes the sixth amino acid from glutamic acid to valine. HbS ($\alpha_2\beta_2^{6\ Glu\rightarrow Val}$) polymerizes reversibly when deoxygenated to form a gelatinous network of fibrous polymers that stiffen the RBC membrane, increase viscosity, and cause dehydration due to potassium leakage and calcium influx **(Fig. 94-3)**. These changes also produce the sickle shape **(Fig. 94-4)**. Sickled cells lose the pliability needed to traverse small capillaries. They possess altered "sticky" membranes that are abnormally adherent to the endothelium of small venules. These abnormalities provoke unpredictable episodes of microvascular vasoocclusion and premature RBC destruction (hemolytic anemia) in the liver and spleen. The rigid adherent cells also clog small capillaries and venules, causing tissue ischemia, acute pain, and gradual end-organ damage. This venoocclusive component usually dominates the clinical course. Prominent manifestations include episodes of ischemic pain (i.e., painful crises) and ischemic malfunction or frank infarction in the spleen, central nervous system, bones, joints, liver, kidneys, and lungs (Fig. 94-3).

Several sickle syndromes occur as the result of inheritance of HbS from one parent and another hemoglobinopathy, such as β thalassemia or HbC ($\alpha_2\beta_2^{6\ Glu\rightarrow Lys}$), from the other parent. The prototype disease, sickle cell anemia, is the homozygous state for HbS **(Table 94-2)**.

Clinical Manifestations of Sickle Cell Anemia Most patients with sickling syndromes suffer from hemolytic anemia, with hematocrits from 15 to 30%, and significant reticulocytosis. Anemia was once thought to exert protective effects against vasoocclusion by reducing blood viscosity. However, natural history and drug therapy trials suggest that an *increase* in the hematocrit and feedback inhibition of reticulocytosis might be beneficial, even at the expense of slightly increased blood viscosity. The role of adhesive reticulocytes in promoting vasoocclusion might account for these paradoxical effects.

Granulocytosis is common. The white count can fluctuate substantially and unpredictably during and between painful crises, infectious episodes, and other intercurrent illnesses. Granulocytes, platelets, and mononuclear inflammatory cells, and the inflammatory mediators that they release at the sites of vasoocclusion, are being increasingly appreciated as key contributors to the initiation and aggravation of the morbidity associated with vasoocclusive crises.

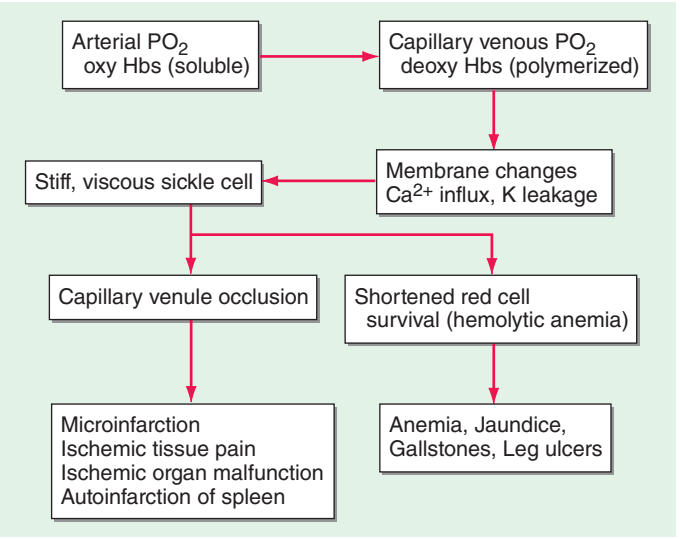

FIGURE 94-3 Pathophysiology of sickle cell crisis.

FIGURE 94-4 Sickle cell anemia. The elongated and crescent-shaped red blood cells seen on this smear represent circulating irreversibly sickled cells. Target cells and a nucleated red blood cell are also seen.

Vasoocclusion causes protean manifestations. Intermittent episodes of vasoocclusion in connective and musculoskeletal structures produce ischemia manifested by acute pain and tenderness, fever, tachycardia, and anxiety. These recurrent episodes, called *painful crises*, are the most common clinical manifestation. Their frequency and severity vary greatly. Pain can develop almost anywhere in the body and may last from a few hours to 2 weeks. Repeated crises requiring hospitalization (>3 episodes per year) correlate with reduced survival in adult life, suggesting that these episodes are associated with accumulation of chronic end-organ damage. Provocative factors include infection, fever, excessive exercise, anxiety, abrupt changes in temperature, hypoxia, or hypertonic dyes.

Repeated microinfarction can destroy tissues having microvascular beds prone to sickling. Thus, splenic function is frequently lost within the first 18–36 months of life, causing susceptibility to infection, particularly by pneumococci. Acute venous obstruction of the spleen (*splenic sequestration crisis*), a rare occurrence in early childhood, may require emergency transfusion and/or splenectomy to prevent trapping of the entire arterial output in the obstructed spleen. Occlusion of retinal vessels can produce hemorrhage, neovascularization, and eventual detachments. Renal papillary necrosis invariably produces isosthenuria. More widespread renal necrosis leads to renal failure in adults, a common late cause of death. Bone and joint ischemia can lead to aseptic necrosis, especially of the femoral or humeral heads, chronic arthropathy, and unusual susceptibility to osteomyelitis, which may be caused by organisms, such as *Salmonella*, rarely encountered in other settings. The *hand-foot syndrome* is caused by painful infarcts of the digits and dactylitis. Stroke is especially common in children; a small subset tends to suffer repeated episodes. Stroke is less common in adults and is often hemorrhagic. A particularly painful complication in males is priapism, due to infarction of the penile venous outflow tracts; permanent impotence is a frequent consequence. Chronic lower leg ulcers probably arise from ischemia and superinfection in the distal circulation.

Acute chest syndrome is a distinctive manifestation characterized by chest pain, tachypnea, fever, cough, and arterial oxygen desaturation. It can mimic pneumonia, pulmonary emboli, bone marrow infarction and embolism, myocardial ischemia, or in situ lung infarction. Acute chest syndrome is thought to be due to in situ sickling within the lung and/or bone marrow microemboli, producing pain and temporary pulmonary dysfunction. Often it is difficult or impossible to distinguish among other possibilities. Pulmonary infarction and pneumonia are the most frequent underlying or concomitant conditions in patients with this syndrome. Repeated episodes of acute chest pain correlate with reduced survival. Acutely, reduction in arterial oxygen saturation is especially ominous because it promotes sickling on a massive scale. Chronic acute or subacute pulmonary crises lead to pulmonary hypertension and cor pulmonale, an increasingly common cause of death as patients survive longer. A possible role played by free plasma HbS in scavenging nitrogen dioxide (NO_2), thus raising pulmonary vascular tone led to trials of sildenafil to restore NO_2 levels. These were terminated because of adverse effects.

Chronic subacute central nervous system damage in the absence of an overt stroke is a distressingly common phenomenon beginning in early childhood. Modern functional imaging techniques have pinpointed circulatory dysfunction due to a likely CNS sickle vasculopathy; these changes correlate with an array of cognitive and behavioral abnormalities in children and young adults. It is important to be aware of these often subtle changes because they can complicate clinical management or be misinterpreted as "difficult patient" behaviors.

Sickle cell syndromes are remarkable for their clinical heterogeneity. Some patients remain virtually asymptomatic into or even through adult life, while others suffer repeated crises requiring hospitalization from early childhood. Patients with sickle thalassemia and sickle-HbE tend to have similar, slightly milder symptoms, perhaps because of the ameliorating effects of the presence of other hemoglobins within the RBC. Hemoglobin SC disease, one of the more common variants of sickle cell anemia, is frequently marked by lesser degrees of hemolytic anemia and a greater propensity for the development of retinopathy and aseptic necrosis of bones. In most respects, however, the clinical manifestations resemble sickle cell anemia. Some rare hemoglobin variants actually aggravate the sickling phenomenon.

The clinical variability in different patients inheriting the same disease-causing mutation (sickle hemoglobin) has made sickle cell disease the focus of efforts to identify modifying genetic polymorphisms in other genes that might account for the heterogeneity. The complexity of the data obtained thus far has dampened the expectation that genome-wide analysis will yield individualized profiles that predict a patient's clinical course. Nevertheless, a number of interesting patterns have emerged from these modifying gene analyses. For example, genes affecting the inflammatory response or cytokine expression appear to be modifying candidates. Genes that affect transcriptional regulation of lymphocytes may also be involved.

Clinical Manifestations of Sickle Cell Trait Sickle cell trait is often asymptomatic. Anemia and painful crises are rare. An uncommon but highly distinctive symptom is painless hematuria often occurring in adolescent males, probably due to papillary necrosis. Isosthenuria is a more common manifestation of the same process.

TABLE 94-2 Clinical Features of Sickle Hemoglobinopathies

CONDITION	CLINICAL ABNORMALITIES	HEMOGLOBIN LEVEL, g/L (g/dL)	MCV, fL	HEMOGLOBIN ELECTROPHORESIS
Sickle cell trait	None; rare painless hematuria	Normal	Normal	HbS/A: 40/60
Sickle cell anemia	Vasoocclusive crises with infarction of spleen, brain, marrow, kidney, lung; aseptic necrosis of bone; gallstones; priapism; ankle ulcers	70–100 (7–10)	80–100	HbS/A: 100/0 HbF: 2–25%
S/β° thalassemia	Vasoocclusive crises; aseptic necrosis of bone	70–100 (7–10)	60–80	HbS/A: 100/0 HbF: 1–10%
S/β+ thalassemia	Rare crises and aseptic necrosis	100–140 (10–14)	70–80	HbS/A: 60/40
Hemoglobin SC	Rare crises and aseptic necrosis; painless hematuria	100–140 (10–14)	80–100	HbS/A: 50/0 HbC: 50%

Sloughing of papillae with urethral obstruction has been reported, as have isolated cases of massive sickling or sudden death due to exposure to high altitudes or extremes of exercise and dehydration. Avoidance of dehydration or extreme physical stress should be advised.

Diagnosis Sickle cell syndromes are suspected on the basis of hemolytic anemia, RBC morphology (Fig. 94-4), and intermittent episodes of ischemic pain. Diagnosis is confirmed by hemoglobin electrophoresis, mass spectroscopy, and the sickling tests already discussed. Thorough characterization of the exact hemoglobin profile of the patient is important, because sickle thalassemia and hemoglobin SC disease have distinct prognoses or clinical features. Diagnosis is usually established in childhood, but occasional patients, often with compound heterozygous states, do not develop symptoms until the onset of puberty, pregnancy, or early adult life. Genotyping of family members and potential parental partners is critical for genetic counseling. Details of the childhood history establish prognosis and need for aggressive or experimental therapies. Factors associated with increased morbidity and reduced survival include more than three crises requiring hospitalization per year, chronic neutrophilia, a history of splenic sequestration or hand-foot syndrome, and second episodes of acute chest syndrome. Patients with a history of cerebrovascular accidents are at higher risk for repeated episodes and require partial exchange transfusion and especially close monitoring using Doppler carotid flow measurements. Patients with severe or repeated episodes of acute chest syndrome may need lifelong transfusion support, using partial exchange transfusion, if possible.

TREATMENT

Sickle Cell Syndromes

Patients with sickle cell syndromes require ongoing continuity of care. Familiarity with the pattern of symptoms provides the best safeguard against excessive use of the emergency room, hospitalization, and habituation to addictive narcotics. Additional preventive measures include regular slit-lamp examinations to monitor development of retinopathy; antibiotic prophylaxis appropriate for splenectomized patients during dental or other invasive procedures; and vigorous oral hydration during or in anticipation of periods of extreme exercise, exposure to heat or cold, emotional stress, or infection. Pneumococcal and *Haemophilus influenzae* vaccines are less effective in splenectomized individuals. Thus, patients with sickle cell anemia should be vaccinated early in life.

The management of an acute painful crisis includes vigorous but careful hydration, thorough evaluation for underlying causes (such as infection), and aggressive analgesia administered by a standing order and/or patient-controlled analgesia (PCA) pump. Morphine (0.1–0.15 mg/kg every 3–4 h) should be used to control severe pain. Bone pain may respond as well to ketorolac (30–60 mg initial dose, then 15–30 mg every 6–8 h). Inhalation of nitrous oxide can provide short-term pain relief, but great care must be exercised to avoid hypoxia and respiratory depression. Nitrous oxide also elevates O_2 affinity, reducing O_2 delivery to tissues. Its use should be restricted to experts. Blockade of the activities of adhesive molecules (e.g., P-selectin) or inflammatory mediators are being used to shorten crises and reduce crisis pain. Many crises can be managed at home with oral hydration and oral analgesia. Use of the emergency room should be reserved for especially severe symptoms or circumstances in which other processes, for example, infection, are strongly suspected. Nasal oxygen should be used as appropriate to protect arterial saturation. Most crises resolve in 1–7 days. Use of blood transfusion should be reserved for extreme cases: transfusions do not shorten the duration of the crisis.

No tests are definitive to diagnose acute painful crisis. Critical to good management is an approach that recognizes that most patients reporting crisis symptoms do indeed have crisis or another significant medical problem. Diligent diagnostic evaluation for underlying causes is imperative, even though these are found infrequently. In adults, the possibility of aseptic necrosis or sickle arthropathy must be considered, especially if pain and immobility become repeated or chronic at a single site. Nonsteroidal anti-inflammatory agents are often effective for sickle cell arthropathy.

Acute chest syndrome is a medical emergency that may require management in an intensive care unit. Hydration should be monitored carefully to avoid the development of pulmonary edema, and oxygen therapy should be especially vigorous for protection of arterial saturation. Diagnostic evaluation for pneumonia and pulmonary embolism should be especially thorough, since these may occur with atypical symptoms. Critical interventions are transfusion to maintain a hematocrit >30, and emergency exchange transfusion if arterial saturation drops to <90%. As patients with sickle cell syndrome increasingly survive into their fifth and sixth decades, end-stage renal failure and pulmonary hypertension are becoming increasingly prominent causes of end-stage morbidity. A sickle cell cardiomyopathy and/or premature coronary artery disease may compromise cardiac function in later years. Sickle cell patients have received kidney transplants, but they often experience an increase in the frequency and severity of crises, possibly due to increased infection as a consequence of immunosuppression.

The most significant advance in the therapy of sickle cell anemia has been the introduction of hydroxyurea as a mainstay of therapy for patients with severe symptoms. Hydroxyurea (10–30 mg/kg per day) increases fetal hemoglobin and may also exert beneficial effects on RBC hydration, vascular wall adherence, and suppression of the granulocyte and reticulocyte counts; dosage is titrated to maintain a white cell count between 5000 and 8000/μL. White cells and reticulocytes may play a major role in the pathogenesis of sickle cell crisis, and their suppression may be an important side benefit of hydroxyurea therapy.

Hydroxyurea should be considered in patients experiencing repeated episodes of acute chest syndrome or with more than three crises per year requiring hospitalization. The utility of this agent for reducing the incidence of other complications (priapism, retinopathy) is under evaluation, as are the long-term side effects. Clinical experience is now sufficient to state that the risk of bone marrow dyscrasias or other neoplasms is minimal. Hydroxyurea offers broad benefits to most patients whose disease is severe enough to impair their functional status; it likely improves survival. HbF levels increase in most patients within a few months.

The antitumor drug 5-azacytidine was the first agent found to elevate HbF. It never achieved widespread use because of concerns about acute toxicity and carcinogenesis. However, low doses of the related agent 5-deoxyazacytidine (decitabine) can elevate HbF with more acceptable toxicity.

Bone marrow transplantation can provide definitive cures but is known to be effective and safe only in children. Clinical trials studying partially myeloablative conditioning regimens ("mini" transplants) are likely to support more widespread use in older patients, and should be considered in adults with significant morbidity. Prognostic features justifying bone marrow transplant are the presence of repeated crises early in life, a high neutrophil count, or the development of hand-foot syndrome. Children at risk for stroke can now be identified through the use of Doppler ultrasound techniques. Prophylactic exchange transfusion appears to substantially reduce the risk of stroke in this population. Children who do suffer a cerebrovascular accident should be maintained for at least 3–5 years on a program of vigorous exchange transfusion, as the risk of second strokes is extremely high. Hydroxyurea therapy could eventually supplant indefinite chronic transfusion in patients responding favorably.

Gene therapy for sickle cell anemia is being intensively pursued, but no safe measures are currently available. The development of newer methods of direct gene correction in situ (e.g., zinc finger nucleases, or "CRISPR" [clustered regularly interspaced short palindromic repeats] technology) could well find clinical use in these patients. Experimental methods of derepressing HbF by manipulating Bcl11a or chromatin looping are also being explored.

TABLE 94-3 Representative Abnormal Hemoglobins with Altered Synthesis or Function

DESIGNATION	MUTATION	POPULATION	MAIN CLINICAL EFFECTS[a]
Sickle or S	$\beta^{6Glu\rightarrow Val}$	African	Anemia, ischemic infarcts
C	$\beta^{6Glu\rightarrow Lys}$	African	Mild anemia; interacts with HbS
E	$\beta^{26Glu\rightarrow Lys}$	Southeast Asian	Microcytic anemia, splenomegaly, thalassemic phenotype
Köln	$\beta^{98Val\rightarrow Met}$	Sporadic	Hemolytic anemia, Heinz bodies when splenectomized
Yakima	$\beta^{99Asp\rightarrow His}$	Sporadic	Polycythemia
Kansas	$\beta^{102Asn\rightarrow Lys}$	Sporadic	Mild anemia
M Iwata	$\alpha^{87His\rightarrow Tyr}$	Sporadic	Methemoglobinemia

[a]See text for details.

UNSTABLE HEMOGLOBINS

Amino acid substitutions that reduce solubility or increase susceptibility to oxidation result in unstable hemoglobins that precipitate, forming inclusion bodies injurious to the RBC membrane. Representative mutations are those that interfere with contact points between the α and β subunits (e.g., Hb Philly [$\beta^{35Tyr\rightarrow Phe}$]), alter the helical segments (e.g., Hb Genova [$\beta^{28Leu\rightarrow Pro}$]), or disrupt interactions of the hydrophobic pockets of the globin subunits with heme (e.g., Hb Köln [$\beta^{98Val\rightarrow Met}$]) **(Table 94-3)**. The inclusions, called *Heinz bodies*, are clinically detectable by staining with supravital dyes such as crystal violet. Removal of these inclusions by the spleen generates pitted, rigid cells that have shortened life spans, producing hemolytic anemia of variable severity, sometimes requiring chronic transfusion support. Splenectomy may be needed to correct the anemia. Leg ulcers and premature gallbladder disease due to bilirubin loading are frequent stigmata.

Unstable hemoglobins occur sporadically, often by spontaneous new mutations. Heterozygotes are often symptomatic because a significant Heinz body burden can develop even when the unstable variant accounts for only a portion of the total hemoglobin. Symptomatic unstable hemoglobins tend to be β-globin variants, because sporadic mutations affecting only one of the four α globins alleles would generate only 20–30% abnormal hemoglobin.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY

High-affinity hemoglobins (e.g., Hb Yakima [$\beta^{99Asp\rightarrow His}$]) bind oxygen more readily but deliver less O_2 to tissues at normal capillary Po_2 levels (Fig. 94-2). Mild tissue hypoxia ensues, stimulating RBC production and erythrocytosis (Table 94-3). In extreme cases, the hematocrits can rise to 60–65%, increasing blood viscosity and producing typical symptoms (headache, somnolence, or dizziness). Phlebotomy may be required. Typical mutations alter interactions within the heme pocket or disrupt the Bohr effect or salt-bond site. Mutations that impair the interaction of HbA with 2,3-BPG can increase O_2 affinity because 2,3-BPG binding lowers O_2 affinity.

Low-affinity hemoglobins (e.g., Hb Kansas [$\beta^{102Asn\rightarrow Lys}$]) bind sufficient oxygen in the lungs, despite their lower oxygen affinity, to achieve nearly full saturation. At capillary oxygen tensions, they lose sufficient amounts of oxygen to maintain homeostasis at a low hematocrit (Fig. 94-2) (*pseudoanemia*). Capillary hemoglobin desaturation can also be sufficient to produce clinically apparent cyanosis. Despite these findings, patients usually require no specific treatment.

METHEMOGLOBINEMIAS

Methemoglobin is generated by oxidation of the heme iron moieties to the ferric state, causing a characteristic bluish-brown muddy color resembling cyanosis. Methemoglobin has such high oxygen affinity that virtually no oxygen is delivered. Levels >50–60% are often fatal.

Congenital methemoglobinemia arises from globin mutations that stabilize iron in the ferric state (e.g., HbM Iwata [$\alpha^{87His\rightarrow Tyr}$], Table 94-3) or from mutations that impair the enzymes that reduce methemoglobin to hemoglobin (e.g., methemoglobin reductase, NADP diaphorase). Acquired methemoglobinemia is caused by toxins that oxidize heme iron, notably nitrate and nitrite-containing compounds, including drugs commonly used in cardiology and anesthesiology.

DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE HEMOGLOBINS, HIGH-AFFINITY HEMOGLOBINS, AND METHEMOGLOBINEMIA

Unstable hemoglobin variants should be suspected in patients with nonimmune hemolytic anemia, jaundice, splenomegaly, or premature biliary tract disease. Severe hemolysis usually presents during infancy as neonatal jaundice or anemia. Milder cases may present in adult life with anemia or only as unexplained reticulocytosis, hepatosplenomegaly, premature biliary tract disease, or leg ulcers. Because spontaneous mutation is common, family history of anemia may be absent. The peripheral blood smear often shows anisocytosis, abundant cells with punctate inclusions, and irregular shapes (i.e., poikilocytosis).

The two best tests for diagnosing unstable hemoglobins are the Heinz body preparation and the isopropanol or heat stability test. Many unstable Hb variants are electrophoretically silent. A normal electrophoresis does not rule out the diagnosis. HPLC or direct gene analysis will provide a definitive diagnosis.

Severely affected patients may require transfusion support for the first 3 years of life, because splenectomy before age 3 is associated with a significantly higher immune deficit. Splenectomy is usually effective thereafter, but occasional patients may require lifelong transfusion support. After splenectomy, patients can develop cholelithiasis and leg ulcers, hypercoagulable states, and susceptibility to overwhelming sepsis. Splenectomy should thus be avoided or delayed unless it is the only alternative. Precipitation of unstable hemoglobins is aggravated by oxidative stress, for example, infection and certain antimalarial drugs, which should be avoided where possible.

High-O_2 affinity hemoglobin variants should be suspected in patients with erythrocytosis. The best test for confirmation is measurement of the P_{50}. A high-O_2 affinity hemoglobin causes a significant left shift (i.e., lower numeric value of the P_{50}); confounding conditions, for example, tobacco smoking or carbon monoxide exposure, can also lower the P_{50}.

High-affinity hemoglobins are often asymptomatic; rubor or plethora may be telltale signs. When the hematocrit approaches 60%, symptoms of high blood viscosity and sluggish flow (headache, lethargy, dizziness, etc.) may be present. These persons may benefit from judicious phlebotomy. Erythrocytosis represents an appropriate attempt to compensate for the impaired oxygen delivery by the abnormal variant. Overzealous phlebotomy may stimulate increased erythropoiesis or aggravate symptoms by thwarting this compensatory mechanism. The guiding principle of phlebotomy should be to improve oxygen delivery by reducing blood viscosity and increasing blood flow rather than restoration of a normal hematocrit. Phlebotomy-induced modest iron deficiency may aid in control.

Low-affinity hemoglobins should be considered in patients with cyanosis or a low hematocrit with no other reason apparent after thorough evaluation. The P_{50} test confirms the diagnosis. Counseling and reassurance are the interventions of choice.

Acquired methemoglobinemia should be suspected in patients with hypoxic symptoms who appear cyanotic but have a Pao_2 sufficiently high that hemoglobin should be fully saturated with oxygen. A history of nitrite or other oxidant ingestions may not always be available; some exposures may be inapparent to the patient, and others may result from suicide attempts. The characteristic muddy appearance of freshly drawn blood can be a critical clue. The best diagnostic test is methemoglobin assay, which is usually available on an emergency basis.

Methemoglobinemia often causes symptoms of cerebral ischemia at levels >15%; levels >60% are usually lethal. Intravenous injection of 1 mg/kg of methylene blue is effective emergency therapy. Milder cases and follow-up of severe cases can be treated orally with methylene blue (60 mg three to four times each day) or ascorbic acid (300–600 mg/d). Congenital methemoglobinemia does not usually require treatment other than avoidance of oxidative drugs or agents. Patient and provider awareness is essential in order that inappropriate evaluations for cyanosis be avoided.

THALASSEMIA SYNDROMES

The thalassemia syndromes are inherited disorders of α- or β-globin biosynthesis. The reduced supply of globin diminishes production of hemoglobin tetramers, causing hypochromia and microcytosis. Unbalanced accumulation of α and β subunits occurs because the synthesis of the unaffected globins proceeds at a normal rate. Unbalanced chain accumulation dominates the clinical phenotype. Clinical severity varies widely, depending on the degree to which the synthesis of the affected globin is impaired, altered synthesis of other globin chains, and coinheritance of other abnormal globin alleles.

CLINICAL MANIFESTATIONS OF β THALASSEMIA SYNDROMES

Mutations causing thalassemia can affect any step in the pathway of globin gene expression: transcription, processing of the mRNA precursor, translation, and posttranslational metabolism of the β-globin polypeptide chain. The most common forms arise from mutations that derange splicing of the mRNA precursor or prematurely terminate translation of the mRNA.

Hypochromia and microcytosis characterize all forms of β thalassemia because of the reduced amounts of hemoglobin tetramers (Fig. 94-5). In heterozygotes (β thalassemia trait), this is the only abnormality seen. Anemia is minimal. In more severe homozygous states, unbalanced α- and β-globin accumulation causes accumulation of highly insoluble unpaired α chains. They form toxic inclusion bodies that kill developing erythroblasts in the marrow. Few of the proerythroblasts beginning erythroid maturation survive. The surviving RBCs bear a burden of inclusion bodies that are detected in the spleen, shortening the RBC life span and producing severe hemolytic anemia. The resulting profound anemia stimulates erythropoietin release and compensatory erythroid hyperplasia, but the marrow response is sabotaged by the ineffective erythropoiesis. Anemia persists. Erythroid hyperplasia can become exuberant and produce masses of extramedullary erythropoietic tissue in the liver and spleen.

Massive bone marrow expansion deranges growth and development. Children develop characteristic "chipmunk" facies due to maxillary marrow hyperplasia and frontal bossing. Thinning and pathologic fracture of long bones and vertebrae may occur due to cortical invasion by erythroid elements and profound growth retardation. Hemolytic anemia causes hepatosplenomegaly, leg ulcers, gallstones, and high-output congestive heart failure. The conscription of caloric resources to support erythropoiesis leads to inanition, susceptibility to infection, endocrine dysfunction, and, in the most severe cases, death during the first decade of life. Chronic transfusions with RBCs improve oxygen delivery, suppress the excessive ineffective erythropoiesis, and prolong life, but the inevitable side effects, notably iron overload, often prove fatal by age 30 years.

Severity is highly variable. Known modulating factors are those that ameliorate the burden of unpaired α-globin inclusions. Alleles associated with milder synthetic defects and coinheritance of α thalassemia trait reduce clinical severity by reducing accumulation of excess α globin. HbF persists to various degrees in β thalassemias. γ-Globin gene chains can substitute for β chains, generating more hemoglobin and reducing the burden of α-globin inclusions. The terms *β thalassemia major* and *β thalassemia intermedia* are used to reflect the clinical heterogeneity. Patients with β thalassemia major require intensive transfusion support to survive. Patients with β thalassemia intermedia have a somewhat milder phenotype and can survive without transfusion. The terms *β thalassemia minor* and *β thalassemia trait* describe asymptomatic heterozygotes for β thalassemia.

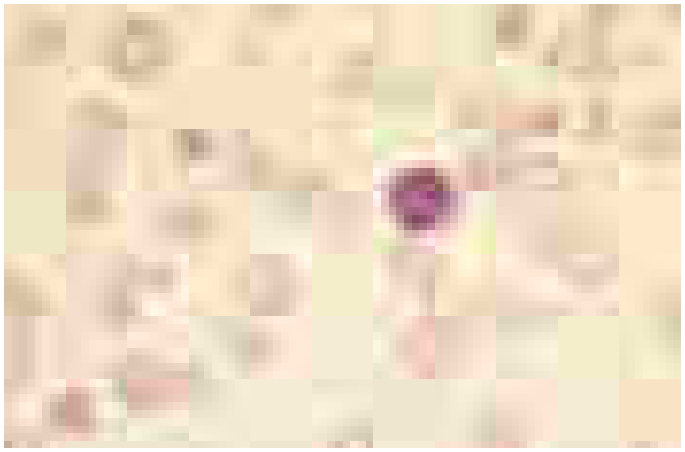

FIGURE 94-5 β Thalassemia intermedia. Microcytic and hypochromic red blood cells are seen that resemble the red blood cells of severe iron-deficiency anemia. Many elliptical and teardrop-shaped red blood cells are noted.

ALPHA THALASSEMIA SYNDROMES

The four classic α thalassemias, most common in Asians, are α thalassemia-2 trait, in which one of the four α-globin loci is deleted; α thalassemia-1 trait, with two deleted loci; HbH disease, with three loci deleted; and hydrops fetalis with Hb Barts, with all four loci deleted (Table 94-4). Nondeletion forms of α thalassemia also exist.

α *Thalassemia-2 trait* is an asymptomatic, silent carrier state. α *Thalassemia-1 trait* resembles β thalassemia minor. Offspring doubly heterozygous for α thalassemia-2 and α thalassemia-1 exhibit a more severe phenotype called *HbH disease*. Heterozygosity for a deletion that removes both genes from the same chromosome (*cis* deletion) is common in Asians and in those from the Mediterranean region, as is homozygosity for α thalassemia-2 (*trans* deletion). Both produce asymptomatic hypochromia and microcytosis.

In *HbH disease*, HbA production is only 25–30% normal. Fetuses accumulate some unpaired γ chains (Hb Barts; γ-chain tetramers). In adults, unpaired β chains accumulate and are soluble enough to form β_4 tetramers called HbH. HbH forms few inclusions in erythroblasts and precipitates in circulating RBC. Patients with HbH disease have thalassemia intermedia characterized by moderately severe hemolytic anemia but milder ineffective erythropoiesis. Survival into mid-adult life without transfusions is common.

The homozygous state for the α thalassemia-1 *cis* deletion (hydrops fetalis) causes total absence of α-globin synthesis. No physiologically useful hemoglobin is produced beyond the embryonic stage. Excess γ globin forms tetramers called *Hb Barts* (γ_4), which has a very high oxygen affinity. It delivers almost no O_2 to fetal tissues, causing tissue asphyxia, edema (hydrops fetalis), congestive heart failure, and death in utero. α Thalassemia-2 trait is common (15–20%) among people of African descent. The *cis* α thalassemia-1 deletion is almost never seen, however. Thus, α thalassemia-2 and the *trans* form of α thalassemia-1 are very common, but HbH disease and hydrops fetalis are rare.

It has been known for some time that some patients with myelodysplasia or erythroleukemia produce RBC clones containing HbH. This phenomenon is due to mutations in the ATRX pathway that affect the LCR of the α-globin gene cluster.

DIAGNOSIS AND MANAGEMENT OF THALASSEMIAS

The diagnosis of β-thalassemia major is readily made during childhood on the basis of severe anemia accompanied by the characteristic signs of massive ineffective erythropoiesis: hepatosplenomegaly, profound microcytosis, a characteristic blood smear (Fig. 94-5), and elevated levels of HbF, HbA_2, or both. Many patients require chronic hypertransfusion therapy designed to maintain a hematocrit of at least 27–30% so that erythropoiesis is suppressed. Splenectomy is required if the annual transfusion requirement (volume of RBCs per kilogram of body weight per year) increases by >50%. Folic acid supplements may be useful. Vaccination with Pneumovax in anticipation of eventual splenectomy is advised, as is close monitoring for infection, leg ulcers, and biliary tract disease. Many patients develop endocrine deficiencies as a result of iron overload. Early endocrine evaluation is required for glucose intolerance, thyroid dysfunction, and delayed onset of puberty or secondary sexual characteristics.

Patients with β thalassemia intermedia exhibit similar stigmata but can survive without chronic hypertransfusion. Management is particularly challenging because a number of factors can aggravate the anemia, including infection, onset of puberty, and development

TABLE 94-4 The α Thalassemias

CONDITION	HEMOGLOBIN A, %	HEMOGLOBIN H (β4), %	HEMOGLOBIN LEVEL, g/L (g/dL)	MCV, fL
Normal	97	0	150 (15)	90
Silent thalassemia: −α/αα	98–100	0	150 (15)	90
Thalassemia trait:−α/−α homozygous α-thal-2[a] or ––/αα heterozygous α-thal-1[a]	85–95	Rare red blood cell inclusions	120–130 (12–13)	70–80
Hemoglobin H disease: ––/−α heterozygous α-thal-1/α-thal-2	70–95	5–30	60–100 (6–10)	60–70
Hydrops fetalis: ––/–– homozygous α-thal-1	0	5–10[b]	Fatal in utero or at birth	

[a]When both α alleles on one chromosome are deleted, the locus is called α-thal-1; when only a single α allele on one chromosome is deleted, the locus is called α-thal-2. [b]90–95% of the hemoglobin is hemoglobin Barts (tetramers of γ chains).

of splenomegaly and hypersplenism. Some patients may eventually benefit from splenectomy. The expanded erythron can cause absorption of excessive dietary iron and hemosiderosis, even without transfusion. Some patients eventually become transfusion dependent.

β Thalassemia minor (i.e., thalassemia trait) usually presents as profound microcytosis and hypochromia with target cells, but only minimal or mild anemia. The mean corpuscular volume is rarely >75 fL; the hematocrit is rarely <30–33%. Hemoglobin analysis classically reveals an elevated HbA_2 (3.5–7.5%), but some forms are associated with normal HbA_2 and/or elevated HbF. Genetic counseling and patient education are essential. Patients with β thalassemia trait should be warned that their blood picture resembles iron deficiency and can be misdiagnosed. They should eschew empirical use of iron, yet iron deficiency requiring replacement therapy can develop during pregnancy or from chronic bleeding.

Persons with α thalassemia trait may exhibit mild hypochromia and microcytosis usually without anemia. HbA_2 and HbF levels are normal. Affected individuals usually require only genetic counseling. HbH disease resembles β thalassemia intermedia, with the added complication that the HbH molecule behaves like moderately unstable hemoglobin. Patients with HbH disease should undergo splenectomy if excessive anemia or a transfusion requirement develops. Oxidative drugs should be avoided. Iron overload leading to death can occur in more severely affected patients.

PREVENTION

Antenatal diagnosis of thalassemia syndromes is now widely available. DNA diagnosis is based on polymerase chain reaction (PCR) amplification of fetal DNA, obtained by amniocentesis or chorionic villus biopsy followed by hybridization to allele-specific oligonucleotide probes or direct DNA sequencing.

THALASSEMIC STRUCTURAL VARIANTS

Thalassemic structural variants are characterized by both defective synthesis and abnormal structure.

HEMOGLOBIN LEPORE

Hb Lepore [$\alpha_2(\delta\beta)_2$] arises by an unequal crossover and recombination event that fuses the proximal end of the δ-gene with the distal end of the closely linked β-gene. It is common in the Mediterranean basin. The resulting chromosome contains only the fused δβ gene. The Lepore (δβ) globin is synthesized poorly because the fused gene is under the control of the weak δ-globin promoter. Hb Lepore alleles have a phenotype like β thalassemia, except for the added presence of 2–20% Hb Lepore. Compound heterozygotes for Hb Lepore and a classic β thalassemia allele may also have severe thalassemia.

HEMOGLOBIN E

HbE (i.e., $\alpha_2\beta_2^{26Glu\rightarrow Lys}$) is extremely common in Cambodia, Thailand, and Vietnam. The gene has become far more prevalent in the United States as a result of immigration of Asian persons, especially in California, where HbE is the most common variant detected. HbE is mildly unstable but not enough to affect RBC life span significantly. Heterozygotes resemble individuals with a mild β-thalassemia trait. HbE homozygosity is a condition associated with mildly asymptomatic microcytosis, hypochromia, and hemoglobin levels rarely <100 g/L (<10 g/dL).

Compound heterozygotes for HbE and a β thalassemia gene can have β thalassemia intermedia or β-thalassemia major, depending on the severity of the coinherited thalassemic gene.

The β^E allele contains a single base change in codon 26 that causes the amino acid substitution. This mutation also activates a cryptic RNA splice site, generating a structurally abnormal globin mRNA that cannot be translated, from about 50% of the initial pre-mRNA molecules. The remaining 40–50% are normally spliced and generate functional mRNA that is translated into β^E-globin because the mature mRNA carries the base change that alters codon 26.

Genetic counseling of the persons at risk for HbE should focus especially on the interaction of HbE with β thalassemia, because HbE homozygosity is a condition associated with microcytosis, hypochromia, and hemoglobin levels rarely below 100 g/L (10 g/dL) and is usually asymptomatic.

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

HPFH is characterized by continued synthesis of high levels of HbF in adult life. No deleterious effects are apparent, even when all of the hemoglobin produced is HbF. These rare patients demonstrate convincingly that prevention or reversal of the fetal to adult hemoglobin switch would provide effective therapy for sickle cell anemia and β thalassemia.

ACQUIRED HEMOGLOBINOPATHIES

The two most important acquired hemoglobinopathies are carbon monoxide poisoning and methemoglobinemia (see above). Carbon monoxide has a higher affinity for hemoglobin than does oxygen; it can replace oxygen and diminish O_2 delivery. Chronic elevation of carboxyhemoglobin levels to 10 or 15%, as occurs in smokers, can lead to secondary polycythemia. Carboxyhemoglobin is cherry red in color and masks the development of cyanosis usually associated with poor O_2 delivery to tissues.

Abnormalities of hemoglobin biosynthesis have also been described in blood dyscrasias. In some patients with myelodysplasia, erythroleukemia, or myeloproliferative disorders, elevated HbF or a mild form of HbH disease may also be seen. The abnormalities are not severe enough to alter the course of the underlying disease.

TREATMENT

Transfusional Hemosiderosis

Chronic blood transfusion can lead to bloodborne infection, alloimmunization, febrile reactions, and lethal iron overload (Chap. 109). A unit of packed RBCs contains 250–300 mg iron (1 mg/mL). The iron assimilated by a single transfusion of 2 units of packed RBCs is thus equal to a 1- to 2-year oral intake of iron. Iron accumulates in chronically transfused patients because no mechanisms exist for

increasing iron excretion: an expanded erythron causes especially rapid development of iron overload because accelerated erythropoiesis promotes excessive absorption of dietary iron. Vitamin C should not be supplemented because it generates free radicals in iron excess states.

Patients who receive >100 units of packed RBCs usually develop hemosiderosis. The ferritin level rises, followed by early endocrine dysfunction (glucose intolerance and delayed puberty), cirrhosis, and cardiomyopathy. Liver biopsy shows both parenchymal and reticuloendothelial iron. The superconducting quantum-interference device (SQUID) is accurate at measuring hepatic iron but not widely available. Cardiac toxicity is often insidious. Early development of pericarditis is followed by dysrhythmia and pump failure. The onset of heart failure is ominous, often presaging death within a year **(Chap. 407)**.

The decision to start long-term transfusion support should also prompt one to institute therapy with iron-chelating agents. Deferoxamine (Desferal) is for parenteral use. Its iron-binding kinetics require chronic slow infusion via a metering pump. The constant presence of the drug improves the efficiency of chelation and protects tissues from occasional releases of the most toxic fraction of iron—low-molecular-weight iron—which may not be sequestered by protective proteins.

Deferoxamine is relatively nontoxic. Occasional cataracts, deafness, and local skin reactions, including urticaria, occur. Skin reactions can usually be managed with antihistamines. Negative iron balance can be achieved, even in the face of a high transfusion requirement, but this alone does not prevent long-term morbidity and mortality in chronically transfused patients. Irreversible end-organ deterioration develops at relatively modest levels of iron overload, even if symptoms do not appear for many years thereafter. To enjoy a significant survival advantage, chelation must begin before 5–8 years of age in β-thalassemia major.

Deferasirox is an oral iron-chelating agent. Single daily doses of 20–30 mg/kg deferasirox produced reductions in liver iron concentration comparable to deferoxamine in long-term transfused adult and pediatric patients. Deferasirox produces some elevations in liver enzymes and slight but persistent increases in serum creatinine, without apparent clinical consequence. Other toxicities are similar to those of deferoxamine. Its toxicity profile is acceptable, although long-term effects are still being evaluated.

EXPERIMENTAL THERAPIES

BONE MARROW TRANSPLANTATION, GENE THERAPY, AND MANIPULATION OF HBF

Bone marrow transplantation provides stem cells able to express normal hemoglobin; it has been used in a large number of patients with β thalassemia and a smaller number of patients with sickle cell anemia. Early in the course of disease, before end-organ damage occurs, transplantation is curative in 80–90% of patients. In highly experienced centers, the treatment-related mortality is <10%. Because survival into adult life is possible with conventional therapy, the decision to transplant is best made in consultation with specialized centers.

Gene therapy of thalassemia and sickle cell disease has proved to be an elusive goal, but experimental advances are raising expectations. New lentivirus vectors appear to be capable of achieving stable synthesis of anti-sickling hemoglobin variants in some cases without insertional mutagenesis that has been seen with other vectors.

Reestablishing high levels of fetal hemoglobin synthesis should ameliorate the symptoms of β-chain hemoglobinopathies. Cytotoxic agents such as hydroxyurea and cytarabine promote high levels of HbF synthesis, probably by stimulating proliferation of the primitive HbF-producing progenitor cell population (i.e., F cell progenitors). Unfortunately, this regimen has not yet been effective in β thalassemia. Butyrates stimulate HbF production, but only transiently. Pulsed or intermittent administration has been found to sustain HbF induction in the majority of patients with sickle cell disease. It is unclear whether butyrates will have similar activity in patients with β thalassemia.

APLASTIC AND HYPOPLASTIC CRISIS IN PATIENTS WITH HEMOGLOBINOPATHIES

Patients with hemolytic anemias sometimes exhibit an alarming decline in hematocrit during and immediately after acute illnesses. Bone marrow suppression occurs in almost everyone during acute and chronic inflammatory illnesses. In patients with short RBC life spans, suppression can affect RBC counts more dramatically. These hypoplastic crises are usually transient and self-correcting before intervention is required.

Aplastic crisis refers to a profound cessation of erythroid activity in patients with chronic hemolytic anemias. It is associated with a rapidly falling hematocrit. Episodes are usually self-limited. Aplastic crises are caused by infection with a particular strain of parvovirus, B19A. Children infected with this virus usually develop permanent immunity. Aplastic crises do not often recur and are rarely seen in adults. Management requires close monitoring of the hematocrit and reticulocyte count. If anemia becomes symptomatic, transfusion support is indicated. Most crises resolve spontaneously within 1–2 weeks.

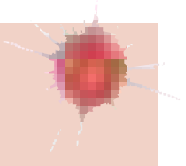
95 Megaloblastic Anemias

A. Victor Hoffbrand



The megaloblastic anemias are a group of disorders characterized by the presence of distinctive morphologic appearances of the developing red cells in the bone marrow. The marrow is usually hypercellular and the anemia is based on ineffective erythropoiesis. The cause is usually a deficiency of either cobalamin (vitamin B_{12}) or folate, but megaloblastic anemia may occur because of genetic or acquired abnormalities that affect the metabolism of these vitamins or because of defects in DNA synthesis not related to cobalamin or folate **(Table 95-1)**. Cobalamin and folate absorption and metabolism are described next, followed by the biochemical basis, clinical and laboratory features, causes, and treatment of megaloblastic anemia.

TABLE 95-1 Causes of Megaloblastic Anemia

Cobalamin deficiency or abnormalities of cobalamin metabolism **(see Tables 95-3, 95-4)**
Folate deficiency or abnormalities of folate metabolism **(see Table 95-5)**
Therapy with antifolate drugs (e.g., methotrexate)
Independent of either cobalamin or folate deficiency and refractory to cobalamin and folate therapy:
Some cases of acute myeloid leukemia, myelodysplasia
Therapy with drugs interfering with synthesis of DNA (e.g., cytosine arabinoside, hydroxyurea, 6-mercaptopurine, azidothymidine [AZT])
Orotic aciduria (responds to uridine)
Thiamine-responsive

COBALAMIN

Cobalamin (vitamin B_{12}) exists in a number of different chemical forms. All have a cobalt atom at the center of a corrin ring. In nature, the vitamin is mainly in the 2-deoxyadenosyl (ado) form, which is located in mitochondria. It is the cofactor for the enzyme L-methylmalonyl coenzyme A (CoA) mutase. The other major natural cobalamin is methylcobalamin, the form in human plasma and in cell cytoplasm. It is the cofactor for methionine synthase. There are also minor amounts of hydroxocobalamin to which methyl- and adocobalamin are converted rapidly by exposure to light.

DIETARY SOURCES AND REQUIREMENTS

Cobalamin is synthesized solely by microorganisms. Ruminants obtain cobalamin from the foregut, but the only source for humans is food of animal origin, for example, meat, fish, and dairy products. Vegetables, fruits, and other foods of nonanimal origin are free from cobalamin unless they are contaminated by bacteria. A normal Western diet contains 5–30 µg of cobalamin daily. Adult daily losses (mainly in the urine and feces) are 1–3 µg (~0.1% of body stores), and because the body does not have the ability to degrade cobalamin, daily requirements are also about 1–3 µg. Body stores are of the order of 2–3 mg, sufficient for 3–4 years if supplies are completely cut off.

ABSORPTION

Two mechanisms exist for cobalamin absorption. One is passive, occurring equally through buccal, duodenal, and ileal mucosa; it is rapid but extremely inefficient, with <1% of an oral dose being absorbed by this process. The normal physiologic mechanism is active; it occurs through the ileum and is efficient for small (a few micrograms) oral doses of cobalamin, and it is mediated by gastric intrinsic factor (IF). Dietary cobalamin is released from protein complexes by enzymes in the stomach, duodenum, and jejunum; it combines rapidly with a salivary glycoprotein that belongs to the family of cobalamin-binding proteins known as haptocorrins (HCs). In the intestine, the HC is digested by pancreatic trypsin and the cobalamin is transferred to IF.

IF (gene at chromosome 11q13) is produced in the gastric parietal cells of the fundus and body of the stomach, and its secretion parallels that of hydrochloric acid. Normally, there is a vast excess of IF. The IF-cobalamin complex passes to the ileum, where IF attaches to a specific receptor (cubilin) on the microvillus membrane of the enterocytes. Cubilin also is present in yolk sac and renal proximal tubular epithelium. Cubilin appears to traffic by means of amnionless (AMN), an endocytic receptor protein that directs sublocalization and endocytosis of cubilin with its ligand IF-cobalamin complex. The cobalamin-IF complex enters the ileal cell, where IF is destroyed. After a delay of about 6 h, the cobalamin appears in portal blood attached to transcobalamin (TC) II.

Between 0.5 and 5 µg of cobalamin enter the bile each day. This binds to IF, and a major portion of biliary cobalamin normally is reabsorbed together with cobalamin derived from sloughed intestinal cells. Because of the appreciable amount of cobalamin undergoing enterohepatic circulation, cobalamin deficiency develops more rapidly in individuals who malabsorb cobalamin than it does in vegans, in whom reabsorption of biliary cobalamin is intact.

TRANSPORT

Two main cobalamin transport proteins exist in human plasma; they both bind cobalamin—one molecule for one molecule. One HC, also known as TC I, is closely related to other cobalamin-binding HCs in milk, gastric juice, bile, saliva, and other fluids. The gene *TCNL* is at chromosome 11q11-q12.3. These HCs differ from each other only in the carbohydrate moiety of the molecule. TC I is derived primarily from the specific granules in neutrophils. Normally, it is about two-thirds saturated with cobalamin, which it binds tightly. TC I does not enhance cobalamin entry into tissues. Glycoprotein receptors on liver cells are involved in the removal of TC I from plasma, and TC I may play a role in the transport of cobalamin analogues (which it binds more effectively than IF) to the liver for excretion in bile.

The other major cobalamin transport protein in plasma is transcobalamin, also known as TC II. The gene is on chromosome 22q11-q13.1. As for IF and HC, there are nine exons. The three proteins are likely to have a common ancestral origin. TC II is synthesized by liver and by other tissues, including macrophages, ileum, and vascular endothelium. It normally carries only 20–60 ng of cobalamin per liter of plasma and readily gives up cobalamin to marrow, placenta, and other tissues, which it enters by receptor-mediated endocytosis involving the TC II receptor and megalin (encoded by the *LRP-2* gene). The TC II cobalamin is internalized by endocytosis via clathrin-coated pits; the complex is degraded, but the receptor probably is recycled to the cell membrane as is the case for transferrin. Export of "free" cobalamin is via the ATP-binding cassette drug transporter alias multidrug resistance protein 1.

FOLATE

DIETARY FOLATE

Folic (pteroylglutamic) acid is a yellow, crystalline, water-soluble substance. It is the parent compound of a large family of natural folate compounds, which differ from it in three respects: (1) they are partly or completely reduced to dihydrofolate (DHF) or tetrahydrofolate (THF) derivatives, (2) they usually contain a single carbon unit **(Table 95-2)**, and (3) 70–90% of natural folates are folate-polyglutamates.

Most foods contain some folate. The highest concentrations are found in liver, yeast, spinach, other greens, and nuts (>100 µg/100 g). The total folate content of an average Western diet is ~250 µg daily, but the amount varies widely according to the type of food eaten and the method of cooking. Folate is easily destroyed by heating, particularly in large volumes of water. Total body folate in the adult is ~10 mg, with the liver containing the largest store. Daily adult requirements are ~100 µg, and so stores are sufficient for only 3–4 months in normal adults and severe folate deficiency may develop rapidly.

ABSORPTION

Folates are absorbed rapidly from the upper small intestine. The absorption of folate polyglutamates is less efficient than that of monoglutamates; on average, ~50% of food folate is absorbed. Polyglutamate forms are hydrolyzed to the monoglutamate derivatives either in the lumen of the intestine or within the mucosa. All dietary folates are converted to 5-methylTHF (5-MTHF) within the small intestinal mucosa before entering portal plasma. The monoglutamates are actively transported across the enterocyte by a proton-coupled folate transporter (PCFT, SCL46A1). This is situated at the apical brush border and is most active at pH 5.5, which is about the pH of the duodenal and jejunal surface. Genetic mutations of this protein underlie hereditary malabsorption of folate (see below). Pteroylglutamic acid at doses >400 µg is absorbed largely unchanged and converted to natural folates in the liver. Lower doses are converted to 5-MTHF during absorption through the intestine.

About 60–90 µg of folate enters the bile each day and is excreted into the small intestine. Loss of this folate, together with the folate of sloughed intestinal cells, accelerates the speed with which folate deficiency develops in malabsorption conditions.

TRANSPORT

Folate is transported in plasma; about one-third is loosely bound to albumin, and two-thirds is unbound. In all body fluids (plasma,

TABLE 95-2 Biochemical Reactions of Folate Coenzymes

REACTION	COENZYME FORM OF FOLATE INVOLVED	SINGLE CARBON UNIT TRANSFERRED	IMPORTANCE
Formate activation	THF	–CHO	Generation of 10-formyl-THF
Purine synthesis			
Formation of glycinamide ribonucleotide	5,10-Methylene-THF	–CHO	Formation of purines needed for DNA, RNA synthesis, but reactions probably not rate-limiting
Formylation of aminoimidazole carboxamide ribonucleotide (AICAR)	10-Formyl (CHO)THF		
Pyrimidine synthesis			
Methylation of deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP)	5,10-Methylene-THF	$-CH_3$	Rate limiting in DNA synthesis Oxidizes THF to DHF Some breakdown of folate at the C-9–N-10 bond
Amino acid interconversion			
Serine–glycine interconversion	THF	$=CH_2$	Entry of single carbon units into active pool
Homocysteine to methionine	5-Methyl(M)THF	$-CH_3$	Demethylation of 5-MTHF to THF; also requires cobalamin, flavine adenine dinucleotide, ATP, and adenosylmethionine
Forminoglutamic acid to glutamic acid in histidine catabolism	THF	–HN–CH=	

Abbreviations: DHF, dihydrofolate; THF, tetrahydrofolate.

cerebrospinal fluid, milk, bile), folate is largely, if not entirely, 5-MTHF in the monoglutamate form. Three types of folate-binding protein are involved. A reduced folate transporter (RFC, SLC19A1) is the major route of delivery of plasma folate (5-MTHF) to cells. Two folate receptors, FR2 and FR3 embedded in the cell membrane by a glycosyl phosphatidylinositol anchor, transport folate into the cell via receptor-mediated endocytosis. The third protein, PCFT, transports folate at low pH from the vesicle to the cell cytoplasm. The reduced folate transporter also mediates uptake of methotrexate by cells.

BIOCHEMICAL FUNCTIONS

Folates (as the intracellular polyglutamate derivatives) act as coenzymes in the transfer of single-carbon units (Fig. 95-1 and Table 95-2). Two of these reactions are involved in purine synthesis and one in pyrimidine synthesis necessary for DNA and RNA replication. Folate is also a coenzyme for methionine synthesis, in which methylcobalamin is also involved and in which THF is regenerated. THF is the acceptor of single carbon units newly entering the active pool via conversion of serine to glycine. Methionine, the other product of the methionine synthase reaction, is the precursor for *S*-adenosylmethionine (SAM), the universal methyl donor involved in >100 methyltransferase reactions (Fig. 95-1).

During thymidylate synthesis, 5,10-methylene-THF is oxidized to DHF. The enzyme DHF reductase converts this to THF. The drugs methotrexate, pyrimethamine, and (mainly in bacteria) trimethoprim inhibit DHF reductase and so prevent formation of active THF coenzymes from DHF. A small fraction of the folate coenzyme is not recycled during thymidylate synthesis but is degraded at the C9-N10 bond.

BIOCHEMICAL BASIS OF MEGALOBLASTIC ANEMIA

The common feature of all megaloblastic anemias is a defect in DNA synthesis that affects rapidly dividing cells in the bone marrow. All conditions that give rise to megaloblastic changes have in common a disparity in the rate of synthesis or availability of the four immediate precursors of DNA: the deoxyribonucleoside triphosphates (dNTPs)—dA(adenine)TP and dG(guanine)TP (purines), dT(thymine)TP, and dC(cytosine)TP (pyrimidines). In deficiencies of either folate or cobalamin, there is failure to convert deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), the precursor of dTTP (Fig. 95-1). This is the case because folate is needed as the coenzyme 5,10-methylene-THF polyglutamate for conversion of dUMP to dTMP; the availability of 5,10-methylene-THF is reduced in either cobalamin or folate deficiency. DNA replication from multiple origins along the chromosome is slower than normal during mitosis, and there is failure of joining up the incomplete replicons with resulting single stranded DNA breaks. An alternative theory for megaloblastic anemia in cobalamin or folate deficiency is misincorporation of uracil into DNA because of the accumulation of deoxyuridine triphosphate (dUTP) at the DNA replication fork as a consequence of the block in conversion of dUMP to dTMP.

COBALAMIN-FOLATE RELATIONS

Folate is required for many reactions in mammalian tissues. Only two reactions in the body are known to require cobalamin. Methylmalonyl-CoA isomerization requires adocobalamin, and the methylation of homocysteine to methionine requires both methylcobalamin and 5-MTHF (Fig. 95-1). This reaction is the first step in the pathway by which 5-MTHF, which enters bone marrow and other cells from plasma, is converted into all the intracellular folate coenzymes. The coenzymes are all polyglutamated (the larger size aiding retention in the cell), but the enzyme folate polyglutamate synthase can use only THF, not MTHF, as substrate. In cobalamin deficiency, MTHF accumulates in plasma, and intracellular folate concentrations fall due to failure of formation of THF, the substrate on which folate polyglutamates are built. This has been termed *THF starvation*, or the *methylfolate trap*.

This theory explains the abnormalities of folate metabolism that occur in cobalamin deficiency (high serum folate, low cell folate, positive purine precursor aminoimidazole carboxamide ribonucleotide [AICAR] excretion; Table 95-2) and also why the anemia of cobalamin deficiency responds to folic acid in large doses.

CLINICAL FEATURES

Many symptomless patients are detected through the finding of a raised mean corpuscular volume (MCV) on a routine blood count. The main clinical features in more severe cases are those of anemia. Anorexia is usually marked, and there may be weight loss, diarrhea, or constipation. Glossitis, angular cheilosis, a mild fever in more severely anemic patients, jaundice (unconjugated), and reversible melanin skin hyperpigmentation also may occur with a deficiency of either folate or cobalamin. Thrombocytopenia sometimes leads to bruising, and this may be aggravated by vitamin C deficiency or alcohol in malnourished patients. The anemia and low leukocyte count may predispose to infections, particularly of the respiratory and urinary tracts. Cobalamin deficiency has also been associated in a few studies with impaired bactericidal function of phagocytes and with osteoporosis.

Neurologic Manifestations Vitamin B_{12} is needed for the myelination of the central nervous system. Its deficiency may cause a bilateral peripheral neuropathy or degeneration (demyelination) of the cervical and thoracic posterior and lateral (pyramidal) tracts of the

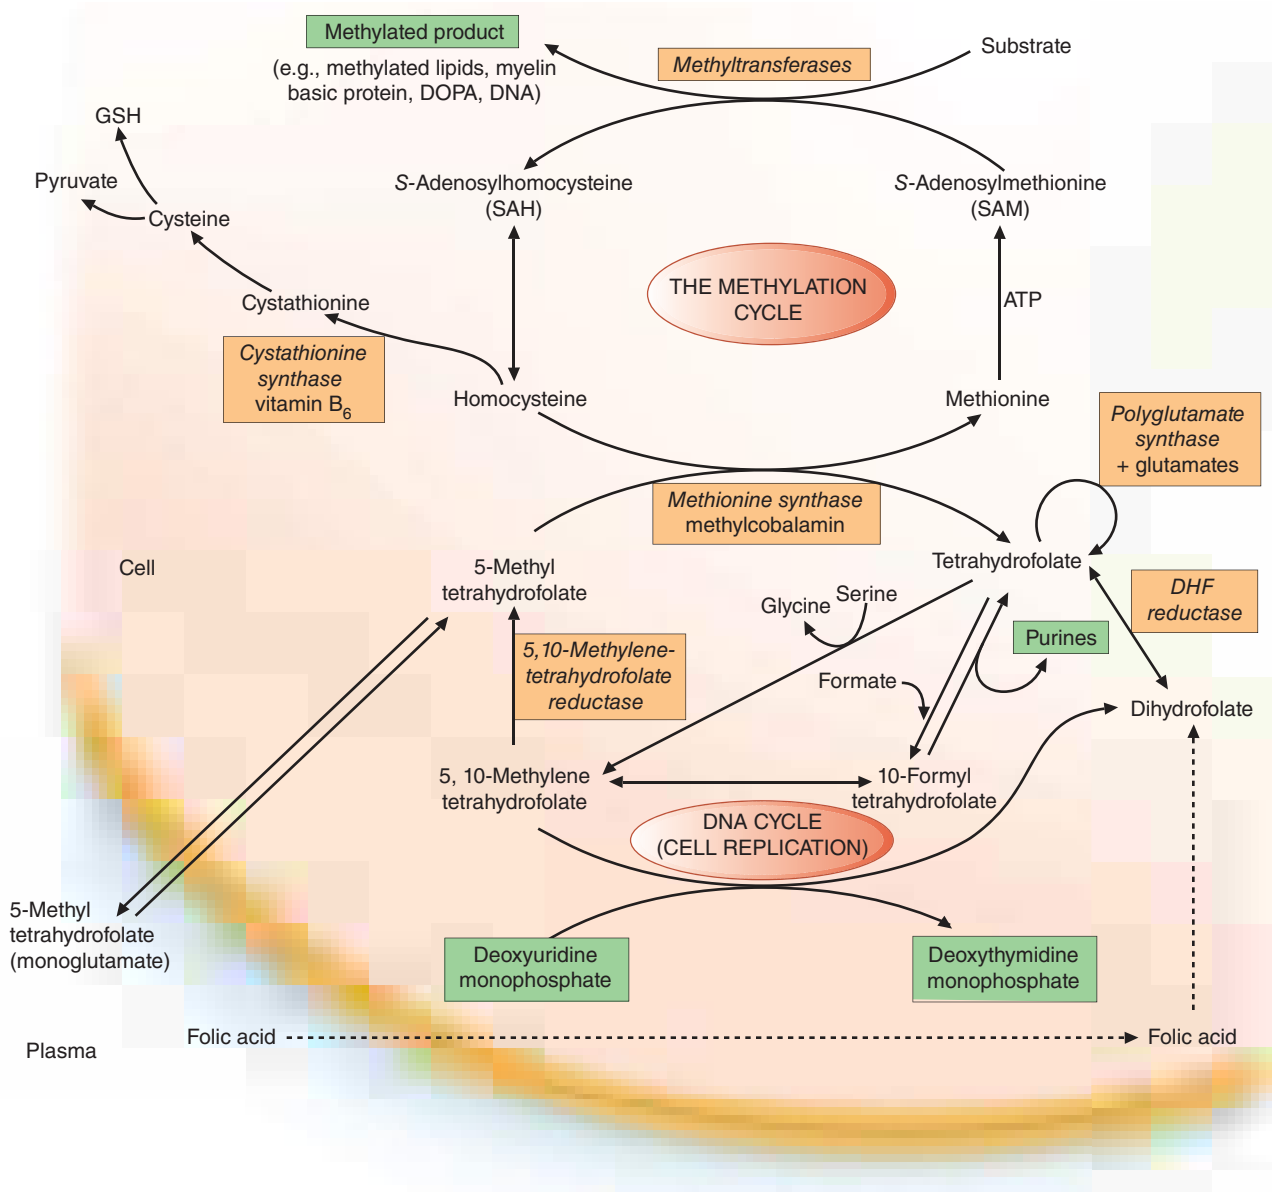


FIGURE 95-1 The role of folates in DNA synthesis and in formation of *S*-adenosylmethionine (SAM), which is involved in numerous methylation reactions. DHF, dihydrofolate; GSH, glutathione. *(Reprinted from AV Hoffbrand et al [eds]: Postgraduate Haematology, 5th ed. Oxford, UK, Blackwell Publishing, 2005; with permission.)*

spinal cord and, less frequently, of the cranial nerves and of the white matter of the brain. Optic atrophy and cerebral symptoms including dementia, depression, psychotic symptoms, and cognitive impairment may be prominent. There may also be anosmia and loss of taste. MRI may show the "spongy" degeneration of the cord.

The patient, more frequently male, typically presents with paresthesias, muscle weakness, or difficulty in walking but sometimes with the dementia, psychotic disturbances, or visual impairment. There is usually loss of proprioception and vibration sensation with positive Romberg and Lhermitte signs. Gait may be ataxic with spasticity (hyperreflexia). Autonomic nervous dysfunction can result in postural hypotension, impotence, and incontinence.

Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. In infancy there may be feeding difficulties, lethargy, and coma. Convulsions and myoclonus have been described. An important clinical problem is the non-anemic patient with neurologic or psychiatric abnormalities and a low or borderline serum cobalamin level. In such patients, it is necessary to try to establish whether there is significant cobalamin deficiency, for example, by careful examination of the blood film, tests for pernicious anemia (PA) by serum gastrin level and for antibodies to IF or parietal cells, along with serum methylmalonic acid (MMA) measurement if available. A trial of cobalamin therapy for at least 3 months will usually also be needed to determine whether the symptoms improve.

The biochemical basis for cobalamin neuropathy remains obscure. Its occurrence in the absence of methylmalonic aciduria in TC II deficiency suggests that the neuropathy is related to the defect in homocysteine-methionine conversion. Accumulation of *S*-adenosylhomocysteine in the brain, resulting in inhibition of transmethylation reactions, has been suggested. Folate deficiency has been suggested to cause organic nervous disease, but this is uncertain, although methotrexate injected into the cerebrospinal fluid may cause brain or spinal cord damage.

Psychiatric disturbance as discussed above is common in both folate and cobalamin deficiencies. This, like the neuropathy, has been attributed to a failure of the synthesis of SAM, which is needed in methylation of biogenic amines (e.g., dopamine) as well as that of proteins, phospholipids, and neurotransmitters in the brain (Fig. 95-1). Associations between lower serum folate or cobalamin levels and higher homocysteine levels and the development of decreased cognitive function and dementia in Alzheimer's disease have been reported. A meta-analysis of randomized, placebo-controlled trials of homocysteine-lowering B-vitamin supplementation of individuals with and

without cognitive impairment, however, showed that supplementation with vitamin B_{12}, vitamin B_6, and folic acid alone or in combination did not improve cognitive function. It is unknown whether prolonged treatment with these B vitamins can reduce the risk of dementia in later life.

GENERAL TISSUE EFFECTS OF COBALAMIN AND FOLATE DEFICIENCIES

Epithelial Surfaces After the marrow, the next most frequently affected tissues are the epithelial cell surfaces of the mouth (with glossitis), stomach, and small intestine and the respiratory, urinary, and female genital tracts. The cells show macrocytosis, with increased numbers of multinucleate and dying cells. The deficiencies may cause cervical smear abnormalities.

Complications of Pregnancy The gonads are also affected, and infertility is common in both men and women with severe deficiency of either vitamin. Maternal folate deficiency has been implicated as a cause of prematurity, and both folate deficiency and cobalamin deficiency have been implicated in recurrent fetal loss and neural tube defects, as discussed below.

Neural Tube Defects Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce by ~70% the incidence of neural tube defects (NTDs) (anencephaly, meningomyelocele, encephalocele, and spina bifida) in the fetus. Most of this protective effect can be achieved by taking folic acid, 0.4 mg daily, at the time of conception.

The incidence of cleft palate and harelip also can be reduced by prophylactic folic acid. There is no clear simple relationship between maternal folate status and these fetal abnormalities, although overall the lower the maternal folate, the greater the risk to the fetus. NTDs also can be caused by antifolate and antiepileptic drugs.

An underlying maternal folate metabolic abnormality has also been postulated. One abnormality has been identified: reduced activity of the enzyme 5,10-methylene-THF reductase (MTHFR) (Fig. 95-1) caused by a common C677T polymorphism in the *MTHFR* gene. In one study, the prevalence of this polymorphism was found to be higher than in controls in the parents of NTD fetuses and in the fetuses themselves: homozygosity for the TT mutation was found in 13% of cases compared with 5% of control subjects. The polymorphism codes for a thermolabile form of MTHFR. The homozygous state results in a lower mean serum and red cell folate level compared with control subjects, as well as significantly higher serum homocysteine levels. Tests for mutations in other enzymes possibly associated with NTDs, for example, methionine synthase and serine–glycine hydroxymethylase, have been negative. Serum vitamin B_{12} levels are also lower in the sera of mothers of NTD infants than in controls. In addition, maternal TC II receptor polymorphisms are associated with increased risk of NTD births. There are, however, no studies showing dietary fortification with vitamin B_{12} reduces the incidence of NTDs.

Cardiovascular Disease Children with severe homocystinuria (blood levels ≥100 μmol/L) due to deficiency of one of three enzymes, methionine synthase, MTHFR, or cystathionine synthase (Fig. 95-1), have vascular disease, for example, ischemic heart disease, cerebrovascular disease, or pulmonary embolus, as teenagers or in young adulthood. Lesser degrees of raised serum homocysteine and low levels of serum folate and homozygous inherited mutations of MTHFR have been found to be associated with cerebrovascular, peripheral vascular, and coronary heart disease and with deep vein thrombosis. Prospective randomized trials of lowering homocysteine levels with supplements of folic acid, vitamin B_{12}, and vitamin B_6 against placebo over a 5-year period in patients with vascular disease or diabetes have not, however, shown a reduction of first event fatal or nonfatal myocardial infarction, nor have these supplements reduced the risk of recurrent cardiovascular disease after an acute myocardial infarct. Meta-analysis showed an 18% reduction in strokes. The benefit for stroke prevention has been confirmed by a large (>20,000 subjects) randomized prospective study in hypertensive subjects in China. This showed a significant reduction in the first incidence of stroke in subjects receiving enalapril and folic acid compared to enalapril alone. This was especially marked in the subjects commencing the prospective trial with the lowest serum folate levels. Venous thrombosis has been reported to be more frequent in folate– or vitamin B_{12}– deficient subjects than in controls and to occur at unusual sites such as cerebral venous sinuses. This was ascribed to raised plasma homocysteine levels in folate or vitamin B_{12} deficiency.

Malignancy Prophylactic folic acid in pregnancy has been found in some but not all studies to reduce the subsequent incidence of acute lymphoblastic leukemia (ALL) in childhood. A significant negative association has also been found with the *MTHFR* C677T polymorphism and leukemias with mixed lineage leukemia (MLL) translocations, but a positive association with hyperdiploidy in infants with ALL or acute myeloid leukemia or with childhood ALL. A second polymorphism in the *MTHFR* gene, A1298C, is also strongly associated with hyperdiploid leukemia. There are various positive and negative associations between polymorphisms in folate-dependent enzymes and the incidence of adult ALL. The C677T polymorphism is thought to lead to increased thymidine pools and "better quality" of DNA synthesis by shunting one-carbon groups toward thymidine and purine synthesis. This may explain its reported association with a lower risk for colorectal cancer. Most but not all studies suggest that prophylactic folic acid also protects against colon adenomas. Other tumors that have been associated with folate polymorphisms or status include follicular lymphoma, breast cancer, and gastric cancer. A meta-analysis of 50,000 individuals given folic acid (0.5–40 mg daily) or placebo in cardiovascular or colon adenoma prevention trials found that folic acid supplementation did not significantly increase or decrease the overall incidence of cancer or of any site-specific cancer during a weighted average scheduled treatment duration of 5.7 years. Because folic acid may "feed" tumors, it probably should be avoided in those with established tumors unless there is severe megaloblastic anemia due to folate deficiency.

HEMATOLOGIC FINDINGS

PERIPHERAL BLOOD

Oval macrocytes, usually with considerable anisocytosis and poikilocytosis, are the main feature **(Fig. 95-2*A*)**. The MCV is usually >100 fL unless a cause of microcytosis (e.g., iron deficiency or thalassemia trait) is present. Some of the neutrophils are hypersegmented (more than five nuclear lobes). There may be leukopenia due to a reduction in granulocytes and lymphocytes, but this is usually $>1.5 \times 10^9$/L; the platelet count may be moderately reduced, rarely to $<40 \times 10^9$/L. The severity of all these changes parallels the degree of anemia. In a nonanemic patient, the presence of a few macrocytes and hypersegmented neutrophils in the peripheral blood may be the only indication of the underlying disorder.

BONE MARROW

In a severely anemic patient, the marrow is hypercellular with an accumulation of primitive cells due to selective death by apoptosis of more mature forms. The erythroblast nucleus maintains a primitive appearance despite maturation and hemoglobinization of the cytoplasm. The cells are larger than normoblasts, and an increased number of cells with eccentric lobulated nuclei or nuclear fragments may be present **(Fig. 95-2*B*)**. Giant and abnormally shaped metamyelocytes and enlarged hyperpolyploid megakaryocytes are characteristic. In severe cases, the accumulation of primitive cells may mimic acute myeloid leukemia, whereas in less anemic patients, the changes in the marrow may be difficult to recognize. The terms *intermediate*, *mild*, and *early* have been used. The term *megaloblastoid* does not mean mildly megaloblastic. It is used to describe cells with both immature-appearing nuclei and defective hemoglobinization and is usually seen in myelodysplasia.

CHROMOSOMES

Bone marrow cells, transformed lymphocytes, and other proliferating cells in the body show a variety of changes, including random breaks, reduced contraction, spreading of the centromere, and exaggeration of secondary chromosomal constrictions and overprominent satellites.

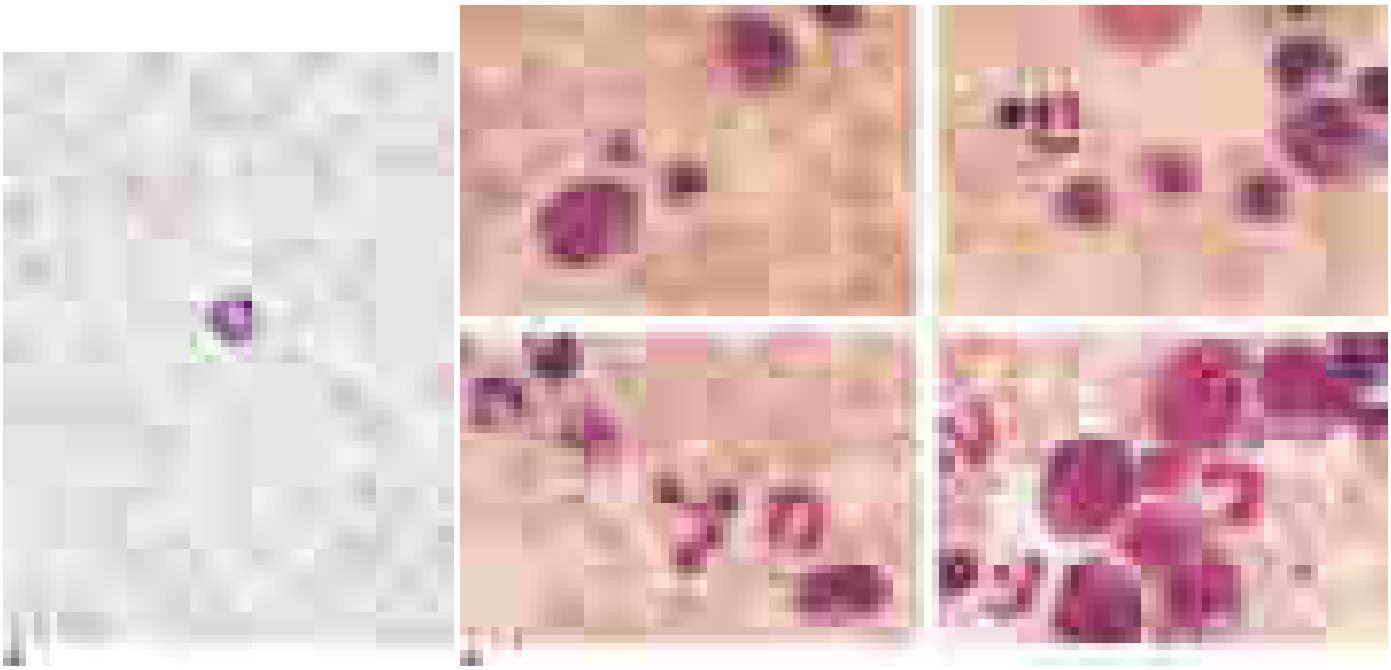

FIGURE 95-2 ***A.*** The peripheral blood in severe megaloblastic anemia. ***B.*** The bone marrow in severe megaloblastic anemia. *(Reprinted from AV Hoffbrand et al [eds]: Postgraduate Haematology, 5th ed. Oxford, UK, Blackwell Publishing, 2005; with permission.)*

Similar abnormalities may be produced by antimetabolite drugs (e.g., cytosine arabinoside, hydroxyurea, and methotrexate) that interfere with either DNA replication or folate metabolism and that also cause megaloblastic appearances.

INEFFECTIVE HEMATOPOIESIS

There is an accumulation of unconjugated bilirubin in plasma due to the death of nucleated red cells in the marrow (ineffective erythropoiesis). Other evidence for this includes raised urine urobilinogen, reduced haptoglobins and positive urine hemosiderin, and a raised serum lactate dehydrogenase. A weakly positive direct antiglobulin test due to complement can lead to a false diagnosis of autoimmune hemolytic anemia.

CAUSES OF COBALAMIN DEFICIENCY

Cobalamin deficiency is usually due to malabsorption. The only other cause is inadequate dietary intake.

INADEQUATE DIETARY INTAKE

Adults Dietary cobalamin deficiency arises in vegans who omit meat, fish, eggs, cheese, and other animal products from their diet. The largest group in the world consists of Hindus, and it is likely that many millions of Indians are at risk of deficiency of cobalamin on a nutritional basis. Subnormal serum cobalamin levels are found in up to 50% of randomly selected, young, adult Indian vegans, but the deficiency usually does not progress to megaloblastic anemia since the diet of most vegans is not totally lacking in cobalamin and the enterohepatic circulation of cobalamin is intact. Dietary cobalamin deficiency may also arise rarely in non-vegetarian individuals who exist on grossly inadequate diets because of poverty or psychiatric disturbance.

Infants Cobalamin deficiency has been described in infants born to severely cobalamin-deficient mothers. These infants develop megaloblastic anemia at about 3–6 months of age, presumably because they are born with low stores of cobalamin and because they are fed breast milk with low cobalamin content. The babies have also shown growth retardation, impaired psychomotor development, and other neurologic sequelae. MRI shows delayed myelination and atrophy.

GASTRIC CAUSES OF COBALAMIN MALABSORPTION

See Tables 95-3 and 95-4.

Formerly, the pathogenesis of B_{12} malabsorption was distinguishable based on the results of a Schilling test in which a radioactive form of B_{12} was administered orally and its appearance in the urine was a sign of absorption. Radioactive B_{12} is no longer available, and Schilling tests are no longer performed. Other approaches to the differential diagnosis of B_{12} malabsorption are now employed.

Pernicious Anemia PA may be defined as a severe lack of IF due to gastric atrophy. It is a common disease in northern Europeans but occurs in all countries and ethnic groups. It is more frequent in people of African than Asian ancestry. The overall incidence is about 120 per 100,000 population in the United Kingdom (UK). The ratio of incidence in men and women among whites is ~1:1.6, and the median age of onset is 70–80 years, with only 10% of patients being <40 years of age. However, in some ethnic groups, notably black individuals and Latin Americans, the age at onset of PA is generally lower. The disease occurs more commonly than by chance in close relatives and in persons with other organ-specific autoimmune diseases, for example, thyroid diseases, vitiligo, hypoparathyroidism, Type 1 diabetes, and Addison's disease. It is also associated with hypogammaglobulinemia, with premature graying or blue eyes, and persons of blood group A. An association with human leukocyte antigen (HLA) 3 has been reported in some but not all series and, in those with endocrine disease, with HLA-B8, -B_{12}, and -BW15. Life expectancy is normal in women once regular

TABLE 95-3 Causes of Cobalamin Deficiency Sufficiently Severe to Cause Megaloblastic Anemia

NUTRITIONAL	VEGANS
Malabsorption	Pernicious anemia
Gastric causes	Congenital absence of intrinsic factor or functional abnormality
	Total or partial gastrectomy
Intestinal causes	Intestinal stagnant loop syndrome: jejunal diverticulosis, ileocolic fistula, anatomic blind loop, intestinal stricture, etc.
	Ileal resection and Crohn's disease
	Selective malabsorption with proteinuria
	Tropical sprue
	Transcobalamin II deficiency
	Fish tapeworm

TABLE 95-4 Malabsorption of Cobalamin May Occur in the Following Conditions but Is Not Usually Sufficiently Severe and Prolonged to Cause Megaloblastic Anemia

Gastric causes
Simple atrophic gastritis (food cobalamin malabsorption)
Zollinger-Ellison syndrome
Gastric bypass or bariatric surgery
Use of proton pump inhibitors
Intestinal causes
Gluten-induced enteropathy
Severe pancreatitis
HIV infection
Radiotherapy
Graft-versus-host disease
Deficiencies of cobalamin, folate, protein, ?riboflavin, ?nicotinic acid
Therapy with colchicine, para-aminosalicylate, neomycin, slow-release potassium chloride, anticonvulsant drugs,?metformin*, cytotoxic drugs
Alcohol

*It is now thought that metformin lowers serum vitamin B_{12} level by lowering the level of TC I.

treatment has begun. Men had a slightly subnormal life expectancy as a result of a higher incidence of carcinoma of the stomach than in control subjects, but current data on their life expectancy are unavailable. Gastric output of hydrochloric acid, pepsin, and IF is severely reduced. The serum gastrin level is raised, and serum pepsinogen I levels are low.

Gastric Biopsy A single endoscopic examination is recommended if PA is diagnosed. Gastric biopsy usually shows atrophy of all layers of the body and fundus, with loss of glandular elements, an absence of parietal and chief cells and replacement by mucous cells, a mixed inflammatory cell infiltrate, and perhaps intestinal metaplasia. The infiltrate of plasma cells and lymphocytes contains an excess of CD4 cells. These are directed against gastric H/K-ATPase. The antral mucosa is usually well preserved. *Helicobacter pylori* infection occurs infrequently in PA, but it has been suggested that *H. pylori* gastritis occurs at an early phase of atrophic gastritis and presents in younger patients as iron-deficiency anemia but in older patients as PA. *H. pylori* is suggested to stimulate an autoimmune process directed against parietal cells, with the *H. pylori* infection then being gradually replaced, in some individuals, by an autoimmune process.

Serum Antibodies Two types of IF immunoglobulin G antibody may be found in the sera of patients with PA. One, the "blocking," or type I, antibody, prevents the combination of IF and cobalamin, whereas the "binding," or type II, antibody prevents attachment of IF to ileal mucosa. Type I occurs in the sera of ~55% of patients, and type II in 35%. IF antibodies cross the placenta and may cause temporary IF deficiency in a newborn infant. Patients with PA also show cell-mediated immunity to IF. Type I antibody has been detected rarely in the sera of patients without PA but with thyrotoxicosis, myxedema, Hashimoto's disease, or diabetes mellitus and in relatives of PA patients. IF antibodies also have been detected in gastric juice in ~80% of PA patients. These gastric antibodies may reduce absorption of dietary cobalamin by combining with small amounts of remaining IF.

Parietal cell antibody is present in the sera of almost 90% of adult patients with PA but is frequently present in other subjects. Thus, it occurs in as many as 16% of randomly selected female subjects age >60 years. The parietal cell antibody is directed against the α and β subunits of the gastric proton pump (H^+, K^+-ATPase).

JUVENILE PERNICIOUS ANEMIA

This usually occurs in older children and resembles PA of adults. Gastric atrophy, achlorhydria, and serum IF antibodies are all present, although parietal cell antibodies are usually absent. About one-half of these patients show an associated endocrinopathy such as autoimmune thyroiditis, Addison's disease, or hypoparathyroidism; in some, mucocutaneous candidiasis occurs.

CONGENITAL INTRINSIC FACTOR DEFICIENCY OR FUNCTIONAL ABNORMALITY

An affected child usually presents with megaloblastic anemia in the first to third year of life; a few have presented as late as the second decade. The child usually has no demonstrable IF but has a normal gastric mucosa and normal secretion of acid. The inheritance is autosomal recessive. Parietal cell and IF antibodies are absent. Variants have been described in which the child is born with IF that can be detected immunologically but is unstable or functionally inactive, unable to bind cobalamin or to facilitate its uptake by ileal receptors.

GASTRECTOMY

After total gastrectomy, cobalamin deficiency is inevitable, and prophylactic cobalamin therapy should be commenced immediately after the operation. After partial gastrectomy, 10–15% of patients also develop this deficiency. The exact incidence and time of onset are most influenced by the size of the resection and the preexisting size of cobalamin body stores.

FOOD COBALAMIN MALABSORPTION

Failure of release of cobalamin from binding proteins in food is believed to be responsible for this condition, which is more common in the elderly. It is associated with low serum cobalamin levels, with or without raised serum levels of MMA and homocysteine. Typically, these patients have normal cobalamin absorption, as measured with crystalline cobalamin, but show malabsorption when a modified test using food-bound cobalamin is used. It is usually due to mild forms of atrophic gastritis or therapy with proton pump inhibitors. Bariatric surgery is likely to be an increasing cause of this form of B_{12} malabsorption and deficiency. The frequency of progression to severe cobalamin deficiency and the reasons for this progression are not clear.

INTESTINAL CAUSES OF COBALAMIN MALABSORPTION

Intestinal Stagnant Loop Syndrome Malabsorption of cobalamin occurs in a variety of intestinal lesions in which there is colonization of the upper small intestine by fecal organisms. This may occur in patients with jejunal diverticulosis, enteroanastomosis, or an intestinal stricture or fistula or with an anatomic blind loop due to Crohn's disease, tuberculosis, or an operative procedure.

Ileal Resection Removal of ≥1.2 m of terminal ileum causes malabsorption of cobalamin. In some patients after ileal resection, particularly if the ileocecal valve is incompetent, colonic bacteria may contribute further to the onset of cobalamin deficiency.

Selective Malabsorption of Cobalamin with Proteinuria (Imerslund's Syndrome; Imerslund-Gräsbeck Syndrome; Congenital Cobalamin Malabsorption; Autosomal Recessive Megaloblastic Anemia; MGA1) This autosomally recessive disease is the most common cause of megaloblastic anemia due to cobalamin deficiency in infancy in Western countries. More than 200 cases have been reported with familial clusters in Finland, Norway, the Middle East, and North Africa. The patients secrete normal amounts of IF and gastric acid but are unable to absorb cobalamin. In Finland, impaired synthesis, processing, or ligand binding of cubilin due to inherited mutations is found. In Norway, mutation of the gene for *AMN* has been reported. Other tests of intestinal absorption are normal. Over 90% of these patients show nonspecific proteinuria, but renal function is otherwise normal, and renal biopsy has not shown any consistent renal defect. A few have shown aminoaciduria and congenital renal abnormalities, such as duplication of the renal pelvis.

Tropical Sprue Nearly all patients with acute and subacute tropical sprue show malabsorption of cobalamin; this may persist as the principal abnormality in the chronic form of the disease, when the patient may present with megaloblastic anemia or neuropathy due to cobalamin deficiency. Absorption of cobalamin usually improves after antibiotic therapy and, in the early stages, folic acid therapy.

Fish Tapeworm Infestation The fish tapeworm (*Diphyllobothrium latum*) lives in the small intestine of humans and accumulates cobalamin from food, rendering the cobalamin unavailable for absorption. Individuals acquire the worm by eating raw or partly cooked fish. Infestation is common around the lakes of Scandinavia, Germany, Japan, North America, and Russia. Megaloblastic anemia or cobalamin neuropathy occurs only in those with a heavy infestation.

Gluten-Induced Enteropathy Malabsorption of cobalamin occurs in ~30% of untreated patients (presumably those in whom the disease extends to the ileum). Cobalamin deficiency is not severe in these patients and is corrected with a gluten-free diet.

Severe Chronic Pancreatitis In this condition, lack of trypsin is thought to cause dietary cobalamin attached to gastric non-IF (R) binder to be unavailable for absorption. It also has been proposed that in pancreatitis, the concentration of calcium ions in the ileum falls below the level needed to maintain normal cobalamin absorption.

HIV Infection Serum cobalamin levels tend to fall in patients with HIV infection and are subnormal in 10–35% of those with AIDS. Malabsorption of cobalamin not corrected by IF has been shown in some, but not all, patients with subnormal serum cobalamin levels. Cobalamin deficiency sufficiently severe to cause megaloblastic anemia or neuropathy is rare.

Zollinger-Ellison Syndrome Malabsorption of cobalamin has been reported in the Zollinger-Ellison syndrome. It is thought that there is a failure to release cobalamin from R-binding protein due to inactivation of pancreatic trypsin by high acidity, as well as interference with IF binding of cobalamin.

Radiotherapy Both total-body irradiation and local radiotherapy to the ileum (e.g., as a complication of radiotherapy for carcinoma of the cervix) may cause malabsorption of cobalamin.

Graft-versus-Host Disease This commonly affects the small intestine. Malabsorption of cobalamin due to abnormal gut flora, as well as damage to ileal mucosa, is common.

Drugs The drugs that have been reported to cause malabsorption of cobalamin are listed in Table 95-4. However, megaloblastic anemia due to these drugs is rare. It has been suggested that metformin lowers serum B_{12} by lowering TC I level rather than causing malabsorption of B_{12}.

ABNORMALITIES OF COBALAMIN METABOLISM

Congenital Transcobalamin II Deficiency or Abnormality Infants with TC II deficiency usually present with megaloblastic anemia within a few weeks of birth. Serum cobalamin and folate levels are normal, but the anemia responds to massive (e.g., 1 mg three times weekly) injections of cobalamin. Some cases show neurologic complications. The protein may be present but functionally inert. Genetic abnormalities found include mutations of an intra-exonic cryptic splice site, extensive deletion, single nucleotide deletion, nonsense mutation, and an RNA editing defect. Malabsorption of cobalamin occurs in all cases, and serum immunoglobulins are usually reduced. Failure to institute adequate cobalamin therapy or treatment with folic acid may lead to neurologic damage.

Congenital Methylmalonic Acidemia and Aciduria Infants with this abnormality are ill from birth with vomiting, failure to thrive, severe metabolic acidosis, ketosis, and mental retardation. Anemia, if present, is normocytic and normoblastic. The condition may be due to a functional defect in either mitochondrial methylmalonyl-CoA mutase or its cofactor adocobalamin. Mutations in the methylmalonyl-CoA mutase are not responsive, or only poorly responsive, to treatment with cobalamin. A proportion of infants with failure of adocobalamin synthesis respond to cobalamin in large doses. Some children have combined methylmalonic aciduria and homocystinuria due to defective formation of both cobalamin coenzymes. This usually presents in the first year of life with feeding difficulties, developmental delay, microcephaly, seizures, hypotonia, and megaloblastic anemia.

Acquired Abnormality of Cobalamin Metabolism: Nitrous Oxide Inhalation Nitrous oxide (N_2O) irreversibly oxidizes methylcobalamin to an inactive precursor; this inactivates methionine synthase. Megaloblastic anemia has occurred in patients undergoing prolonged N_2O anesthesia (e.g., in intensive care units). A neuropathy resembling cobalamin neuropathy has been described in dentists and anesthetists who are exposed repeatedly to N_2O. Methylmalonic aciduria does not occur as adocobalamin is not inactivated by N_2O.

CAUSES OF FOLATE DEFICIENCY
(Table 95-5)

NUTRITIONAL
Dietary folate deficiency is common. Indeed, in most patients with folate deficiency a nutritional element is present. Certain individuals are particularly prone to have diets containing inadequate amounts of folate (Table 95-5). In the United States and other countries where fortification of the diet with folic acid has been adopted, the prevalence of folate deficiency has dropped dramatically and is now almost restricted to high-risk groups with increased folate needs. Nutritional folate deficiency occurs in kwashiorkor and scurvy and in infants with repeated infections or those who are fed solely on goats' milk, which has a low folate content.

MALABSORPTION
Malabsorption of dietary folate occurs in tropical sprue and in gluten-induced enteropathy. In the rare congenital recessive syndrome of selective malabsorption of folate due to mutation of the PCFT, there is an associated defect of folate transport into the cerebrospinal fluid, and these patients show megaloblastic anemia, which responds to

TABLE 95-5 Causes of Folate Deficiency

Dietary[a]
Particularly in: old age, infancy, poverty, alcoholism, chronic invalids, and the psychiatrically disturbed; may be associated with scurvy or kwashiorkor
Malabsorption
Major causes of deficiency
Tropical sprue, gluten-induced enteropathy in children and adults, and in association with dermatitis herpetiformis, specific malabsorption of folate, intestinal megaloblastosis caused by severe cobalamin or folate deficiency
Minor causes of deficiency
Extensive jejunal resection, Crohn's disease, partial gastrectomy, congestive heart failure, Whipple's disease, scleroderma, amyloid, diabetic enteropathy, systemic bacterial infection, lymphoma, sulfasalazine (Salazopyrin)
Excess utilization or loss
Physiologic
Pregnancy and lactation, prematurity
Pathologic
Hematologic diseases: chronic hemolytic anemias, sickle cell anemia, thalassemia major, myelofibrosis
Malignant diseases: carcinoma, lymphoma, leukemia, myeloma
Inflammatory diseases: tuberculosis, Crohn's disease, psoriasis, exfoliative dermatitis, malaria
Metabolic disease: homocystinuria
Excess urinary loss: congestive heart failure, active liver disease
Hemodialysis, peritoneal dialysis
Antifolate drugs[b]
Anticonvulsant drugs (phenytoin, primidone, barbiturates), sulfasalazine
Nitrofurantoin, tetracycline, antituberculosis (less well documented)
Mixed causes
Liver diseases, alcoholism, intensive care units

[a]In severely folate-deficient patients with causes other than those listed under Dietary, poor dietary intake is often present. [b]Drugs inhibiting dihydrofolate reductase are discussed in the text.

physiologic doses of folic acid given parenterally but not orally. They also show mental retardation, convulsions, and other central nervous system abnormalities. Minor degrees of malabsorption may also occur after jejunal resection or partial gastrectomy, in Crohn's disease, and in systemic infections, but in these conditions, if severe deficiency occurs, it is usually largely due to poor nutrition. Malabsorption of folate has been described in patients receiving sulfasalazine (Salazopyrin), cholestyramine, and triamterene.

EXCESS UTILIZATION OR LOSS

Pregnancy Folate requirements are increased by 200–300 µg to ~400 µg daily in a normal pregnancy, partly because of transfer of the vitamin to the fetus but mainly because of increased folate catabolism due to cleavage of folate coenzymes in rapidly proliferating tissues. Megaloblastic anemia due to this deficiency is prevented by prophylactic folic acid therapy. It occurred in 0.5% of pregnancies in the UK and other Western countries before prophylaxis with folic acid, but the incidence is much higher in countries where the general nutritional status is poor.

Prematurity A newborn infant, whether full term or premature, has higher serum and red cell folate concentrations than does an adult. However, a newborn infant's demand for folate has been estimated to be up to 10 times that of adults on a weight basis, and the neonatal folate level falls rapidly to the lowest values at about 6 weeks of age. The falls are steepest and are liable to reach subnormal levels in premature babies, a number of whom develop megaloblastic anemia responsive to folic acid at about 4–6 weeks of age. This occurs particularly in the smallest babies (<1500 g birth weight) and those who have feeding difficulties or infections or have undergone multiple exchange transfusions. In these babies, prophylactic folic acid should be given.

Hematologic Disorders Folate deficiency frequently occurs in chronic hemolytic anemia, particularly in sickle cell disease, autoimmune hemolytic anemia, and congenital spherocytosis. In these and other conditions of increased cell turnover (e.g., myelofibrosis, malignancies), folate deficiency arises because it is not completely reutilized after performing coenzyme functions.

Inflammatory Conditions Chronic inflammatory diseases such as tuberculosis, rheumatoid arthritis, Crohn's disease, psoriasis, exfoliative dermatitis, bacterial endocarditis, and chronic bacterial infections cause deficiency by reducing the appetite and increasing the demand for folate. Systemic infections also may cause malabsorption of folate. Severe deficiency is virtually confined to the patients with the most active disease and the poorest diet.

Homocystinuria This is a rare metabolic defect in the conversion of homocysteine to cystathionine. Folate deficiency occurring in most of these patients may be due to excessive utilization because of compensatory increased conversion of homocysteine to methionine.

Long-Term Dialysis Because folate is only loosely bound to plasma proteins, it is easily removed from plasma by dialysis. In patients with anorexia, vomiting, infections, and hemolysis, folate stores are particularly likely to become depleted. Routine folate prophylaxis is now given.

Congestive Heart Failure, Liver Disease Excess urinary folate losses of >100 µg per day may occur in some of these patients. The explanation appears to be release of folate from damaged liver cells.

ANTIFOLATE DRUGS

A large number of epileptics who are receiving long-term therapy with phenytoin or primidone, with or without barbiturates, develop low serum and red cell folate levels. The exact mechanism is unclear. Alcohol may also be a folate antagonist, as patients who are drinking spirits may develop megaloblastic anemia that will respond to normal quantities of dietary folate or to physiologic doses of folic acid only if alcohol is withdrawn. Macrocytosis of red cells is associated with chronic alcohol intake even when folate levels are normal. Inadequate folate intake is the major factor in the development of deficiency in spirit-drinking alcoholics. Beer is relatively folate-rich in some countries, depending on the technique used for brewing.

The drugs that inhibit DHF reductase include methotrexate, pyrimethamine, and trimethoprim. Methotrexate has the most powerful action against the human enzyme, whereas trimethoprim is most active against the bacterial enzyme and is likely to cause megaloblastic anemia only when used in conjunction with sulfamethoxazole in patients with preexisting folate or cobalamin deficiency. The activity of pyrimethamine is intermediate. The antidote to these drugs is folinic acid (5-formyl-THF).

CONGENITAL ABNORMALITIES OF FOLATE METABOLISM

Some infants with congenital defects of folate enzymes (e.g., cyclohydrolase or methionine synthase) have had megaloblastic anemia.

DIAGNOSIS OF COBALAMIN AND FOLATE DEFICIENCIES

The diagnosis of cobalamin or folate deficiency has traditionally depended on the recognition of the relevant abnormalities in the peripheral blood and analysis of the blood levels of the vitamins.

COBALAMIN DEFICIENCY

Serum Cobalamin This is measured by an automated enzyme-linked immunosorbent assay (ELISA) or competitive-binding luminescence assay (CBLA). Normal serum levels range from 118–148 pmol/L (160–200 ng/L) to ~738 pmol/L (1000 ng/L). In patients with megaloblastic anemia due to cobalamin deficiency, the level is usually <74 pmol/L (100 ng/L). In general, the more severe the deficiency, the lower is the serum cobalamin level. In patients with spinal cord damage due to the deficiency, levels are very low even in the absence of anemia. Values between 74 and 148 pmol/L (100 and 200 ng/L) are regarded as borderline. They may occur, for instance, in pregnancy, in patients with megaloblastic anemia due to folate deficiency. They may also be due to heterozygous, homozygous, or compound heterozygous mutations of the gene *TCN1* that codes for HC (transcobalamin I). There is then no clinical or hematologic abnormality. The serum cobalamin level is sufficiently robust, cost-effective, and most convenient to rule out cobalamin deficiency in the vast majority of patients suspected of having this problem. However, problems have arisen with commercial CBLA assays involving IF in PA patients with intrinsic antibodies in serum. These antibodies may cause false normal serum vitamin B_{12} levels in up to 50% of cases tested. Where clinical indications of PA are strong, a normal serum vitamin B_{12} does not rule out the diagnosis. Serum MMA levels will be elevated in untreated PA (see below).

Folate deficiency, transcobalamin 1 (HC) deficiency, oral contraceptives, and multiple myeloma have all been associated with low serum B_{12} levels that do not indicate B_{12} deficiency. On the other hand, high serum B_{12} levels are usually due to raised serum transcobalamin 1 levels and can be due to the presence of liver, renal, or myeloproliferative diseases or to cancer of the breast, colon, or liver.

Serum Methylmalonate and Homocysteine In patients with cobalamin deficiency sufficient to cause anemia or neuropathy, the serum MMA level is raised. Sensitive methods for measuring MMA and homocysteine in serum have been introduced and recommended for the early diagnosis of cobalamin deficiency, even in the absence of hematologic abnormalities or subnormal levels of serum cobalamin. Serum MMA levels fluctuate, however, in patients with renal failure. Mildly elevated serum MMA and/or homocysteine levels occur in up to 30% of apparently healthy volunteers, with serum cobalamin levels up to 258 pmol/L (350 ng/L) and normal serum folate levels; 15% of elderly subjects, even with cobalamin levels >258 pmol/L (>350 ng/L), have this pattern of raised metabolite levels. These findings bring into question the exact cutoff points for normal MMA and homocysteine levels. It is also unclear at present whether these mildly raised metabolite levels have clinical consequences.

Serum homocysteine is raised in both early cobalamin and folate deficiency but may be raised in other conditions, for example, chronic renal disease, alcoholism, smoking, pyridoxine deficiency, hypothyroidism, and therapy with steroids, cyclosporine, and other drugs. Levels are also higher in serum than in plasma, in men than in premenopausal women, in women taking hormone replacement therapy or in oral contraceptive users, and in elderly persons and patients with several inborn errors of metabolism affecting enzymes in transsulfuration pathways of homocysteine metabolism. Thus, homocysteine levels must be carefully interpreted for diagnosis of cobalamin or folate deficiency.

Tests for the Cause of Cobalamin Deficiency Only vegans, strict vegetarians, or people living on a totally inadequate diet will become vitamin B_{12} deficient because of inadequate intake. Studies of cobalamin absorption once were widely used, but difficulty in obtaining radioactive cobalamin and ensuring that IF preparations are free of viruses has made these tests obsolete. Tests to diagnose PA include serum gastrin, which is raised; serum pepsinogen I, which is low in PA (90–92%) but also in other conditions; and gastric endoscopy. Tests for IF and parietal cell antibodies are also used, as well as tests for individual intestinal diseases.

FOLATE DEFICIENCY

Serum Folate This is also measured by an ELISA technique. In most laboratories, the normal range is from 11 nmol/L (2 µg/L) to ~82 nmol/L (15 µg/L). The serum folate level is low in all folate-deficient patients. It also reflects recent diet. Because of this, serum folate may be low before there is hematologic or biochemical evidence of deficiency. Serum folate rises in severe cobalamin deficiency because of the block in conversion of MTHF to THF inside cells; raised levels have also been reported in the intestinal stagnant loop syndrome due to absorption of bacterially synthesized folate.

Red Cell Folate The red cell folate assay is a valuable test of body folate stores. It is less affected than the serum assay by recent diet and traces of hemolysis. In normal adults, concentrations range from 880 to 3520 µmol/L (160–640 µg/L) of packed red cells. Subnormal levels occur in patients with megaloblastic anemia due to folate deficiency but also in nearly two-thirds of patients with severe cobalamin deficiency. False-normal results may occur if a folate-deficient patient has received a recent blood transfusion or if a patient has a raised reticulocyte count. Serum homocysteine assay is discussed earlier.

Tests for the Cause of Folate Deficiency The diet history is important. Tests for transglutaminase antibodies are performed to confirm or exclude celiac disease. If positive, duodenal biopsy is needed. An underlying disease causing increased folate breakdown should also be excluded.

TREATMENT

Cobalamin and Folate Deficiency

It is usually possible to establish which of the two deficiencies, folate or cobalamin, is the cause of the anemia and to treat only with the appropriate vitamin. In patients who enter the hospital severely ill, however, it may be necessary to treat with both vitamins in large doses once blood samples have been taken for cobalamin and folate assays and a bone marrow biopsy has been performed (if deemed necessary). Transfusion is usually unnecessary and inadvisable. If it is essential, packed red cells should be given slowly, one or two units only, with the usual treatment for heart failure if present. Potassium supplements have been recommended to obviate the danger of the hypokalemia but are not necessary. Occasionally, an excessive rise in platelets occurs after 1–2 weeks of therapy. Antiplatelet therapy, for example, aspirin, should be considered if the platelet count rises to $>800 \times 10^9$/L.

COBALAMIN DEFICIENCY

It is usually necessary to treat patients who have developed cobalamin deficiency with lifelong regular cobalamin injections. In the UK, the form used is hydroxocobalamin; in the United States, cyanocobalamin. In a few instances, the underlying cause of cobalamin deficiency can be permanently corrected, for example, fish tapeworm, tropical sprue, or an intestinal stagnant loop that is amenable to surgery. The indications for starting cobalamin therapy are a well-documented megaloblastic anemia or other hematologic abnormalities and neuropathy due to the deficiency. Patients with borderline serum cobalamin levels but no hematologic or other abnormality may be followed to make sure that the cobalamin deficiency does not progress (see below). If malabsorption of cobalamin or rises in serum MMA levels have been demonstrated, however, these patients also should be given regular maintenance cobalamin therapy. Cobalamin should be given routinely to all patients who have had a total gastrectomy or ileal resection. Patients who have undergone gastric reduction for control of obesity or who are receiving long-term treatment with proton pump inhibitors should be screened and, if necessary, given cobalamin replacement.

Replenishment of body stores should be complete with six 1000-µg IM injections of hydroxocobalamin given at 3- to 7-day intervals. More frequent doses are usually used in patients with cobalamin neuropathy, but there is no evidence that they produce a better response. Allergic reactions are rare and may require desensitization or antihistamine or glucocorticoid cover. For maintenance therapy, 1000 µg hydroxocobalamin IM once every 3 months is satisfactory. Because of the poorer retention of cyanocobalamin, protocols generally use higher and more frequent doses, for example, 1000 µg IM, monthly, for maintenance treatment.

Because a small fraction of cobalamin can be absorbed passively through mucous membranes even when there is complete failure of physiologic IF-dependent absorption, large daily oral doses (1000–2000 µg) of cyanocobalamin are used in PA for replacement (especially in Canada and Sweden) and maintenance of normal cobalamin status in, for example, food malabsorption of cobalamin. Sublingual therapy has also been proposed for those in whom injections are difficult because of a bleeding tendency and who may not tolerate oral therapy. If oral therapy is used, it is important to monitor compliance, particularly with elderly, forgetful patients. This author prefers parenteral therapy for initial treatment, particularly in severe anemia or if a neuropathy is present, and for maintenance in PA. Oral B_{12} therapy even with low doses of 50 µg daily may have a larger role in treating food malabsorption of B_{12}.

For treatment of patients with subnormal serum vitamin B_{12} levels with a normal MCV and no hypersegmentation of neutrophils, a negative IF antibody test in the absence of tests of B_{12} absorption is problematic. Some (perhaps 15%) cases may be due to TC I (HC) deficiency. Homocysteine and/or MMA measurements may help, but in the absence of these tests and with otherwise normal gastrointestinal function, repeat serum B_{12} assay after 6–12 months may help one decide whether to start cobalamin therapy.

Vitamin B_{12} injections are used in a wide variety of diseases, often neurologic, despite normal serum B_{12} and folate levels and a normal blood count and in the absence of randomized, double-blind, controlled trials. These conditions include multiple sclerosis and chronic fatigue syndrome/myalgic encephalomyelitis (ME). It seems probable that any benefit is due to the placebo effect of a usually painless, pink injection. In ME, oral B_{12} therapy, despite providing equally large amounts of B_{12}, has not been beneficial, supporting the view of the effect of the injections being placebo only.

FOLATE DEFICIENCY

Oral doses of 5–15 mg folic acid daily are satisfactory, as sufficient folate is absorbed from these extremely large doses even in patients with severe malabsorption. The length of time therapy must be continued depends on the underlying disease. It is customary to continue therapy for about 4 months, when all folate-deficient red cells will have been eliminated and replaced by new folate-replete populations.

Before large doses of folic acid are given, cobalamin deficiency must be excluded and, if present, corrected; otherwise cobalamin

neuropathy may develop despite a response of the anemia of cobalamin deficiency to folate therapy. Studies in the United States, however, suggest that there is no increase in the proportion of individuals with low serum cobalamin levels and no anemia since food fortification with folic acid, but it is unknown if there has been a change in incidence of cobalamin neuropathy.

Long-term folic acid therapy is required when the underlying cause of the deficiency cannot be corrected and the deficiency is likely to recur, for example, in chronic dialysis or hemolytic anemias. It may also be necessary in gluten-induced enteropathy that does not respond to a gluten-free diet. Where mild but chronic folate deficiency occurs, it is preferable to encourage improvement in the diet after correcting the deficiency with a short course of folic acid. In any patient receiving long-term folic acid therapy, it is important to measure the serum cobalamin level at regular (e.g., once-yearly) intervals to exclude the coincidental development of cobalamin deficiency.

Folinic Acid (5-Formyl-THF) This is a stable form of fully reduced folate. It is given orally or parenterally to overcome the toxic effects of methotrexate or other DHF reductase inhibitors, for example, trimethoprim or cotrimoxazole.

PROPHYLACTIC FOLIC ACID

Prophylactic folic acid is used in chronic dialysis patients and in parenteral feeds. Prophylactic folic acid has been used to reduce homocysteine levels to prevent cardiovascular disease and for cognitive function in the elderly, but there are no firm data to show any benefit.

Pregnancy In over 70 countries (but none in Europe), food is fortified with folic acid (in grain or flour) to reduce the risk of NTDs. Nevertheless, folic acid, 400 µg daily, should be given as a supplement before and throughout pregnancy to prevent megaloblastic anemia and reduce the incidence of NTDs, even in countries with fortification of the diet. The levels of fortification provide up to 400 µg daily on average in Chile, but in most countries, it is nearer to 200 µg, so periconceptual folic acid is still needed. Most if not all the folic acid used in fortification and eaten over three meals a day will be converted during absorption to methyltetrahydrofolate. This compound will not correct the anemia in B_{12} deficiency. Studies in early pregnancy show significant lack of compliance with the folic acid supplements, emphasizing the benefit of food fortification. Supplemental folic acid reduces the incidence of birth defects in babies born to diabetic mothers. In women who have had a previous fetus with an NTD, 5 mg daily is recommended when pregnancy is contemplated and throughout the subsequent pregnancy.

Infancy and Childhood The incidence of folate deficiency is so high in the smallest premature babies during the first 6 weeks of life that folic acid (e.g., 1 mg daily) should be given routinely to those weighing <1500 g at birth and to larger premature babies who require exchange transfusions or develop feeding difficulties, infections, or vomiting and diarrhea.

The World Health Organization currently recommends routine supplementation with iron and folic acid in children in countries where iron deficiency is common and child mortality, largely due to infectious diseases, is high. However, some studies suggest that in areas where malaria rates are high, this approach may increase the incidence of severe illness and death. Even where malaria is rare, there appears to be no survival benefit.

MEGALOBLASTIC ANEMIA NOT DUE TO COBALAMIN OR FOLATE DEFICIENCY OR ALTERED METABOLISM

This may occur with many antimetabolic drugs (e.g., hydroxyurea, cytosine arabinoside, 6-mercaptopurine) that inhibit DNA replication. Antiviral nucleoside analogues used in treatment of HIV infection may also cause macrocytosis and megaloblastic marrow changes. In the rare disease orotic aciduria, two consecutive enzymes in purine synthesis are defective. The condition responds to therapy with uridine, which bypasses the block. In thiamine-responsive megaloblastic anemia, there is a genetic defect in the high-affinity thiamine transport (*SLC19A2*) gene. This causes defective RNA ribose synthesis through impaired activity of transketolase, a thiamine-dependent enzyme in the pentose cycle. This leads to reduced nucleic acid production. It may be associated with diabetes mellitus and deafness and the presence of many ringed sideroblasts in the marrow. The explanation is unclear for megaloblastic changes in the marrow in some patients with acute myeloid leukemia and myelodysplasia.

96 Hemolytic Anemias

Lucio Luzzatto

DEFINITIONS

A finite life span is a distinct characteristic of red cells. Hence, a logical, time-honored classification of anemias is in three groups: (1) decreased production of red cells, (2) increased destruction of red cells, and (3) acute blood loss. Decreased production is covered in **Chaps. 93, 94, and 98**; acute blood loss in **Chap. 97**; increased destruction is covered in this chapter.

All patients who are anemic as a result of either increased destruction of red cells or acute blood loss have one important element in common: the anemia results from overconsumption of red cells from the peripheral blood, whereas the supply of cells from the bone marrow is normal (indeed, it is usually increased). On the other hand, these two groups differ in that the consequences of physical loss of red cells from the bloodstream or *from* the body itself, as in acute hemorrhage, is fundamentally different from destruction of red cells *within* the body, as in hemolytic anemias (HAs).

With respect to primary etiology, HAs may be *inherited* or *acquired*; from a clinical point of view, they may be more *acute* or more *chronic*, and they may vary from mild to very severe; the site of hemolysis may be predominantly *intravascular* or *extravascular*. With respect to mechanisms, HAs may be due to *intracorpuscular* causes or to *extracorpuscular* causes **(Table 96-1)**. But before reviewing the individual types of HA, it is appropriate to consider what general features they have in common, in terms of clinical aspects and of pathophysiology.

GENERAL CLINICAL AND LABORATORY FEATURES

The clinical presentation of a patient with anemia is greatly influenced in the first place by whether the onset is abrupt or gradual, and HAs are

TABLE 96-1 Classification of Hemolytic Anemias[a]

	INTRACORPUSCULAR DEFECTS	EXTRACORPUSCULAR FACTORS
Inherited	Hemoglobinopathies Enzymopathies Membrane-cytoskeletal defects	Familial (atypical) hemolytic-uremic syndrome
Acquired	Paroxysmal nocturnal hemoglobinuria (PNH)	Mechanical destruction (microangiopathic) Toxic agents Drugs Infectious Autoimmune

[a]Hereditary causes correlate with intracorpuscular defects because these defects are due to inherited mutations; the one exception is PNH because the defect is due to an acquired somatic mutation. Similarly, acquired causes correlate with extracorpuscular factors because mostly these factors are exogenous; the one exception is familial hemolytic-uremic syndrome (HUS; often referred to as atypical HUS) because here an inherited abnormality allows complement activation to be excessive, with bouts of production of membrane attack complex capable of destroying normal red cells. Interestingly, in both PNH and aHUS hemolysis is complement-mediated.

no exception. A patient with autoimmune HA or with favism may be a medical emergency, whereas a patient with mild hereditary spherocytosis (HS) or with cold agglutinin disease (CAD) may be diagnosed after years. This is due in large measure to the remarkable ability of the body to adapt to anemia when it is slowly progressing **(Chap. 59)**.

What differentiates HAs from other anemias is that the patient has signs and symptoms arising directly from hemolysis **(Table 96-2)**. At the clinical level, the main sign is *jaundice*; in addition, the patient may report discoloration of the urine. In many cases of HA, the spleen is enlarged because it is a preferential site of hemolysis; and in some cases, the liver may be enlarged as well. In all severe congenital forms of HA, there may be also skeletal changes due to overactivity of the bone marrow: they are never as severe as in thalassemia major because there is less ineffective erythropoiesis, or none at all.

The laboratory features of HA are related to (i) hemolysis per se, (ii) the erythropoietic response of the bone marrow. In most cases hemolysis is largely extravascular, and it produces an increase in unconjugated bilirubin and aspartate aminotransferase (AST) in the serum; urobilinogen will be increased in both urine and stool. If hemolysis is mainly intravascular, the telltale sign is hemoglobinuria (often associated with hemosiderinuria); in the serum there is free hemoglobin, lactate dehydrogenase (LDH) is increased, and haptoglobin is reduced. In contrast, the serum bilirubin level may be normal or only mildly elevated. The main sign of the erythropoietic response by the bone marrow is an increase in reticulocytes (a test all too often neglected in the initial workup of a patient with anemia). Usually the increase will be reflected in both the percentage of reticulocytes (the more commonly quoted figure) and in the absolute reticulocyte count (the more definitive parameter). The increased number of reticulocytes is associated with an increased mean corpuscular volume (MCV) in the blood count. On the blood smear, this is reflected in the presence of macrocytes; there is also polychromasia, and sometimes one sees nucleated red cells. In most cases, a bone marrow aspirate is not necessary in the diagnostic workup; if it is done, it will show erythroid hyperplasia. In practice, once an HA is suspected, specific tests will usually be required for a definitive diagnosis of a specific type of HA.

TABLE 96-2 Features Common to Most Patients with a Hemolytic Disorder

General examination	Jaundice, pallor
Other physical findings	Spleen may be enlarged; bossing of skull in severe congenital cases
Hemoglobin level	From normal to severely reduced
MCV, MCH	Usually increased
Reticulocytes	Usually Increased
Bilirubin	Almost always increased (mostly unconjugated)
LDH	Increased (up to 10× normal with intravascular hemolysis)
Haptoglobin	Reduced to absent if hemolysis is at least in part intravascular)

Abbreviations: LDH, lactate dehydrogenase; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume.

GENERAL PATHOPHYSIOLOGY

The mature red cell is the product of a developmental pathway that brings the phenomenon of differentiation to an extreme. An orderly sequence of events produces synchronous changes, whereby the gradual accumulation of a huge amount of hemoglobin in the cytoplasm (to a final level of 340 g/L, i.e., about 5 m*M*) goes hand in hand with the gradual loss of cellular organelles and of biosynthetic abilities. In the end, the erythroid cell undergoes a process that has features of apoptosis, including nuclear pyknosis and eventually extrusion of the nucleus. However, the final result is more altruistic than suicidal; the cytoplasmic body, instead of disintegrating, is now able to provide oxygen to all cells in the human organism for some remaining 120 days of the red cell life span.

As a result of this unique process of differentiation and maturation, intermediary metabolism is drastically curtailed in mature red cells **(Fig. 96-1)**; for instance, cytochrome-mediated oxidative

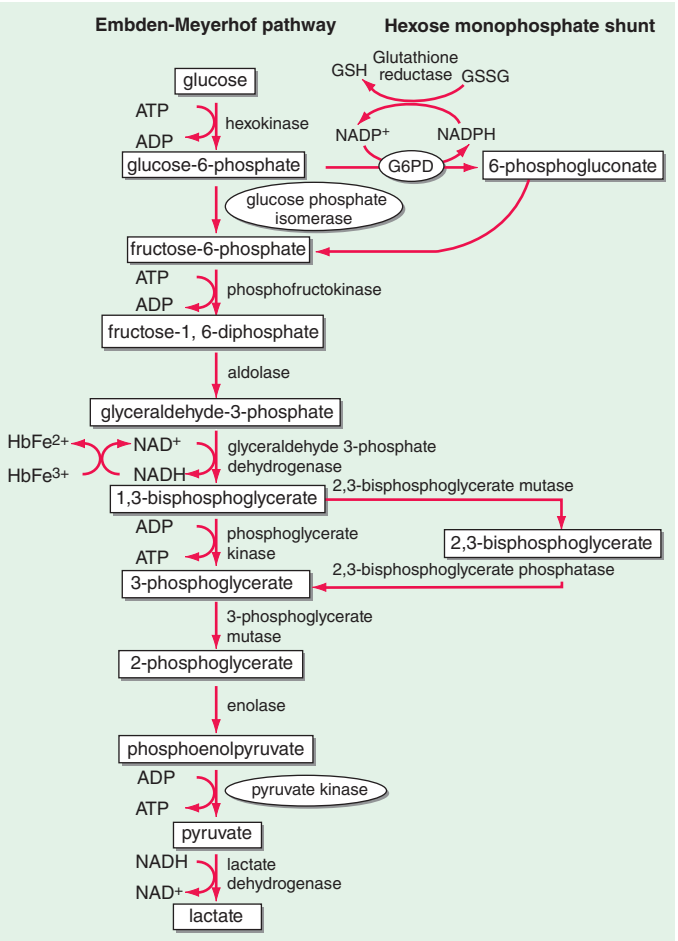

FIGURE 96-1 Red blood cell (RBC) metabolism. The Embden-Meyerhof pathway (glycolysis) generates ATP required for cation transport and for membrane maintenance. The generation of NADH maintains hemoglobin iron in a reduced state. The hexose monophosphate shunt generates NADPH that is used to reduce glutathione, which protects the red cell against oxidant stress; the 6-phosphogluconate, after decarboxylation, can be recycled via pentose sugars to glycolysis. Regulation of the 2,3-bisphosphoglycerate level is a critical determinant of oxygen affinity of hemoglobin. Enzyme deficiency states in order of prevalence: glucose 6-phosphate dehydrogenase (G6PD) > pyruvate kinase > glucose-6-phosphate isomerase > rare deficiencies of other enzymes in the pathway. The more common enzyme deficiencies are encircled.

phosphorylation has been lost with the loss of mitochondria (through a process of physiologic autophagy); therefore, there is no backup to anaerobic glycolysis, which in the red cell is the only provider of adenosine triphosphate (ATP). Also, the capacity of making protein has been lost with the loss of ribosomes. This places the cell's limited metabolic apparatus at risk, because if any protein component deteriorates, it cannot be replaced, as it would be in most other cells; and in fact the activity of most enzymes gradually decreases as red cells age. At the same time, during their long time in circulation, various red cell components inevitably accumulate damage; in senescent red cells, the membrane protein band 3 molecules (see below and Fig. 96-1), having bound hemichromes on their intracellular domains, tend to cluster. Now they bind anti–band 3 IgG antibodies (present in most people) and C3 complement fragments; thus they become opsonized and are eventually removed by phagocytosis in the reticuloendothelial system.

Another consequence of the relative simplicity of red cells is that they have a very limited range of ways to manifest distress under hardship; in essence, any sort of metabolic failure will eventually lead either to structural damage to the membrane or to failure of the cation pump. In either case, the life span of the red cell is reduced, which is the definition of a *hemolytic disorder*. If the rate of red cell destruction exceeds the capacity of the bone marrow to produce more red cells, the hemolytic disorder will manifest as HA.

Thus, the essential pathophysiologic process common to all HAs is an increased red cell turnover; and in many HAs, this is due at least in part to an acceleration of the senescence process described above. The gold standard for proving that the life span of red cells is reduced (compared to the normal value of about 120 days) is a *red cell survival* study, which can be carried out by labeling the red cells with ^{51}Cr and measuring the fall in radioactivity over several days or weeks (this classic test can now be replaced by a methodology using the nonradioactive isotope ^{15}N). If the hemolytic event is transient, it does not usually cause any long-term consequences, except for an increased requirement for erythropoietic factors, particularly folic acid. However, if hemolysis is recurrent or persistent, the increased bilirubin production favors the formation of gallstones. If a considerable proportion of hemolysis takes place in the spleen, as is often the case, splenomegaly may become increasingly a feature, and hypersplenism may develop, with consequent neutropenia and/or thrombocytopenia.

The increased red cell turnover also has metabolic consequences. In normal subjects, the iron from effete red cells is very efficiently recycled by the body; however, with chronic intravascular hemolysis, the persistent hemoglobinuria will cause considerable iron loss, needing replacement. With chronic extravascular hemolysis, the opposite problem, iron overload, is more common, especially if the patient needs frequent blood transfusions; however, if erythropoiesis is massively increased, the hepcidin-mediated regulation of iron absorption may be disturbed, to the extent that iron overload may set in even without blood transfusion. In the long run, in the absence of iron-chelation therapy iron overload will cause secondary hemochromatosis; this will cause damage particularly to the liver, eventually leading to cirrhosis; and to the heart muscle, eventually causing heart failure.

Compensated Hemolysis versus Hemolytic Anemia Red cell destruction is a potent stimulus for erythropoiesis, which is mediated by erythropoietin (EPO) produced by the kidney. This mechanism is so effective that in many cases the increased output of red cells from the bone marrow can fully balance an increased destruction of red cells. In such cases, we say that hemolysis is *compensated*. The pathophysiology of compensated hemolysis is similar to what we have just described, except there is no anemia. This notion is important from the diagnostic point of view, because a patient with a hemolytic condition, even an inherited one, may present without anemia; and it is also important from the point of view of management because compensated hemolysis may become "decompensated," i.e., anemia may suddenly appear in certain circumstances, for instance in pregnancy, folate deficiency, or renal failure interfering with adequate EPO production. Another general feature of chronic HAs is seen when any intercurrent condition, such as an acute infection, depresses erythropoiesis. When this happens, in view of the increased rate of red cell turnover, the effect will be predictably much more marked than in a person who does not have hemolysis. The most dramatic example is infection by parvovirus B19, which may cause a rather precipitous fall in hemoglobin—an occurrence sometimes referred to as *aplastic crisis*.

INHERITED HEMOLYTIC ANEMIAS

There are three essential components in the red cell: (1) hemoglobin, (2) the membrane-cytoskeleton complex, and (3) the metabolic machinery necessary to keep hemoglobin and the membrane-cytoskeleton complex in working order. Diseases caused by inherited abnormalities of hemoglobin, or hemoglobinopathies, are covered in **Chap. 94**. Here we will deal with diseases of the other two components.

Hemolytic Anemias due to Abnormalities of the Membrane-Cytoskeleton Complex The detailed architecture of the red cell membrane is complex, but its basic design is relatively simple **(Fig. 96-2)**. The lipid bilayer incorporates phospholipids and cholesterol, and it is spanned by a number of proteins that have their hydrophobic transmembrane domain(s) embedded in the membrane; most of these proteins also extend to both the outside (extracellular domains) and the inside of the cell (cytoplasmic domains). Other proteins are tethered to the membrane through a glycosylphosphatidylinositol (GPI) anchor; these have only an extracellular domain, and they include ion channels, receptors for complement components, and receptors for other ligands. The most abundant red cell membrane proteins are glycophorins and the so-called *band 3*, an anion transporter. The extracellular domains of many of these proteins are heavily glycosylated, and they carry antigenic determinants that correspond to blood groups. Underneath the membrane, and tangential to it, is a network of other proteins that make up the cytoskeleton. The main

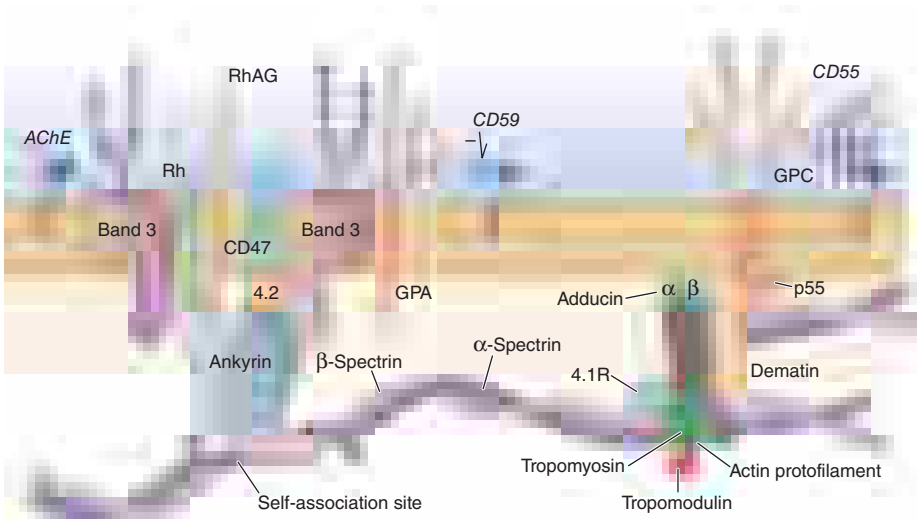

FIGURE 96-2 The red cell membrane. In this figure, one sees, within the lipid bilayer, several membrane proteins, of which band 3 (anion exchanger 1 [AE1]) is the most abundant; the α-β spectrin dimers that associate to form most of the cytoskeleton; and several proteins (e.g., ankyrin) that connect the membrane to the cytoskeleton. In addition, as examples of glycosylphosphatidylinositol (GPI)-linked proteins, one sees acetylcholinesterase (AChE) and the two complement-regulatory proteins CD59 and CD55. The (non-realistic) shapes of the protein moieties of the GPI-linked proteins are meant to indicate that each one of them is different from others and that, unlike with the other membrane proteins shown, the entire polypeptide chain is extracellular. Branched lines symbolize carbohydrate moiety of proteins. The molecules are obviously not drawn to the same scale. Additional explanations can be found in the text. *(From N Young et al: Clinical Hematology. Copyright Elsevier, 2006; with permission.)*

cytoskeletal protein is spectrin, the basic unit of which is a dimer of α-spectrin and β-spectrin. The membrane is physically linked to the cytoskeleton by a third set of proteins (including ankyrin and the so-called *band 4.1* and *band 4.2*), which thus make these two structures intimately connected to each other.

The membrane-cytoskeleton complex has essentially three functions: It is an envelope for the red cell cytoplasm, it maintains the normal red cells shape, it provides highly specific cross-membrane transport of electrolytes and of metabolites such as glucose. In the membrane-cytoskeleton complex the individual components are so intimately integrated with each other that an abnormality of almost any of them will be disturbing or disruptive, causing structural or functional failure, which results ultimately in hemolysis. These abnormalities are almost invariably inherited mutations; thus, diseases of the membrane-cytoskeleton complex belong to the category of inherited HAs. Before the red cells lyse, they often exhibit more or less specific morphologic changes that alter the normal biconcave disk shape. Thus, the majority of the diseases in this group have been known for over a century as hereditary spherocytosis (HS) and *hereditary elliptocytosis* (HE; as well as more rare ones like *stomatocytosis*, *xerocytosis*, etc). Now that their molecular basis has been elucidated, it has emerged **(see Table 96-3)** that, although we are dealing with monogenic disorders, there is no one-to-one correlation between a certain gene and a certain disorder. Rather, what has been regarded as a single disorder (e.g., HS) can arise through mutation of one of several genes; conversely, what have been regarded as different disorders can arise through different mutations of the very same gene **(Fig. 96-3)**.

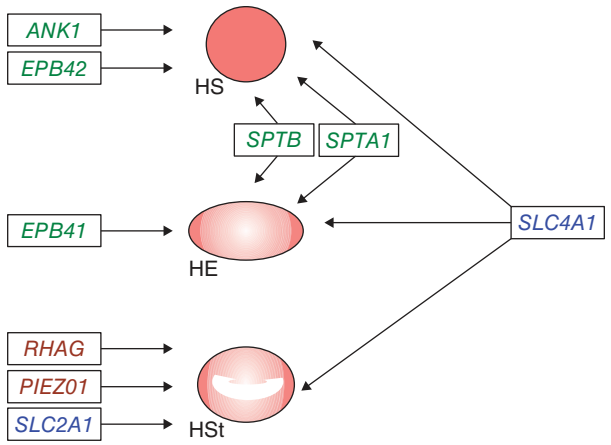

FIGURE 96-3 Hereditary spherocytosis (HS), hereditary elliptocytosis (HE), and hereditary stomatocytosis (HSt) are three morphologically distinct forms of congenital hemolytic anemia. It has emerged that each one can arise from mutation of one of several genes and that different mutations of the same gene can give one or another form. (See also Table 96-3.)

HEREDITARY SPHEROCYTOSIS This is a relatively common type of genetically determined HA, with an estimated frequency of at least 1 in 5000. Its identification is credited to Minkowksy and Chauffard, who, at the end of the nineteenth century, reported families who had the presence of numerous spherocytes in the peripheral blood **(Fig. 96-4*A*)**. In vitro studies revealed that the red cells were abnormally susceptible to lysis in hypotonic media; indeed, the presence of *osmotic fragility* became the main diagnostic test for HS. Today we know that HS, thus defined, is genetically heterogeneous; i.e., it can arise from a variety of mutations in one of several genes (Table 96-3). It has been also recognized that the inheritance of HS is not always autosomal dominant (with the patient being heterozygous); indeed, some of the most severe forms are instead autosomal recessive (with the patient being homozygous).

TABLE 96-3 Inherited Diseases of the Red Cell Membrane-Cytoskeleton Complex

GENE	CHROMOSOMAL LOCATION	PROTEIN PRODUCED	DISEASE(S) WITH CERTAIN MUTATIONS (INHERITANCE)	COMMENTS
SPTA1	1q22-q23	α-Spectrin	HS (recessive) HE (dominant)	Rare Mutations of this gene account for about 65% of HE. More severe forms may be due to coexistence of an otherwise silent mutant allele.
SPTB	14q23-q24.1	β-Spectrin	HS (dominant) HE (dominant)	Rare Mutations of this gene account for about 30% of HE, including some severe forms.
ANK1	8p11.2	Ankyrin	HS (dominant)	May account for majority of HS.
SLC4A1	17q21	Band 3; also known as AE (anion exchanger) or AE1	HS (dominant) Southeast Asia ovalocytosis (dominant) Stomatocytosis	Mutations of this gene may account for about 25% of HS. Polymorphic mutation (deletion of 9 amino acids); in heterozygotes clinically asymptomatic and protective against *Plasmodium falciparum.* Certain specific missense mutations shift protein function from anion exchanger to cation conductance.
EPB41	1p33-p34.2	Band 4.1	HE (dominant)	Mutations of this gene account for about 5% of HE, mostly with prominent morphology but little/no hemolysis in heterozygotes; severe hemolysis in homozygotes.
EPB42	15q15-q21	Band 4.2	HS (recessive)	Mutations of this gene account for about 3% of HS.
RHAG	6p21.1-p11	Rhesus-associated glycoprotein	Chronic nonspherocytic hemolytic anemia (recessive)	Very rare; associated with total loss of all Rh antigens. One specific mutation in this gene causes overhydrated stomatocytosis.
PIEZO1	16q23-q24	PIEZO1 (mechanosensitive cation channel)	Dehydrated hereditary stomatocytosis (dominant)	Also known as xerocytosis with pseudohyperkalemia. Patients may present with perinatal edema.
KCNN4	19q13.31	KCNN4 Intermediate conductance calcium-activated potassium channel protein 4	Dehydrated hereditary stomatocytosis (dominant)	Clinical presentation similar to that of *PIEZO1* mutants.
SLC2A1	1p34.2,	GLUT1 glucose transporter	Over-hydrated hereditary stomatocytosis	Associated with serious neurological manifestations.

Abbreviations: HE, hereditary elliptocytosis; HS, hereditary spherocytosis.

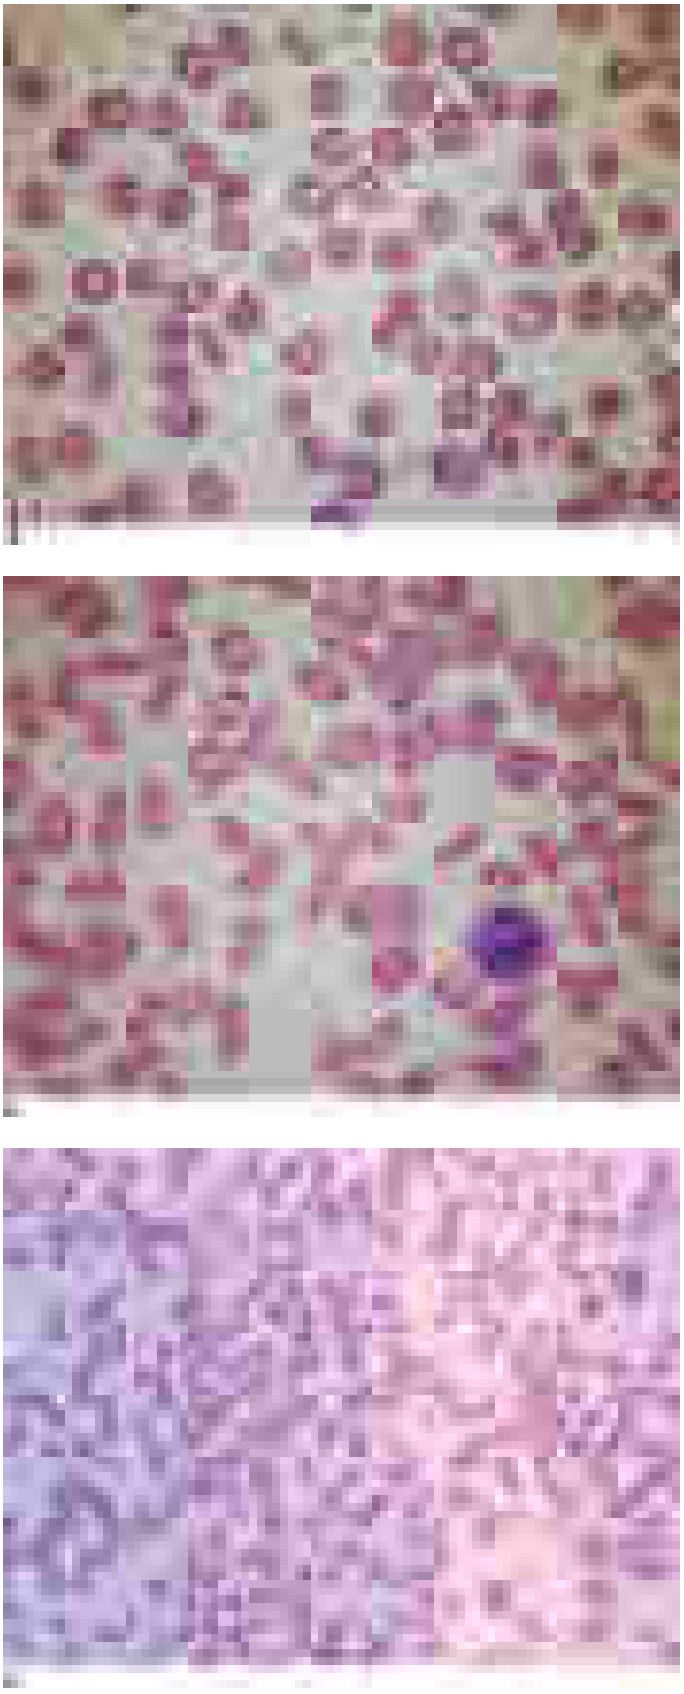

FIGURE 96-4 Peripheral blood smear from patients with membrane-cytoskeleton abnormalities. ***A.*** Hereditary spherocytosis. ***B.*** Hereditary elliptocytosis, heterozygote. ***C.*** Elliptocytosis, with both alleles of the α-spectrin gene mutated.

Clinical Presentation and Diagnosis The spectrum of clinical severity of HS is broad. Severe cases may present in infancy with severe anemia, whereas mild cases may present in young adults or even later in life. The main clinical findings are jaundice, an enlarged spleen, and often gallstones; indeed, it may be the finding of gallstones in a young person that triggers diagnostic investigations.

The variability in clinical manifestations that is observed among patients with HS is largely due to the different underlying molecular lesions (Table 96-3). Not only are mutations of several genes involved: even different mutations of the same gene can give very different clinical manifestations. In milder cases, hemolysis is often compensated (see above), but changes in clinical expression may be seen even in the same patient because intercurrent conditions (e.g., pregnancy, infection) may cause decompensation. The anemia is usually normocytic, with the characteristic morphology that gives the disease its name. An increased mean corpuscular hemoglobin concentration (MCHC >34) on an ordinary blood count report should raise the suspicion of HS, because HS is almost the only condition in which this abnormality occurs. It has been apparent for a long time that the spleen plays a special role in HS through a dual mechanism. On one hand, like in many other HAs, the spleen itself is a major site of destruction; on the other hand, transit through the splenic circulation makes the defective red cells more spherocytic and, therefore, accelerates their demise, even though that may take place elsewhere.

When there is a family history, it is usually easy to make a diagnosis based on features of HA and typical red cell morphology. However, there may be no family history for at least two reasons. First, the patient may have a de novo mutation, i.e., a mutation that has taken place in a germ cell of one of his parents or early after zygote formation. Second, the patient may have a recessive form of HS (Table 96-3). In such cases, more extensive laboratory investigations are required, including osmotic fragility, the acid glycerol lysis test, the eosin-5′-maleimide (EMA)–binding test, and SDS-gel electrophoresis of membrane proteins; these tests are usually carried out in laboratories with special expertise in this area. Sometimes a definitive diagnosis can be obtained only by molecular studies demonstrating a mutation in one of the genes underlying HS (Table 96-3).

TREATMENT

Hereditary Spherocytosis

We do not have a causal treatment for HS; i.e., no way has yet been found to correct the basic defect in the membrane-cytoskeleton structure. Given the special role of the spleen in HS (see above), it has long been thought that an almost obligatory therapeutic measure was splenectomy. Because this operation may have more than trivial consequences, today we have more articulate recommendations, based on disease severity, as follows. In mild cases, avoid splenectomy; in moderate cases, delay splenectomy until puberty; in severe cases, proceed with splenectomy at the age of 4–6. It is also helpful, whenever possible, to know about the outcome of splenectomy in the patient's affected relatives. Antipneumococcal vaccination before splenectomy is imperative, whereas penicillin prophylaxis after splenectomy is controversial. Along with splenectomy, cholecystectomy should not be carried out automatically; it should be carried out, usually by the laparoscopic approach, when clinically indicated.

HEREDITARY ELLIPTOCYTOSIS HE is at least as heterogeneous as HS, both from the genetic point of view (Table 96-3, Fig. 96-3) and from the clinical point of view. Again, it is the shape of the red cells **(Fig. 96-4*B*)** that gives the name to the condition, but there is no direct correlation between the elliptocytic morphology and clinical severity. In fact, some mild or even asymptomatic cases may have nearly 100% elliptocytes (or ovalocytes); whereas in severe cases all kinds of bizarre poikilocytes may predominate. Clinical features and recommended management are similar to those outlined above for HS. Although the spleen may

not have the specific role it has in HS, in severe cases, splenectomy may be beneficial. The prevalence of HE causing clinical disease is similar to that of HS. However, one particular in-frame deletion of nine amino acids in the *SLC4A1* gene encoding band 3, which underlies the so-called *Southeast Asia ovalocytosis* (SAO), has a frequency of up to 7% in certain populations, presumably as a result of malaria selection; it is asymptomatic in heterozygotes and probably lethal in homozygotes.

Disorders of Cation Transport These rare conditions with autosomal dominant inheritance are characterized by increased intracellular sodium in red cells, with concomitant loss of potassium; indeed, they are sometimes discovered through the incidental finding, in a blood test, of a high serum K^+ (*pseudohyperkalemia*). In patients from some families, the cation transport disturbance is associated with gain of water; as a result, the red cells are overhydrated (low MCHC), and on a blood smear, the normally round-shaped central pallor is replaced by a linear-shaped central pallor, which has earned this disorder the name *stomatocyto*sis (Fig. 96-3). In patients from other families, instead, the red cells are dehydrated (high MCHC), and their consequent rigidity has earned this disorder the name *xerocytosis*. One would surmise that in these disorders the primary defect may be in a cation transporter; indeed, xerocytosis results from mutations in *PIEZO1*. In other patients with stomatocytosis, mutations are found in other genes also related to solute transport (Table 96-3), including *SLC4A1* (encoding band 3), the Rhesus gene *RHAG*, and the glucose transporter gene *SLC2A1* responsible for a special form called cryohydrocytosis, an unusual variant in which the red cells swell and burst when they are cooled. In vivo hemolysis can vary from relatively mild to quite severe. From the practical point of view, it is important to know that in stomatocytosis splenectomy is strongly contraindicated because it has been followed in a significant proportion of cases by severe thromboembolic complications.

Enzyme Abnormalities When there is an important defect in a component of the membrane cytoskeleton complex, hemolysis is a direct consequence of the fact that the very structure of the red cell is compromised. Instead, when one of the enzymes is defective, the consequences will depend on the precise role of that enzyme in the metabolic machinery of the red cell. This machinery has two main functions: (1) to provide energy in the form of ATP and (2) to prevent oxidative damage to hemoglobin and to other proteins by providing sufficient reductive potential; the key molecule for this is NADPH.

ABNORMALITIES OF THE GLYCOLYTIC PATHWAY Because red cells, in the course of their differentiation, have sacrificed not only their nucleus and their ribosomes but also their mitochondria, they rely exclusively on the anaerobic portion of the glycolytic pathway for producing ATP, most of which is required by the red cell for cation transport against a concentration gradient across the membrane. If this fails due to a defect of any of the enzymes of the glycolytic pathway (Table 96-4), the result will be hemolytic disease.

Pyruvate Kinase Deficiency Abnormalities of the glycolytic pathway are all inherited and all rare. Among them, deficiency of pyruvate kinase (PK) is the least rare, with an estimated prevalence in most populations of the order of 1:10,000. However, recently, a polymorphic PK mutation

	Glutathione reductase	*GSR:* 8p12	Very rare	Cataracts	AHA from exogenous trigger (favism)
	γ-Glutamylcysteine synthase	*GCLC*; 6p12.1	Very rare	CNS	Mutations affect catalytic subunit
	Cytochrome b5 reductase	*CYB5R3*: 22q13.2	Rare	CNS	Methemoglobinemia rather than hemolysis
Nucleotide Metabolism					
	Adenylate kinase (AK)	*AK1*; 9q34.11	Very rare	CNS	May benefit from splenectomy
	Pyrimidine 5' nucleotidase (P5N)	*NTSC3A*; 7p14.3	Rare (3)[a]		May benefit from splenectomy

[a]The numbers from (1) to (4) indicate the ranking order of these enzymopathies in terms of frequency. [b]PFK deficiency is associated with increased glycogen in muscle, and it is also known as glycogen storage disease type VII or Tarui's disease. [c]Occasional report of successful treatment of the hematologic manifestations by BMT.

Abbreviations: AHA, acquired hemolytic anemia; CNS, central nervous system; NM, neuromuscular.

(E277K) was found in some African populations, with heterozygote frequencies of 1–7%, suggesting that this may be another malaria-related polymorphism. The clinical picture of homozygous (or biallelic) PK deficiency is that of an HA that often presents in the newborn with neonatal jaundice; the jaundice persists, and it is often associated with reticulocytosis. The anemia is of variable severity; sometimes it is so severe as to require regular blood transfusion treatment, whereas sometimes it is mild, bordering on a nearly compensated hemolytic disorder. As a result, the diagnosis may be delayed: in some cases it is made, for instance, in a young woman during her first pregnancy, when the anemia may get worse. The delay in diagnosis may be caused in part by the fact that the anemia is often remarkably well tolerated, because the metabolic block at the last step in glycolysis causes an increase in 2,3-bisphosphoglycerate (or DPG; Fig. 96-1), a major effector of the hemoglobin-oxygen dissociation curve; thus, the oxygen delivery to the tissues is enhanced, a remarkable compensatory feat.

TREATMENT

Pyruvate Kinase Deficiency

The management of PK deficiency is mainly supportive. In view of the marked increase in red cell turnover, oral folic acid supplements should be given constantly. Blood transfusion should be used as necessary, and iron chelation may be required even in some patients who, though not receiving blood transfusion, may be developing iron overload (see "General Pathophysiology" above). In patients who have more severe disease splenectomy may be beneficial, as the anemia improves (paradoxically, reticulocytes often increase considerably). There is a single case report of curative treatment of PK deficiency by bone marrow transplantation (BMT) from an HLA-identical PK-normal sibling. This seems a viable option for severe cases when a sibling donor is available. Prenatal diagnosis has been carried out in a mother who had already had an affected child. A clinical trial of a small molecule that is a specific PK ligand and may increase the stability and/or catalytic efficiency of mutant PK is currently on-going. Rescue of inherited PK deficiency through lentiviral-mediated human PK gene transfer has been successful in mice.

Other Glycolytic Enzyme Abnormalities All of these defects are rare to very rare (Table 96-4), and most of them cause HA with varying degrees of severity. It is not unusual for the presentation to be in the guise of severe neonatal jaundice, which may require exchange transfusion; if the anemia is less severe, it may present later in life, or it may even remain asymptomatic and be detected incidentally when a blood count is done for unrelated reasons. The spleen is often enlarged. When other systemic manifestations occur, they can involve the central nervous system (sometimes entailing severe mental retardation, particularly in the case of triose phosphate isomerase deficiency), the neuromuscular system, or both (see Table 96-4). This is not altogether surprising, if we consider that these are housekeeping genes, i.e., expressed in all tissues. The *diagnosis* of HA is usually not difficult, thanks to the triad of normomacrocytic anemia, reticulocytosis, and hyperbilirubinemia. Enzymopathies should be considered in the differential diagnosis of any chronic Coombs-negative HA. Unlike with membrane disorders, in most cases of glycolytic enzymopathies morphologic abnormalities are conspicuous by their absence. A definitive diagnosis can be made only by demonstrating the deficiency of an individual enzyme by quantitative assays; these are carried out in only a few specialized laboratories. If a particular molecular abnormality is already known in the family, then one could test directly for that defect at the DNA level, thus bypassing the need for enzyme assays. Of course the time may be getting nearer when a patient will present with her or his exome already sequenced, and we will need to concentrate on which genes to look up within the file. The principles for the management of these conditions are similar as for PK deficiency. In isolated cases of glycolytic enzyme abnormalities BMT has been carried out successfully: although unfortunately non-hematologic manifestations, if any, are not reversed.

ABNORMALITIES OF REDOX METABOLISM • Glucose 6-Phosphate Dehydrogenase (G6PD) Deficiency G6PD is a housekeeping enzyme critical in the redox metabolism of all aerobic cells (Fig. 96-1). In red cells, its role is even more critical because it is the only source of NADPH, which directly and via glutathione (GSH) defends these cells against oxidative stress **(Fig. 96-5)**. G6PD deficiency-related HA is a prime example of an HA due to interaction between an intracorpuscular cause and an extracorpuscular cause because in the majority of cases hemolysis is triggered by an exogenous agent. Although a decrease in G6PD activity is present in most tissues of G6PD-deficient subjects, in other cells the decrease is much less pronounced than in red cells, and it does not seem to impact on clinical expression.

GENETIC CONSIDERATIONS

The *G6PD* gene is X-linked, and this has important implications. First, because males have only one *G6PD* gene (i.e., they are hemizygous for this gene), they must be either normal or G6PD deficient. By contrast, females, who have two *G6PD* genes, can be either normal or deficient (homozygous) or intermediate (heterozygous). Second, as a result of the phenomenon of X chromosome inactivation, heterozygous females are genetic mosaics, with a highly variable ratio of G6PD-normal to G6PD-deficient cells and an equally variable degree of clinical expression; some heterozygotes can be just as affected as hemizygous males. The enzymatically active form of G6PD is either a dimer or a tetramer of a single protein subunit of 514 amino acids. G6PD-deficient subjects have been found invariably to have mutations in the coding region of the *G6PD* gene (Fig. 96-5). Almost all of the nearly 200 different mutations known are single missense point mutations, entailing single amino acid replacements in the G6PD protein. In most cases, these mutations cause G6PD deficiency by decreasing the in vivo stability of the protein; thus, the physiologic decrease in G6PD activity that takes place with red cell aging is greatly accelerated. In some cases, an amino acid replacement can also affect the catalytic function of the enzyme.

Among these mutations, those underlying chronic nonspherocytic hemolytic anemia (CNSHA; see below) are a discrete subset. This much more severe clinical phenotype can be ascribed in some cases to adverse qualitative changes (for instance, a decreased affinity for the substrate, glucose 6-phosphate) or simply to the fact that the enzyme deficit is more extreme because of a more severe instability of the enzyme. For instance, a cluster of mutations map at or near the dimer interface, and clearly they compromise severely the formation of the dimer.

Epidemiology G6PD deficiency is widely distributed in tropical and subtropical parts of the world (Africa, Southern Europe, the Middle East, Southeast Asia, and Oceania) **(Fig. 96-6)** and wherever people from those areas have migrated. A conservative estimate is that at least 400 million people have a *G6PD* deficiency gene. In several of these areas, the frequency of a *G6PD* deficiency gene may be as high as 20% or more. It would be quite extraordinary for a trait that causes significant pathology to spread widely and reach high frequencies in many populations without conferring some biologic advantage. Indeed, G6PD is one of the best-characterized examples of genetic polymorphisms in the human species. Clinical field studies and in vitro experiments strongly support the view that G6PD deficiency has been selected by *Plasmodium falciparum* malaria because it confers a relative resistance against this highly lethal infection. As in other cases of balanced polymorphism, it is heterozygotes, therefore females, who are protected. Different G6PD variants underlie G6PD deficiency in different parts of the world. Some of the more widespread variants are G6PD Mediterranean on the shores of that sea, in the Middle East, and in India; G6PD A– in Africa, in the Middle East, and in Southern Europe; G6PD Vianchan and G6PD Mahidol in Southeast Asia; G6PD Canton in China; and G6PD Union worldwide. The heterogeneity of polymorphic G6PD variants is proof of their independent origin, and it supports the notion that they have been selected by a common environmental agent, in keeping with the concept of convergent evolution (Fig. 96-6).

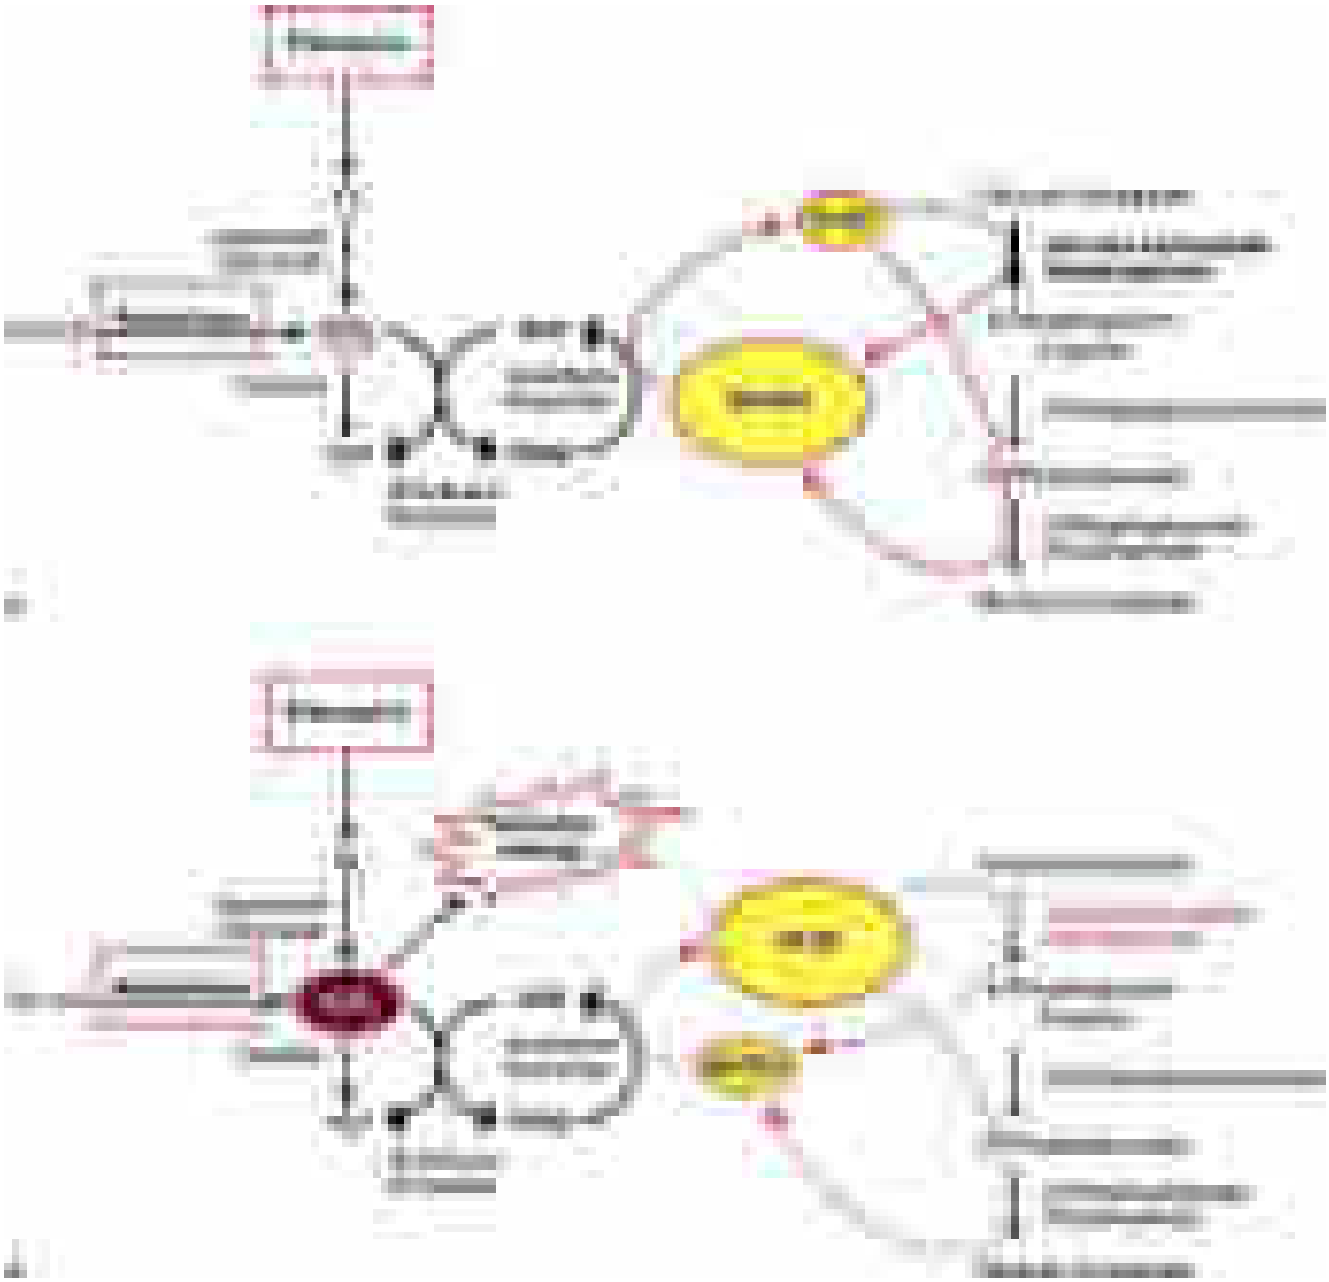

FIGURE 96-5 The role of G6PD in protecting red cells from oxidative damage. ***A.*** In G6PD-normal red cells, G6PD and 6-phosphogluconate dehydrogenase – two of the enzymes of the pentose phosphate pathway—provide ample supply of NADPH, which in turn regenerates GSH when this is oxidized by reactive oxygen species (e.g., O_2^- and H_2O_2). O_2^- is one of the most reactive oxygen species that can be generated from the metabolism of pro-oxidant compounds such as primaquine; rasburicase, on the other hand, produces directly hydrogen peroxide in equimolar amount to uric acid degraded. ***B.*** In G6PD-deficient red cells, where the enzyme activity is reduced, NADPH production is limited, and it may not be sufficient to cope with the excess of reactive oxygen species generated in the presence of pro-oxidant compounds. This diagram also explains why a defect in glutathione reductase has very similar consequences to G6PD deficiency.

Clinical Manifestations The vast majority of people with G6PD deficiency remain clinically asymptomatic throughout their lifetime; however, all of them have an increased risk of developing neonatal jaundice (NNJ) and a risk of developing acute HA (AHA) when challenged by a number of oxidative agents. NNJ related to G6PD deficiency is very rarely present at birth; the peak incidence of clinical onset is between day 2 and day 3, and in most cases, the anemia is not severe. However, NNJ can be very severe in some G6PD-deficient babies, especially in association with prematurity, infection, and/or environmental factors (such as naphthalene-camphor balls, which may be used in babies' bedding and clothing); and the risk of severe NNJ is also increased by the coexistence of a monoallelic or biallelic mutation in the uridyl transferase gene (*UGT1A1*; the same mutations are associated with Gilbert's syndrome). If inadequately managed, NNJ associated with G6PD deficiency can produce kernicterus and permanent neurologic damage.

AHA can develop as a result of three types of triggers: (1) fava beans, (2) infections, and (3) drugs **(Table 96-5)**. Typically, a hemolytic attack starts with malaise, weakness, and abdominal or lumbar pain. After an interval of several hours to 2–3 days, the patient develops jaundice and often dark urine. The onset can be extremely abrupt, especially with favism in children. The anemia is moderate to extremely severe, usually normocytic and normochromic, and due partly to intravascular hemolysis; hence, it is associated with hemoglobinemia, hemoglobinuria, high LDH, and low or absent plasma haptoglobin. The blood film shows anisocytosis, polychromasia, and spherocytes; in addition, the most typical feature of G6PD deficiency is the presence of bizarre poikilocytes, with red cells that appear to have unevenly distributed hemoglobin ("hemighosts") and red cells that appear to have had parts of them bitten away ("bite cells" or "blister cells") **(Fig. 96-7)**. A classical test, now rarely carried out, is supravital staining with methyl violet, which, if done promptly, reveals the presence of Heinz bodies (consisting of

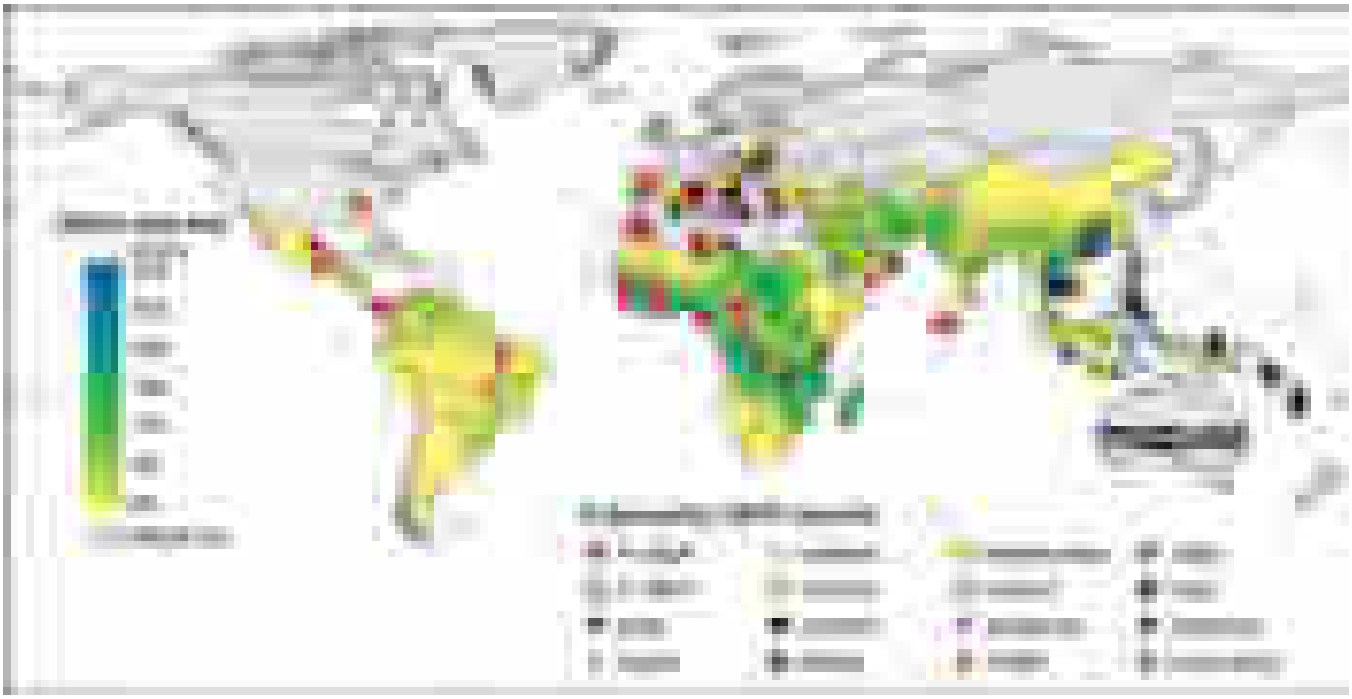

FIGURE 96-6 Epidemiology of glucose 6-phosphate dehydrogenase (G6PD) deficiency throughout the world. Color shades on the map indicate the median allele frequency of G6PD deficiency in malaria endemic and malaria-eliminating countries, according to a geostatistical model. Each colored circle illustrates the geographic distribution of one polymorphic G6PD allele present in more than one population. Dark grey circles indicate "local" polymorphic variants that have been detected only in one population. *(From L Luzzatto et al: Hematology/Oncology Clinics of North America, 30:373, 2016.)*

precipitates of denatured hemoglobin and hemichromes), which are regarded as a signature of oxidative damage to red cells (they are also seen with unstable hemoglobins). Not only LDH is high; also unconjugated bilirubin is high, indicating that there is also extravascular hemolysis. The most serious threat from AHA in adults is the development of acute renal failure (this is exceedingly rare in children). Once the threat of acute anemia is over and in the absence of comorbidity, full recovery from AHA associated with G6PD deficiency is the rule.

It was primaquine (PQ)-induced AHA that led to the discovery of G6PD deficiency, but this drug has not been very prominent subsequently because it is not necessary for the treatment of life-threatening *P. falciparum* malaria. Today there is a revival of interest in PQ because it is the only effective agent for eliminating the gametocytes of *P. falciparum* (thus preventing further transmission) and for eliminating the hypnozoites of *Plasmodium vivax* (thus preventing endogenous relapse). In countries aiming to eliminate malaria, there may be a call for mass administration of PQ; this ought to be associated with G6PD testing. At the other end of the historic spectrum, the latest addition to the list of potentially hemolytic drugs (Table 96-5) is rasburicase; again G6PD testing ought to be made mandatory before giving this drug because fatal cases have been reported in newborns with kidney injury and in adults with tumor lysis syndrome.

Although drug-induced AHA has been prominent in the study of G6PD deficiency, the commonest clinical manifestations are in fact NNJ and favism, both of which are of public health importance in many populations. Contrary to beliefs that are still widespread, fava bean pollen inhalation does not cause favism, and other beans are safe.

A very small minority of subjects with G6PD deficiency have CNSHA of variable severity. The patient is nearly always a male, usually with a history of NNJ, who may present with anemia, unexplained jaundice, or gallstones later in life. The spleen may be enlarged. The severity of anemia ranges in different patients from borderline to transfusion dependent. The anemia is usually normomacrocytic, with reticulocytosis. Bilirubin and LDH are increased. Although hemolysis is, by

All rights reserved.)*

definition, chronic in these patients, they are also vulnerable to acute oxidative damage, and therefore the same agents that can cause AHA in people with the ordinary type of G6PD deficiency will cause severe exacerbations in people with CNSHA associated with G6PD deficiency. In some cases of CNSHA, the deficiency of G6PD is so severe in granulocytes that it becomes rate-limiting for their oxidative burst, with consequent increased susceptibility to some bacterial infections.

Laboratory Diagnosis The suspicion of G6PD deficiency can be confirmed by semi-quantitative methods often referred to as screening tests, which are suitable for population studies and can correctly classify male subjects, in the steady state, as G6PD normal or G6PD-deficient. However, in clinical practice, a diagnostic test is usually needed when the patient has had a hemolytic attack; this implies that the oldest, most G6PD-deficient red cells have been selectively destroyed, and young red cells, having higher G6PD activity, are being released into the circulation. Under these conditions, only a quantitative test can give a definitive result. In males, this test will identify normal hemizygotes and G6PD-deficient hemizygotes; among females, some heterozygotes will be missed, but those who are at most risk of hemolysis will be identified. Of course, G6PD deficiency also can be diagnosed by DNA testing. Currently easy-to-use "point of care" tests for G6PD deficiency are becoming available, geared especially to the prospect of mass administration of PQ or other anti-malarials.

TREATMENT

G6PD Deficiency

The AHA of G6PD deficiency is largely preventable by avoiding exposure to triggering factors of previously screened subjects. Of course, the practicability and cost-effectiveness of screening depend on the prevalence of G6PD deficiency in each individual community. Favism is entirely preventable in G6PD-deficient subjects by not eating fava beans. Drug-induced hemolysis can be prevented by testing for G6PD deficiency before prescribing; in many cases one can use alternative drugs. When AHA develops and once its cause is recognized, no specific treatment is needed in most cases. However, if the anemia is severe, it may be a medical emergency, especially in children, requiring immediate action, including blood transfusion. This has been the case with an antimalarial drug combination containing dapsone (called Lapdap, introduced in 2003) that has caused severe acute hemolytic episodes in children with malaria in several African countries; after a few years, the drug was taken off the market. If there is acute renal failure, hemodialysis may be necessary, but if there is no previous kidney disease, recovery is the rule. The management of NNJ associated with G6PD deficiency is no different from that of NNJ due to other causes.

In cases with CNSHA, if the anemia is not severe, regular folic acid supplements and regular hematologic surveillance will suffice. It will be important to avoid exposure to potentially hemolytic drugs, and blood transfusion may be indicated when exacerbations occur, mostly in concomitance with intercurrent infection. In rare patients, regular blood transfusions may be required, in which case appropriate iron chelation should be instituted. Unlike in HS, there is no evidence of selective red cell destruction in the spleen; however, in practice, splenectomy has proven beneficial in severe cases.

Other Abnormalities of the Redox System As mentioned previously, GSH is a key player in the defense against oxidative stress. Inherited defects of GSH metabolism are exceedingly rare, but each one can give rise to chronic HA (Table 96-4). A rare, peculiar, severe but usually self-limited HA occurring in the first month of life, called *infantile poikilocytosis*, may be associated with deficiency of glutathione peroxidase (GSHPX) due not to an inherited abnormality, but to transient nutritional deficiency of selenium, an element essential for the activity of GSHPX.

PYRIMIDINE 5′-NUCLEOTIDASE (P5N) DEFICIENCY P5N is a key enzyme in the catabolism of nucleotides arising from the degradation of nucleic acids that takes place in the final stages of erythroid cell maturation. How exactly its deficiency causes HA is not well understood, but a highly distinctive feature of this condition is a morphologic abnormality of the red cells known as *basophilic stippling*. The condition is rare, but it probably ranks third in frequency among red cell enzyme defects (after G6PD deficiency and PK deficiency). The anemia is lifelong, of variable severity, and may benefit from splenectomy.

Familial (Atypical) Hemolytic-Uremic Syndrome (aHUS)

This term is used to designate a group of rare disorders, mostly affecting children, characterized by microangiopathic HA with presence of fragmented erythrocytes in the peripheral blood smear, thrombocytopenia (usually mild), and acute renal failure. (The word *atypical* in this phrase should be consigned to history: it was introduced originally to distinguish this condition from the hemolytic-uremic syndrome [HUS] caused by infection with *Escherichia coli* producing the Shiga toxin, regarded as *typical*.) The genetic basis of atypical HUS (aHUS) has been elucidated. Studies of >100 families have revealed that those family members who developed HUS had mutations in any one of several genes encoding complement regulatory proteins: complement factor H (*CFH*), CD46 or membrane cofactor protein (*MCP*), complement factor I (*CFI*), complement component C3, complement factor B (*CFB*), thrombomodulin, and others. Thus, whereas all other inherited HAs are due to intrinsic red cell abnormalities, this group is unique in that hemolysis results from an inherited defect external to red cells (Table 96-1). Because the regulation of the complement cascade has considerable redundancy, in the steady state, any of the above abnormalities can be tolerated. However, when an intercurrent infection or some other trigger briskly activates complement the deficiency of one of the complement regulators becomes critical. Endothelial cells get damaged, especially in the kidney; at the same time, and partly as a result of this, there will be brisk hemolysis (thus, the more common Shiga toxin–related HUS **(Chap. 161)** can be regarded as a phenocopy of aHUS). aHUS is a severe disease, with up to 15% mortality in the acute phase and up to 50% of cases progressing to end-stage renal disease (ESRD). Not infrequently, aHUS undergoes spontaneous remission; but because its basis is an inherited abnormality, it is not surprising that, given renewed exposure to a trigger, the syndrome will tend to recur; when it does, the prognosis is always serious. The traditional treatment has been plasma exchange, which will supply the deficient complement regulator. This has changed since the introduction of the anti-C5 complement inhibitor eculizumab (see "Paroxysmal Nocturnal Hemoglobinuria") was found to greatly ameliorate the microangiopathic picture, with improvement in platelet counts and in renal function, thus abrogating the need for plasma exchange, which is not always effective and not free of complications. Since the basis of aHUS is genetic, and even after complete remission relapses are always possible, there is a rationale for continuing eculizumab indefinitely, especially in order to prevent ESRD. Patients who relapsed after discontinuing

TABLE 96-6 Diseases and Clinical Situations in Which Hemolysis Is Largely Intravascular

	ONSET/TIME COURSE	MAIN MECHANISM	APPROPRIATE DIAGNOSTIC PROCEDURE	COMMENTS
Mismatched blood transfusion	Abrupt	Nearly always ABO incompatibility	Repeat cross-match	
Paroxysmal nocturnal hemoglobinuria (PNH)	Chronic with acute exacerbations	Complement (C)-mediated destruction of CD59(−) red cells	Flow cytometry to display a CD59(−) red cell population	Exacerbations due to C activation through any pathway
Paroxysmal cold hemoglobinuria (PCH)	Acute	Immune lysis of normal red cells	Test for Donath-Landsteiner antibody	Often triggered by viral infection
Septicemia	Very acute	Exotoxins produced by *Clostridium perfringens*	Blood cultures	Other organisms may be responsible
Microangiopathic	Acute or chronic	Red cell fragmentation	Red cell morphology on blood smear	Different causes ranging from endothelial damage to hemangioma to leaky prosthetic heart valve
March hemoglobinuria	Abrupt	Mechanical destruction	Targeted history taking	
Favism	Acute	Destruction of older fraction of G6PD-deficient red cells	G6PD assay	Triggered by ingestion of large dish of fava beans[a]

[a]The trigger of acute hemolytic anemia, often with hemoglobinuria, can be infection or a drug (see Table 96-5) rather than fava beans.

Abbreviation: G6PD, glucose 6-phosphate dehydrogenase.

eculizumab have responded again. Discontinuation of eculizumab might be reasonable especially in patients heterozygous for a MCP mutation. However, there is no evidence base at the moment for balancing the pros and cons of lifetime eculizumab (a very expensive drug).

ACQUIRED HEMOLYTIC ANEMIA

Mechanical Destruction of Red Cells Although red cells are characterized by the remarkable deformability that enables them to squeeze through capillaries narrower than themselves for thousands of times in their lifetime, there are at least two situations in which they succumb to shear, if not to wear and tear; the result is intravascular hemolysis, resulting in hemoglobinuria **(Table 96-6)**. One situation is acute and self-inflicted, *march hemoglobinuria*. Why sometimes a marathon runner may develop this complication, whereas on another occasion, this does not happen, we do not know (perhaps her or his footwear needs attention). A similar syndrome may develop after prolonged barefoot ritual dancing or intense playing of bongo drums. The other situation is chronic and iatrogenic (it has been called *microangiopathic hemolytic anemia*). It takes place in patients with prosthetic heart valves, especially when paraprosthetic regurgitation is present. If the hemolysis consequent on mechanical trauma to the red cells is mild, and if the supply of iron is adequate, the loss may be largely compensated; if more than mild anemia develops, reintervention to correct regurgitation may be required.

Infection By far the most frequent infectious cause of HA, in endemic areas, is malaria **(Chap. 219)**. In other parts of the world, the most frequent direct cause is probably Shiga toxin–producing *E. coli* O157:H7, now recognized as the main etiologic agent of HUS, which is more common in children than in adults **(Chap. 156)**. Life-threatening intravascular hemolysis, due to a toxin with lecithinase activity, occurs with *Clostridium perfringens* sepsis, particularly following open wounds, septic abortion, or as a disastrous accident due to a contaminated blood unit. Rarely, and if at all in children, HA is seen with sepsis or endocarditis from a variety of organisms. In addition, bacterial and viral infections can cause HA by indirect mechanisms (see previous section on G6PD deficiency and Table 96-6).

Immune Hemolytic Anemias These can arise through at least two distinct mechanisms. First, when an antibody directed against a certain molecule (e.g., a drug) reacts with that molecule, red cells may get caught in the reaction (the so-called *innocent bystander* mechanism: see section below on Hemolytic Anemia from Toxic Agents and Drugs), whereby they are damaged or destroyed. Second, and more frequently, a true auto-antibody is directed against a red cell antigen, i.e., a molecule present on the surface of red cells.

AUTOIMMUNE HEMOLYTIC ANEMIA (AIHA) This latter mechanism is common to a group of rare disorders (AIHA), with an estimated incidence in the United States of about $2/10^5$/year. AIHA can be serious, since even with appropriate management the mortality is of the order of 5–10%.

Clinical Features The onset is often abrupt and can be dramatic. The hemoglobin level may drop, within days, to as low as 4 g/dL; the massive red cell removal will produce jaundice; and sometimes the spleen is enlarged. When this triad is present, the suspicion of AIHA must be high. When hemolysis is (in part) intravascular, the telltale sign will be hemoglobinuria, which the patient may report or about which we must enquire or test for.

There are few situations in hematology where one laboratory test is so informative as the direct antiglobulin test developed in 1945 by R. R. A. Coombs, and known since then by this name. The currently recommended version of this test uses in the first instance a "broad spectrum" reagent: i.e., one that will detect not only immunoglobulins (Ig) but also complement (C) components (usually C3 fragments) bound to the surface of the patient's red cells. If the test is positive (and barring special circumstances such as previous blood transfusion), it is practically diagnostic of AIHA; and one can then determine, by using specific reagents, whether Ig or C or both are implicated. The sensitivity of the Coombs test varies depending on the techniques that are used: in general, the test is positive if there are an average of at least 400 molecules of Ig and/or C on each red cell; but with more advanced techniques the sensitivity can be pushed to as low as 40 molecules per red cell: therefore liaison with a specialized laboratory is desirable. In the past the diagnosis of "Coombs-negative AIHA" was regarded as a last resort, but it is important to know that a patient with this label may have severe AIHA, because if the antibody is powerful (high affinity/avidity), few molecules may be sufficient to opsonize red cells. Based on the Coombs test findings as well as on the thermal characteristics and the antigenic specificities of the auto-antibodies **(Table 96-7)**, AIHA has been classified into subtypes.

Warm Antibody AIHA This is the more common type of AIHA. As the name suggests, the auto-antibody reacts best at 37°C: it will often react with most red cells, but it is usually Rhesus-specific (sometimes specifically anti-e). Warm antibody AIHA may be seen in isolation (and it is then called *idiopathic*) or as part of a systemic auto-immune disorder such as systemic lupus erythematosus (SLE: sometimes AIHA may be the first manifestation that leads to a diagnosis of SLE). Like all auto-immune diseases, AIHA must arise from a dysregulation of immunity. It is therefore not surprising that it is increasingly being recognized in chronic lymphocytic leukemia (CLL), whether treated or untreated; after BMT; and after solid organ transplantation entailing immuno-suppressive treatment. Recently, warm antibody AIHA has also occurred as a side effect of the use of immune checkpoint inhibitors, such as nivolumab, in patients with various types of cancer.

TABLE 96-7 Classification of Acquired Immune Hemolytic Anemias

CLINICAL SETTING	TYPE OF ANTIBODY: COLD, MOSTLY IgM, OPTIMAL TEMPERATURE 4°C–30°C	TYPE OF ANTIBODY: WARM, MOSTLY IgG, OPTIMAL TEMPERATURE 37°C; OR MIXED
Primary	CAD	AIHA (idiopathic)
Secondary to viral infection	EBV CMV Other	HIV Viral vaccines
Secondary to other infection	Mycoplasma infection: paroxysmal cold hemoglobinuria	
Secondary to/ associated with other disease	CAD in: Waldenström's disease Lymphoma	AIHA in: SLE CLL Other malignancy Chronic inflammatory disorders (e.g., IBD) After allogeneic HSCT After immune checkpoint modulating drugs
Secondary to drugs: drug-induced immune hemolytic anemia	Small minority (e.g., with lenalidomide)	Majority: currently most common culprit drugs are cefotetan, ceftriaxone, piperacillin
	Drug-dependent: antibody destroys red cells only when drug present (e.g., rarely penicillin)	
	Drug-independent: antibody can destroy red cells even when drug no longer present (e.g., methyldopa)	

Abbreviations: AIHA, autoimmune hemolytic anemia; CAD, cold agglutinin disease; CLL, chronic lymphocytic leukemia; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HSCT, hematopoietic stem cell transplantation; IBD, inflammatory bowel disease; SLE, systemic lupus erythematosus.

Once a red cell is coated by an autoantibody it will be destroyed by one or more mechanisms. In most cases, the Fc portion of the antibody will be recognized by the Fc receptor of macrophages, and this will trigger erythrophagocytosis. Thus, destruction of red cells will take place wherever macrophages are abundant, i.e., in the spleen, liver, and bone marrow (*extravascular hemolysis* see **Fig. 96-8**). Because of the special anatomy of the spleen, this organ is particularly efficient in trapping antibody-coated red cells, and often this is the predominant site of red cell destruction. In some cases, the nature of the antibody is such (usually an IgM antibody) that the antigen-antibody complex on the surface of red cells is able to activate complement (C); as a result, a large amount of membrane attack complex (MAC) will form, and the red cells may be destroyed directly (*intravascular hemolysis*).

The hematological picture of AIHA includes in most cases reticulocytosis, as the bone marrow responds to anemia: but in some cases reticulocytes may not be increased because they themselves are attacked by the auto-antibody, and this may signify the disease is more severe. In some cases AIHA can be associated, on first presentation or subsequently, with autoimmune thrombocytopenia (Evans' syndrome): this too usually signals severe disease. Evans' syndrome may be a manifestation of common variable immune deficiency, and in children it may suggest one of several primary immune deficiency syndromes.

TREATMENT

Warm Antibody Autoimmune Hemolytic Anemia

Severe acute AIHA can be a medical emergency. The immediate treatment almost invariably includes transfusion of red cells. This may pose a special problem because many or all of the blood units cross-matched may be incompatible. In these cases, it is often correct, if paradoxical, to transfuse ABO-matched but incompatible blood: the rationale being that the transfused red cells will be destroyed no less—but no more—than the patient's own red cells, and in the meantime the patient stays alive. A situation like this requires close liaison and understanding between the clinical unit treating the patient and the blood transfusion/serology lab. Whenever the anemia is not immediately life threatening, blood transfusion should be withheld (because compatibility problems may increase with each unit of blood transfused), and medical treatment started immediately with prednisone (1 mg/kg per day), which will produce a remission promptly in at least one-half of patients. Rituximab (anti-CD20), previously regarded as second-line treatment, is increasingly being used at a relatively low dose (100 mg/wk × 4), together with prednisone as part of first-line treatment. It is especially encouraging that this approach seems to reduce the rate of relapse, a common occurrence in AIHA. For patients who do relapse or are refractory to medical treatment, one may have to consider splenectomy: this procedure does not cure the disease, but it can produce significant benefit by removing a major site of hemolysis, thus improving the anemia and/or reducing the need for other therapies (e.g., the dose of prednisone); of course splenectomy is not free of risk, as it entails increased risk of sepsis and of thrombosis. Since the introduction of rituximab, azathioprine, cyclophosphamide, cyclosporine, and intravenous immunoglobulin have become second- or third-line agents. In very rare severe refractory cases, one may have to consider myelo-immuno-ablative chemotherapy followed by rescue with either autologous or allogeneic hematopoietic stem cell transplantation.

PAROXYSMAL COLD HEMOGLOBINURIA (PCH) PCH is a rather rare form of AIHA occurring mostly in children, usually triggered by a viral infection, usually self-limited, and characterized by the involvement of the so-called Donath-Landsteiner antibody. In vitro, this antibody has unique serologic features; it has anti-P specificity and binds to red cells only at a low temperature (optimally at 4°C), but when the temperature is shifted to 37°C, lysis of red cells takes place in the presence of complement. Consequently, in vivo there is intravascular hemolysis, resulting in hemoglobinuria. Clinically the differential diagnosis must include other causes of hemoglobinuria (Table 96-6), but the presence of the Donath-Landsteiner antibody will prove PCH. Active supportive treatment, including blood transfusion, may be needed to control the anemia; subsequently, recovery is the rule.

COLD AGGLUTININ DISEASE This designation is used for a form of AIHA that usually affects the elderly and has special clinical and pathologic features. First, CAD is characteristically a chronic condition—in contrast to the abrupt onset of warm antibody AIHA. Second, the term *cold* refers to the fact that the autoantibody involved reacts with red cells poorly or not at all at 37°C, whereas it reacts strongly at lower temperatures. As a result, hemolysis is more prominent the more the body is exposed to the cold. The antibody is usually IgM; usually it has an anti-I specificity (the I antigen is present on the red cells of almost everybody), and it may have a very high titer (1:100,000 or more has been observed). Third, the antibody is produced by an expanded B lymohocyte clone (a low-grade mature B cell lymphoma): and sometimes the antibody concentration in the serum is high enough to show up as a spike in plasma protein electrophoresis, i.e., as a monoclonal gammopathy. Indeed, since we are dealing with a clonal disease and the antibody is IgM, CAD must be regarded as a form of Waldenström macroglobulinemia **(see Chap. 107)**. The unique biologic properties of the IgM produced in a patient with CAD give the clinical picture of HA, often well before other clinical features of WM become manifest.

In mild forms of CAD, avoidance of exposure to cold may be all that is needed to enable the patient to have a reasonably comfortable quality of life; but in more severe forms, the management of CAD is not easy. Plasma exchange will remove antibody and is, therefore, in theory, a rational approach, but it is laborious and must be carried out at frequent intervals if it is to be beneficial. The management of CAD has changed significantly with the advent of the anti-CD20 antibody rituximab: up to 60% of patients respond. If remission is followed by relapse

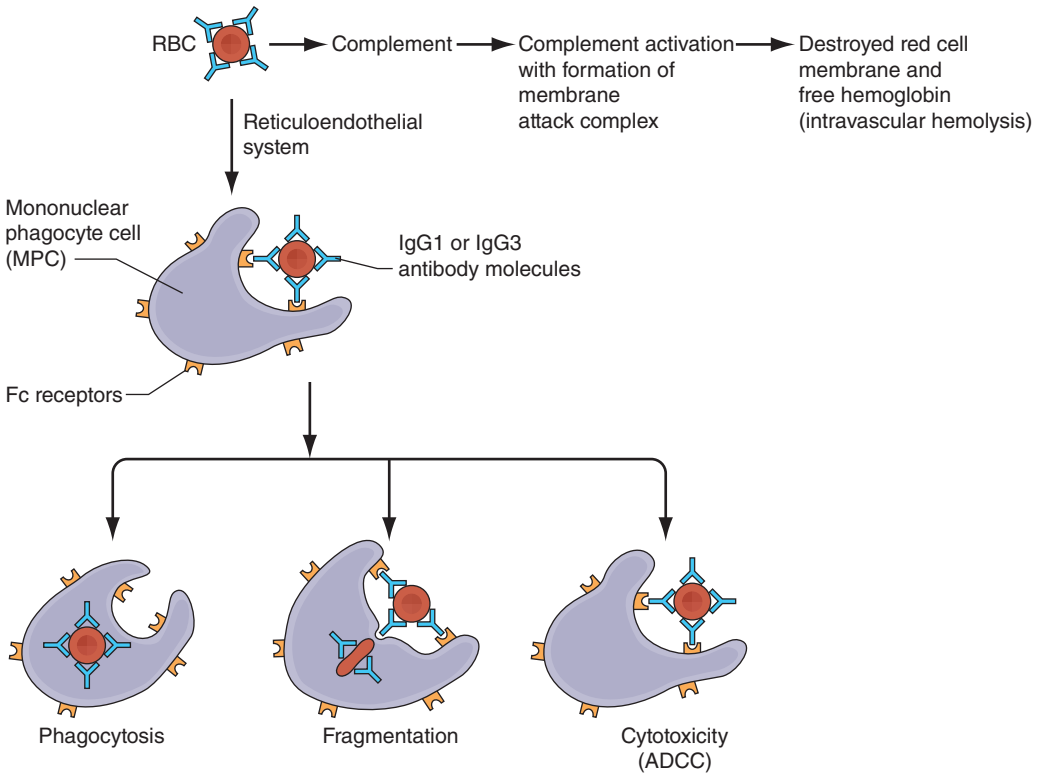

FIGURE 96-8 Mechanism of antibody-mediated immune destruction of red blood cells (RBCs). The three bottom images illustrate three different modalities of extravascular hemolysis. ADCC, antibody-dependent cell-mediated cytotoxicity. *(From N Young et al: Clinical Hematology. Philadelphia, Elsevier, 2006; with permission.)*

a new course of rituximab may be again effective, and remissions may be more durable with a rituximab-fludarabine combination. Therefore, even in the absence of a formal trial, rituximab has become de facto first-line treatment: especially since previously used immunosuppressive/cytotoxic agents such as azathioprine or cyclophosphamide, although they can reduce the antibody titer, have limited clinical efficacy and, in view of the chronic nature of CAD, their side effects may prove unacceptable. Unlike in AIHA, prednisone and splenectomy are ineffective. In terms of supportive treatment blood transfusion may be helpful—in spite of the fact that red cells from the donor, being I-positive, will survive no longer than those of the patient: both the blood bag and the patient's extremities must be kept warm during transfusion.

Hemolytic Anemia from Toxic Agents and Drugs A number of chemicals with oxidative potential, whether medicinal or not, can cause hemolysis even in people who are not G6PD-deficient (for which see above). Examples are hyperbaric oxygen (or 100% oxygen), nitrates, chlorates, methylene blue, dapsone, cisplatin, and numerous aromatic (cyclic) compounds. Other chemicals may be hemolytic through non-oxidative, largely unknown mechanisms; examples include arsine, stibine, copper, and lead. The HA caused by lead poisoning is characterized by basophilic stippling; it is in fact a phenocopy of that seen in P5N deficiency (see above), suggesting it is mediated at least in part by lead inhibiting this enzyme.

In these cases, hemolysis appears to be mediated by a direct chemical action on red cells. But drugs can cause hemolysis through at least two other mechanisms. (1) A drug can behave as a hapten and induce antibody production; in rare subjects, this happens, for instance, with penicillin. Upon a subsequent exposure, red cells are caught, as innocent bystanders, in the reaction between penicillin and anti-penicillin antibodies. Hemolysis will subside as soon as penicillin administration is stopped. (2) A drug can trigger, perhaps through mimicry, the production of an antibody against a red cell antigen. The best known example is methyldopa, an antihypertensive agent no longer in use, which in a small fraction of patients stimulated the production of the Rhesus antibody anti-e. In patients who have this antigen, the anti-e is a true autoantibody, which then causes true AIHA (see above). Usually this will gradually subside once methyldopa is discontinued.

Severe intravascular hemolysis can be caused by the venom of certain snakes (cobras and vipers), and HA can also follow spider bites.

Paroxysmal Nocturnal Hemoglobinuria (PNH) PNH is an acquired chronic HA characterized by persistent intravascular hemolysis with occasional or frequent recurrent exacerbations. In addition to (i) hemolysis, there may be (ii) pancytopenia and (iii) a distinct tendency to venous thrombosis. This triad makes PNH a truly unique clinical condition; however, when not all of these three features are manifest on presentation, the diagnosis is often delayed, although it can always be made by appropriate laboratory investigations (see below).

PNH is encountered in all populations throughout the world, but it is a rare disease, with an estimated prevalence of ~5 per million (it may be somewhat less rare in Southeast Asia and in the Far East). PNH has about the same frequency in men and women. PNH is not inherited, and it has never been reported as a congenital disease, but it can present in small children or as late as in the seventies, although most patients are young adults.

CLINICAL FEATURES When seeking medical attention, the patient may report that one morning, she or he "passed blood instead of urine" **(Fig. 96-9)**. This distressing or frightening event may be regarded as the classic presentation; however, more frequently, this symptom is not noticed or not reported. Indeed, the patient often presents simply as a problem in the differential diagnosis of *anemia*, whether symptomatic or discovered incidentally. Sometimes the anemia is associated from the outset with neutropenia, thrombocytopenia, or both, thus signaling an element of bone marrow failure (see below). Some patients may present with recurrent attacks of severe abdominal pain eventually found to be related to thrombosis in abdominal veins, or attributable to NO depletion associated with intravascular hemolysis. When thrombosis affects the hepatic vein it may produce acute hepatomegaly and ascites, i.e., a full-fledged Budd-Chiari syndrome, which, in the absence of liver disease, ought to raise the suspicion of PNH.

The *natural history* of PNH can extend over decades. In the past, with supportive treatment only, the median survival was estimated to be about 10–20 years; with the most common cause of death being venous thrombosis, followed by infection secondary to severe neutropenia and

FIGURE 96-9 Consecutive urine samples from a patient with paroxysmal nocturnal hemoglobinuria (PNH). The variation in the severity of hemoglobinuria within hours is probably unique to this condition.

hemorrhage secondary to severe thrombocytopenia. Rarely (estimated 1–2% of all cases), PNH may terminate in acute myeloid leukemia. On the other hand, full spontaneous recovery from PNH has been documented, albeit rarely.

LABORATORY INVESTIGATIONS AND DIAGNOSIS The most consistent blood finding is anemia, which may range from mild to moderate to very severe. The anemia is usually normo-macrocytic, with unremarkable red cell morphology. If the MCV is high, it is usually largely accounted for by reticulocytosis, which may be quite marked (up to 20%, or up to 400,000/μL). The anemia may become microcytic if the patient is allowed to become iron-deficient as a result of chronic iron loss through hemoglobinuria. Unconjugated bilirubin is mildly or moderately elevated; LDH is typically markedly elevated (values in the thousands are common); and haptoglobin is usually undetectable. All of these findings make the diagnosis of HA compelling. Hemoglobinuria may be overt in a random urine sample; if it is not, it may be helpful to obtain serial urine samples (Fig. 96-9) because hemoglobinuria can vary dramatically from day to day and even from hour to hour. The bone marrow is usually cellular, with marked to massive erythroid hyperplasia, often with mild to moderate dyserythropoietic features (these overlap with those seen in myelodysplastic syndromes, but PNH remains a separate entity). At some stage of the disease, the marrow may become hypocellular or even frankly aplastic (see below).

The definitive diagnosis of PNH must be based on the demonstration that a substantial proportion of the patient's red cells have an increased susceptibility to complement (C), due to the deficiency on their surface of proteins (particularly CD59 and CD55) that normally protect the red cells from activated C. The sucrose hemolysis test is unreliable; in contrast, the acidified serum (Ham) test is highly reliable but is carried out only in a few labs. The gold standard today is flow cytometry, which can be carried out on granulocytes as well as on red cells, and has a very high sensitivity. In PNH, characteristically, one sees a bimodal distribution of cells, with a discrete population that is CD59 and CD55 negative. Although very small populations of CD59(-) cells are of interest in terms of pathophysiology (particularly of aplastic anemia [AA]), no patient should be diagnosed with PNH unless their proportion is substantial: in first approximation at least 5% of the total red cells and at least 20% of the total granulocytes.

PATHOPHYSIOLOGY Hemolysis in PNH is mainly intravascular and is due to an intrinsic abnormality of the red cell, which makes it exquisitely sensitive to activated C, whether C is activated through the alternative pathway or through an antigen-antibody reaction (classic pathway). The former mechanism is mainly responsible for chronic hemolysis in PNH; the latter explains why the hemolysis can be dramatically exacerbated in the course of a viral or bacterial infection. Hypersusceptibility to C is due to deficiency in the red cell membrane of several protective proteins **(Fig. 96-10)**, among which CD59 is the most important because it is able to hinder the insertion into the membrane of C9 polymers. The molecular basis for the deficiency of these proteins has been pinpointed not to a defect in any of the respective genes, but rather to the shortage of a unique glycolipid molecule, GPI (Fig. 96-2), which, through a peptide bond, anchors these proteins to the surface membrane of cells. The shortage of GPI is due in turn to a somatic mutation in an X-linked gene, called *PIGA*, required for an early step in GPI biosynthesis. As a result, the patient's marrow is a mosaic of mutant and nonmutant cells, and the peripheral blood always contains both GPI-negative (PNH) cells and GPI-positive (non-PNH) cells. Thrombosis is one of the most immediately life-threatening complications of PNH and yet one of the least understood in its pathogenesis. It could be that deficiency of CD59 on the PNH platelet causes inappropriate platelet activation; however, other mechanisms are possible.

BONE MARROW FAILURE (BMF) AND RELATIONSHIP BETWEEN PNH AND APLASTIC ANEMIA (AA) It is not unusual that patients with firmly established PNH have a previous history of AA, sometimes well-documented; indeed, BMF preceding overt PNH is probably the rule rather than the exception. On the other hand, sometimes a patient with PNH becomes less hemolytic and more pancytopenic and ultimately has the clinical picture of AA. The relationship between PNH and AA manifested in the clinical course of patients may reflect a close link in pathogenesis. AA is thought to be an organ-specific autoimmune disease, in which T cells cause damage to hematopoietic stem cells via an as yet unidentified molecular target. The same may be true of PNH, and in this condition the target might be the GPI molecule itself. This would explain why GPI-negative (PNH) stem cells are spared; *PIGA* mutations can be demonstrated in normal people. Thus, PNH results from the combined action of two factors: failure of normal hematopoiesis and massive expansion of a PNH clone. There is evidence from mouse models that PNH stem cells do not expand on their own, and there is evidence from human patients that expansion is associated with negative selection against GPI-positive cells by GPI-specific T cells. Thus, PNH is a prime example of a clonal disease that is not malignant.

TREATMENT

Paroxysmal Nocturnal Hemoglobinuria

Until 10 years ago there were essentially two treatment options for PNH: either allogeneic BMT, providing a definitive cure at the cost of non-negligible risks; or continued supportive treatment for what, unlike other acquired HAs, may be a lifelong condition. A major advance has been the introduction in 2007 of a humanized monoclonal antibody, eculizumab, which binds to the complement component C5 near the site that, when cleaved, will trigger the distal part of the complement cascade leading to formation of the MAC. With C5 blocked, the patient is relieved of intravascular hemolysis and of its attendant consequences, including hemoglobinuria. In the majority of those patients who needed regular blood transfusion, the transfusion requirement is either abolished or significantly reduced. For many PNH patients, eculizumab has meant a real improvement in the quality of life, as well as a decrease in complications, particularly thrombosis. At the same time, it is important to know that in patients on eculizumab the PNH red cells, now protected from being lysed through the MAC, do still bind C3 fragments and thus become opsonized. Therefore hemolysis continues, but it is now extravascular. The extent to which this happens depends in part on a genetic polymorphism of the complement receptor CR1. Those patients who, on eculizumab, are still receiving blood transfusion are at risk of iron overload. Based on its half-life, eculizumab must be administered intravenously every 14 days: a trial of a long-lived anti-C5 antibody is currently under way, and other complement inhibitors are under experimentation.

Eculizumab is very expensive and therefore not accessible to patients in many parts of the world. Therefore, the management of PNH by supportive treatment is still very important. Folic acid supplements (at least 3 mg/d) are mandatory; the serum iron should be checked periodically, and iron supplements should be administered as appropriate. Transfusion of filtered red cells should be used

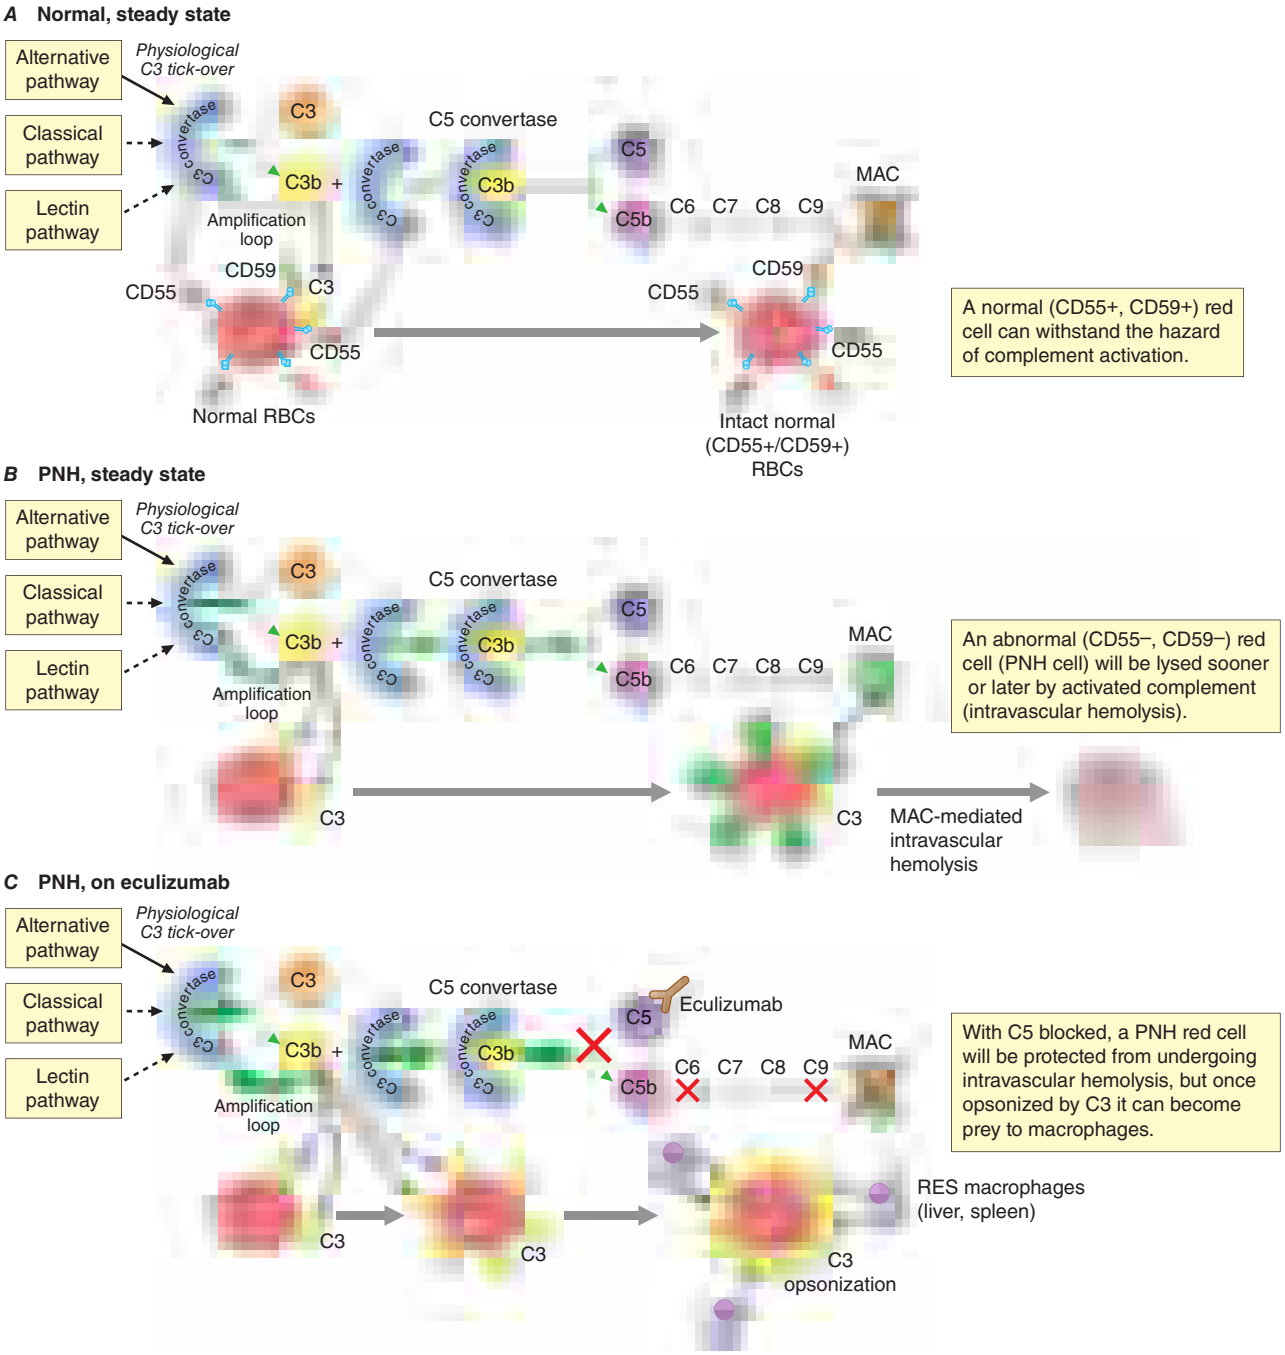

FIGURE 96-10 The complement cascade and the fate of red cells. ***A.*** Normal red cells are protected from complement activation and subsequent hemolysis by CD55 and CD59. These two proteins, being GPI-linked, are missing from the surface of PNH red cells as a result of a somatic mutation of the X-linked *PIG-A* gene that encodes a protein required for an early step of the GPI molecule biosynthesis. ***B.*** In the steady state, PNH erythrocytes suffer from spontaneous (tick-over) complement activation, with consequent intravascular hemolysis through formation of the membrane attack complex (MAC); when extra complement is activated through the classical pathway, an exacerbation of hemolysis will result. ***C.*** On eculizumab, PNH erythrocytes are protected from hemolysis from the inhibition of C5 cleavage; however, upstream complement activation may lead to C3 opsonization and possible extravascular hemolysis. GPI, glycosylphosphatidylinositol; PNH, paroxysmal nocturnal hemoglobinuria. *(From L Luzzatto et al: Haematologica 95:523, 2010.)*

whenever necessary, which, for some patients, means quite frequently. Long-term glucocorticoids are not indicated because there is no evidence that they have any effect on chronic hemolysis; in fact, they are contraindicated because their side effects are considerable. A short course of prednisone may be useful when an inflammatory process exacerbates hemolysis. Any patient who has had venous thrombosis or who has a genetically determined thrombophilic state in addition to PNH should be on regular anticoagulant prophylaxis. With thrombotic complications that do not resolve otherwise, thrombolytic treatment with tissue plasminogen activator may be indicated.

Where eculizumab is available the proportion of PNH patients receiving BMT has decreased significantly. However, when an HLA-identical sibling is available, BMT should be taken into consideration for any young patient with severe PNH; and for patients with the so-called PNH-AA syndrome, since eculizumab has no effect on BMF. For these patients immunosuppressive treatment with antithymocyte globulin and cyclosporine A may be an alternative, and it may be compatible with concurrent administration of eculizumab.

97 Anemia Due to Acute Blood Loss

Dan L. Longo

Blood loss causes anemia by two main mechanisms: (1) by the direct loss of red cells; and (2) if the loss of blood is protracted, it will gradually deplete iron stores, eventually resulting in iron deficiency. The latter type of anemia is covered in **Chap. 93**; here, we are concerned with the former type, that is, *posthemorrhagic anemia*, which follows *acute* blood loss. This can be *external* (e.g., after trauma or obstetric hemorrhage) or *internal* (e.g., from bleeding in the gastrointestinal tract, rupture of the spleen, rupture of an ectopic pregnancy, subarachnoid hemorrhage). In any of these cases, after the sudden loss of a large amount of blood, there are three clinical/pathophysiologic stages. (1) At first, the dominant feature is hypovolemia, which poses a threat particularly to organs that normally have a high blood supply, like the brain and the kidneys; therefore, loss of consciousness and acute renal failure are major threats. It is important to note that at this stage an ordinary blood count will not show anemia because the hemoglobin concentration is not affected. (2) Next, as an emergency response, baroreceptors and stretch receptors will cause release of vasopressin and other peptides, and the body will shift fluid from the extravascular to the intravascular compartment, producing hemodilution; thus, the hypovolemia gradually converts to anemia. The degree of anemia will reflect the amount of blood lost. If after 3 days the hemoglobin is, for example, 7 g/dL, it means that about half of the entire blood has been lost. (3) Provided bleeding does not continue, the bone marrow response will gradually ameliorate the anemia. In this phase of the process, the reticulocyte count and erythropoietin levels will be elevated.

The diagnosis of acute posthemorrhagic anemia (APHA) is usually straightforward, although sometimes internal bleeding episodes (e.g., after a traumatic injury), even when large, may not be immediately obvious. Whenever an abrupt fall in hemoglobin has taken place, whatever history is given by the patient, APHA should be suspected. Supplementary history may have to be obtained by asking the appropriate questions, and appropriate investigations (e.g., a sonogram or an endoscopy) may have to be carried out.

TREATMENT

Anemia Due to Acute Blood Loss

With respect to treatment, a two-pronged approach is imperative. (1) In many cases, the blood lost needs to be replaced promptly. Unlike with many chronic anemias, when finding and correcting the cause of the anemia is the first priority and blood transfusion may not be even necessary because the body is adapted to the anemia, with acute blood loss the reverse is true; because the body is not adapted to the anemia, blood transfusion takes priority. (2) While the emergency is being confronted, it is imperative to stop the hemorrhage and to eliminate its source.

In an acute hemorrhage situation, plasma may be preferred to saline for volume expansion since dilution of clotting factors with crystalloid may interfere with hemostasis.

A special type of APHA is blood loss during and immediately after surgery, which can be substantial (e.g., up to 2 L in the case of a radical prostatectomy). Of course with elective surgical procedures, the patient's own stored blood may be available (through preoperative autologous blood donation), and in any case, blood loss ought to have been carefully monitored/measured. The fact that this blood loss is iatrogenic dictates that ever more effort should be invested in optimizing its management. **The special features of transfusion medicine are discussed in Chap. 109.**

A Holy Grail of emergency medicine for a long time has been the idea of a blood substitute that would be universally available, suitable for all recipients, easy to store and to transport, safe, and as effective as blood itself. Two main paths have been pursued: (1) fluorocarbon synthetic chemicals that bind oxygen reversibly, and (2) artificially modified hemoglobins, known as hemoglobin-based oxygen carriers (HBOCs). Although there are numerous anecdotal reports of the use of both approaches in humans, and although HBOCs have reached the stage of phase 2–3 clinical trials, no "blood substitute" has yet become standard treatment.

98 Bone Marrow Failure Syndromes Including Aplastic Anemia and Myelodysplasia

Neal S. Young

The hypoproliferative anemias are normochromic, normocytic, or macrocytic and are characterized by a low reticulocyte count. Hypoproliferative anemia is also a prominent feature of hematologic diseases that are described as bone marrow failure states; these include aplastic anemia, myelodysplastic syndrome (MDS), pure red cell aplasia (PRCA), and myelophthisis. Anemia in these disorders is often not a solitary or even the major hematologic finding. More frequent in bone marrow failure is *pancytopenia*: anemia, leukopenia, and thrombocytopenia. Low blood counts in the marrow failure diseases result from deficient hematopoiesis, as distinguished from blood count depression due to peripheral destruction of red cells (hemolytic anemias), platelets (idiopathic thrombocytopenic purpura [ITP] or due to splenomegaly), and granulocytes (as in the immune leukopenias). Marrow damage and dysfunction also may be secondary to infection, inflammation, or cancer.

Hematopoietic failure syndromes are classified by dominant morphologic features of the bone marrow **(Table 98-1)**. Although practical distinction among these syndromes usually is clear, some processes are so closely related that the diagnosis may be complex. Separation between aplastic anemia and hypocellular MDS can be particularly difficult. Further, identification of constitutional genetic risk factors

TABLE 98-1 Differential Diagnosis of Pancytopenia

Pancytopenia with Hypocellular Bone Marrow	
Acquired aplastic anemia	
Constitutional aplastic anemia (Fanconi anemia, dyskeratosis congenita, and others)	
Hypocellular myelodysplastic syndrome	
Rare aleukemic leukemia	
Some acute lymphoid leukemia	
Rare lymphomas of bone marrow	
Copper deficiency

Legionnaires' disease	
Anorexia nervosa, starvation	
Mycobacterium	

has blurred the distinction between acquired and inherited marrow failure. Patients may seem to suffer from two or three related diseases simultaneously, or one diagnosis may appear to evolve into another. Many of these syndromes share an immune-mediated mechanism of marrow destruction and some element of genomic instability resulting in a higher rate of malignant transformation.

It is important that the internist and general practitioner recognize the marrow failure syndromes, as their prognosis may be poor if the patient is untreated; effective therapies are often available but sufficiently complicated in their choice and delivery so as to warrant the care of a hematologist or oncologist. The identification of genes in which pathogenic mutations are etiologic for anemia, leukopenia, and thrombocytopenia, and the commercial availability of assays based on sophisticated DNA sequencing and functional consequences of mutations, should allow precise diagnosis early, by the primary care internist and pediatrician as well as by a specialist.

APLASTIC ANEMIA

DEFINITION

Aplastic anemia is pancytopenia with bone marrow hypocellularity. Acquired aplastic anemia is distinguished from iatrogenic aplasia, marrow hypocellularity after intensive cytotoxic chemotherapy for cancer, and from usually accidental physical and chemical injury, as in radiation poisoning. Aplastic anemia can also be constitutional. Genetic diseases such as Fanconi anemia and dyskeratosis congenita usually (but not always) present in early childhood and have typical physical anomalies. Telomere diseases (see Chap. 470) and hematologic manifestations of mutations in genes such as *GATA2*, *RUNX1*, and *MPL* can present as marrow failure in normal-appearing adults. Acquired aplastic anemia is often stereotypical in its manifestations, with the abrupt onset of low blood counts in a previously well young adult; seronegative hepatitis or a course of an incriminated medical drug may precede the onset. The diagnosis in these instances is uncomplicated. Sometimes blood count depression is moderate or incomplete, resulting in anemia, leukopenia, and thrombocytopenia in some combination. Aplastic anemia is related to both paroxysmal nocturnal hemoglobinuria (PNH; Chap. 96) and to MDS, and a clear distinction among these disorders may not be possible.

EPIDEMIOLOGY

The incidence of acquired aplastic anemia in Europe and Israel is two cases per million persons annually. In Thailand and China, rates of five to seven per million have been established. Men and women are affected with equal frequency, but the age distribution is biphasic, with the major peak in the teens and twenties and a second rise in older adults.

ETIOLOGY

The origins of aplastic anemia have been inferred from several recurring clinical associations (Table 98-2); unfortunately, these relationships are not reliable in an individual patient and may not be etiologic. In addition, although most cases of aplastic anemia are idiopathic, little other than history separates these cases from those with a presumed etiology such as a drug exposure.

Radiation Marrow aplasia is a major acute sequela of radiation. Radiation damages DNA; tissues dependent on active mitosis are

TABLE 98-2 Classification of Aplastic Anemia and Single Cytopenias

ACQUIRED	INHERITED/CONSTITUTIONAL
Aplastic Anemia	
Secondary	Fanconi anemia
Radiation	Dyskeratosis congenita/telomere disease
Drugs and chemicals	Shwachman-Diamond syndrome
Regular effects	Familial aplastic anemia/leukemia predisposition syndromes: *GATA2*, *RUNX1*, *CTLA4*, and others
Idiosyncratic reactions	
Viruses	
Epstein-Barr virus (infectious mononucleosis)	
Hepatitis (non-A, non-B, non-C hepatitis)	Nonhematologic syndromes (Down, Dubowitz, Seckel)
Parvovirus B19 (transient aplastic crisis, pure red cell aplasia [PRCA])	
HIV-1 (AIDS)	
Immune diseases	
Eosinophilic fasciitis	
Hypoimmunoglobulinemia	
Large granular lymphocytosis (LGL)	
Thymoma/thymic carcinoma	
Graft-versus-host disease in immunodeficiency	
Paroxysmal nocturnal hemoglobinuria (PNH)	
Pregnancy

Cytopenias	
PRCA (see Table 98-4)	Congenital PRCA (Diamond-Blackfan anemia)
Neutropenia/agranulocytosis	
Idiopathic	Kostmann syndrome
Drugs, toxins	Shwachman-Diamond syndrome
LGL	Reticular dysgenesis
Pure white cell aplasia (+/– thymoma)	
Thrombocytopenia	
Drugs, toxins	Amegakaryocytic thrombocytopenia
Acquired amegakaryocytic thrombocytopenia	Thrombocytopenia with absent radii
	Other rare germline mutations

particularly susceptible. Nuclear accidents involve not only power plant workers but also employees of hospitals, laboratories, and industry (food sterilization, metal radiography, etc.), as well as innocents exposed to stolen, misplaced, or misused sources. Whereas the radiation dose can be approximated from the rate and degree of decline in blood counts, dosimetry by reconstruction of the exposure can help to estimate the patient's prognosis and also to protect medical personnel from contact with radioactive tissue and excreta. MDS and leukemia, but probably not aplastic anemia, are late effects of radiation.

Chemicals Benzene is a notorious cause of bone marrow failure: epidemiologic, clinical, and laboratory data link benzene to aplastic anemia, acute leukemia, and blood and marrow abnormalities. For leukemia, incidence is correlated with cumulative exposure, but susceptibility must also be important because only a minority of even heavily exposed workers develop myelotoxicity. The employment history is important, especially in industries where benzene is used for a secondary purpose, usually as a solvent. Benzene-related blood diseases have declined with regulation of industrial exposure. Although benzene is no longer generally available as a household solvent, exposure to its metabolites occurs in the normal diet and in the environment. The association between marrow failure and other chemicals is much less well substantiated.

Drugs (Table 98-3) Many chemotherapeutic drugs have marrow suppression as a major toxicity; effects are dose dependent and will occur in all recipients. In contrast, idiosyncratic reactions to a large and diverse group of drugs may lead to aplastic anemia without a clear dose-response relationship. A large international study in Europe in the 1980s quantitated drug relationships, especially for nonsteroidal analgesics, sulfonamides, thyrostatic drugs, some psychotropics, penicillamine, allopurinol, and gold. Association does not equal causation: a drug may have been used to treat the first symptoms of bone marrow failure (antibiotics for fever or a preceding viral illness) or provoked the first symptom of a preexisting disease (petechiae by nonsteroidal anti-inflammatory agents administered to the thrombocytopenic patient). In the context of total drug use, idiosyncratic reactions, although individually devastating, are rare events. Risk estimates are usually lower when determined in population-based studies. Furthermore, the low absolute risk is also made more obvious: even a 10- or 20-fold increase in risk translates, in a rare disease, to just a handful of drug-induced aplastic anemia cases among hundreds of thousands of exposed persons.

TABLE 98-3 Some Drugs and Chemicals Associated with Aplastic Anemia

Agents that regularly produce marrow depression as major toxicity in commonly used doses or normal exposures:
Cytotoxic drugs used in cancer chemotherapy: *alkylating agents*, *antimetabolites*, *antimitotics*, some antibiotics
Agents that frequently but not inevitably produce marrow aplasia:
Benzene
Agents associated with aplastic anemia but with a relatively low probability:
Chloramphenicol
Insecticides
Antiprotozoals: *quinacrine* and chloroquine, mepacrine
Nonsteroidal anti-inflammatory drugs (including *phenylbutazone*, indomethacin, ibuprofen, sulindac, aspirin)
Anticonvulsants (*hydantoins*, *carbamazepine*, phenacemide, felbamate)
Heavy metals (*gold*, arsenic, bismuth, mercury)
Sulfonamides: some antibiotics, antithyroid drugs (methimazole, methylthiouracil, propylthiouracil), antidiabetes drugs (tolbutamide, chlorpropamide), carbonic anhydrase inhibitors (acetazolamide and methazolamide)
Antihistamines (*cimetidine*, chlorpheniramine)
D-Penicillamine
Estrogens (in pregnancy and in high doses in animals)
Agents whose association with aplastic anemia is more tenuous:
Other antibiotics (streptomycin, tetracycline, methicillin, mebendazole, trimethoprim/sulfamethoxazole, flucytosine)
Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon)
Allopurinol
Methyldopa
Quinidine
Lithium
Guanidine
Potassium perchlorate
Thiocyanate
Carbimazole

Note: Terms set in italics show the most consistent association with aplastic anemia.

Infections Posthepatitis marrow failure accounts for ~5% of etiologies in most series. Patients are usually young men who have recovered from a bout of liver inflammation 1–2 months earlier; the subsequent pancytopenia is very severe. The hepatitis is seronegative (non-A, non-B, non-C); intensive laboratory efforts including deep sequencing have not disclosed an infectious agent. Fulminant liver failure in childhood also follows seronegative hepatitis, and marrow failure occurs at a high rate in these patients. Aplastic anemia can rarely follow infectious mononucleosis. Parvovirus B19 does not usually cause generalized bone marrow failure. Transient, mild blood count depression is frequent in the course of many viral and bacterial infections.

Immunologic Diseases Aplasia is a major consequence and the inevitable cause of death in *transfusion-associated graft-versus-host disease* (GVHD) that can occur after infusion of nonirradiated blood products to an immunodeficient recipient. Aplastic anemia is strongly associated with the rare collagen vascular syndrome eosinophilic fasciitis that is characterized by painful induration of subcutaneous tissues (Chap. 353). Thymoma and hypoimmunoglobulinemia are occasional associations with aplastic anemia. Pancytopenia with marrow hypoplasia can also occur in systemic lupus erythematosus (SLE).

Pregnancy Aplastic anemia very rarely may occur and recur during pregnancy and resolve with delivery or with spontaneous or induced abortion.

Paroxysmal Nocturnal Hemoglobinuria An acquired mutation in the *PIG-A* gene in a hematopoietic stem cell is required for the development of PNH, but *PIG-A* mutations probably occur commonly in normal individuals. If the PIG-A mutant stem cell proliferates, the result is a clone of progeny deficient in glycosylphosphatidylinositol-linked cell surface membrane proteins (Chap. 96). Small clones of deficient cells can be detected by sensitive flow cytometry tests in one-half or more of patients with aplastic anemia at the time of presentation. Functional studies of bone marrow from PNH patients, even those with mainly hemolytic manifestations, show evidence of defective hematopoiesis. Patients with an initial clinical diagnosis of PNH, especially younger individuals, may later develop frank marrow aplasia and pancytopenia; patients with an initial diagnosis of aplastic anemia may suffer later from hemolytic PNH years after recovery of blood counts.

Constitutional Disorders Fanconi anemia, an autosomal recessive disorder, manifests as congenital developmental anomalies, progressive pancytopenia, and an increased risk of malignancy. Chromosomes in Fanconi anemia are susceptible to DNA cross-linking agents, the basis for a diagnostic assay. Patients with Fanconi anemia typically have short stature, café au lait spots, and anomalies involving the thumb, radius, and genitourinary tract. At least 17 different genetic defects (all but one with an identified gene) have been defined; the most common, type A Fanconi anemia, is due to a mutation in *FANCA*. Most of the Fanconi anemia gene products form a protein complex that activates FANCD2 by monoubiquitination to play a role in the cellular response to DNA damage and especially interstrand cross-linking.

Dyskeratosis congenita is characterized by the triad of mucous membrane leukoplasia, dystrophic nails, reticular hyperpigmentation, and with the development of aplastic anemia in childhood (Chapter 470). Dyskeratosis congenita is due to mutations in genes of the telomere repair complex, which acts to maintain telomere length in replicating

cells: the X-linked variety is due to mutations in the *DKC1* (*dyskerin*) gene; the more unusual autosomal dominant type is due to mutation in *TERC*, which encodes an RNA template, and *TERT*, which encodes the catalytic reverse transcriptase, telomerase. Mutations can also occur in genes like *TNF2* that encode shelterin proteins, which bind telomere DNA.

In Shwachman-Diamond syndrome, presentation is early in life with neutropenia with pancreatic insufficiency and malabsorption; most patients have compound heterozygous mutations in *SBDS* that may affect both ribosomal biogenesis (as in Diamond-Blackfan anemia; see below) and marrow stroma function.

While these constitutional syndromes can on occasion present in adults, genetic mutations are also risk factors for bone marrow failure. In the recently recognized telomeropathies **(see Chap. 470)**, mutations in *TERT* and *TERC* have subtle effects on hematopoietic function. Typical presentations include moderate aplastic anemia, which can be chronic and not progressive, and isolated macrocytic anemia or thrombocytopenia. Physical anomalies are usually not present, but early hair graying is a clue to the diagnosis. A family history may disclose pulmonary fibrosis and hepatic cirrhosis. Variable penetrance means that *TERT* and *TERC* mutations represent risk factors for marrow failure, as family members with the same mutations may have normal or only slight hematologic abnormalities but more subtle evidence of (compensated) hematopoietic insufficiency.

PATHOPHYSIOLOGY

Bone marrow failure results from severe damage to the hematopoietic cell compartment. In aplastic anemia, replacement of the bone marrow by fat is apparent in the morphology of the biopsy specimen **(Fig. 98-1)** and magnetic resonance imaging (MRI) of the spine. Cells bearing the CD34 antigen, a marker of early hematopoietic cells, are greatly diminished, and in functional studies, committed and primitive progenitor cells are virtually absent; in vitro assays have suggested that the stem cell pool is reduced to ≤1% of normal in severe disease at the time of presentation.

Constitutional Genetic Syndromes

An intrinsic stem cell defect exists for the constitutional aplastic anemias: cells from patients with Fanconi anemia exhibit chromosome damage and death on exposure to certain chemical agents. Telomeres are short in some patients with aplastic anemia, due to heterozygous mutations in genes of the telomere repair complex. Telomeres may also shorten physiologically in acquired marrow failure due to replicative demands on a limited stem cell pool.

Chemical and Drug Injury

Extrinsic damage to the marrow follows massive physical or chemical insults such as high doses of radiation and toxic chemicals. For the more common idiosyncratic reaction to modest doses of medical drugs, altered drug metabolism has been invoked as a mechanism. The metabolic pathways of many drugs and chemicals, especially if they are polar and have limited water solubility, involve enzymatic degradation to highly reactive electrophilic compounds; these intermediates are toxic because of their propensity to bind to cellular macromolecules. For example, derivative hydroquinones and quinolones are responsible for benzene-induced tissue injury. Excessive generation of toxic intermediates or failure to detoxify the intermediates may be genetically determined and apparent only on specific drug challenge; the complexity and specificity of the pathways imply multiple susceptibility loci and would provide an explanation for the rarity of idiosyncratic drug reactions.

Immune-Mediated Stem Cell Destruction

The recovery of marrow function in some patients prepared for bone marrow transplantation with antilymphocyte globulin first suggested that aplastic anemia might be immune mediated. Consistent with this hypothesis was the frequent failure of simple bone marrow transplantation from a syngeneic twin, without conditioning cytotoxic chemotherapy, which also argued both *against* simple stem cell absence as the cause and *for* the presence of a host factor producing marrow failure. Laboratory data support an important role for the immune system in aplastic anemia. Blood and bone marrow cells of patients can suppress normal hematopoietic progenitor cell growth, and removal of T cells from aplastic anemia bone marrow improves colony formation in vitro. Increased numbers of activated cytotoxic T cell clones are observed in aplastic anemia patients and usually decline with successful immunosuppressive therapy; type 1 cytokines are implicated; and interferon γ (IFN-γ) induces Fas expression on CD34 cells, leading to apoptotic cell death. The early immune system events in aplastic anemia are not well understood, but an oligoclonal, T cell response implies antigenic stimulus. The rarity of aplastic anemia despite common exposures (medicines, seronegative hepatitis) suggests that genetically determined features of the immune response can convert a normal physiologic response into a sustained abnormal autoimmune process, including polymorphisms in histocompatibility antigens, cytokine genes, and genes that regulate T cell polarization and effector function.

CLINICAL FEATURES

History

Aplastic anemia can appear abruptly or insidiously. Bleeding is the most common early symptom; a complaint of days to weeks of easy bruising, oozing from the gums, nose bleeds, heavy menstrual flow, and sometimes petechiae will have been noticed. With thrombocytopenia, massive hemorrhage is unusual, but small amounts of bleeding in the central nervous system can result in catastrophic intracranial

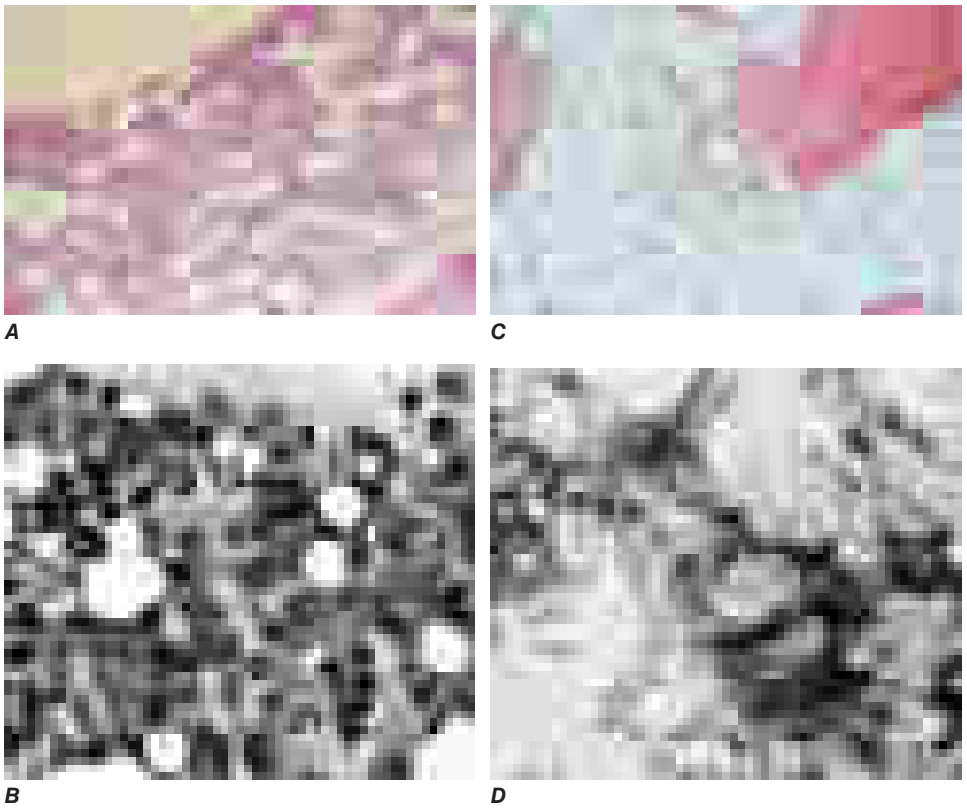

FIGURE 98-1 Normal and aplastic bone marrow. *A.* Normal bone marrow biopsy. ***B.*** Normal bone marrow aspirate smear. The marrow is normally 30–70% cellular, and there is a heterogeneous mix of myeloid, erythroid, and lymphoid cells. ***C.*** Aplastic anemia biopsy. ***D.*** Marrow smear in aplastic anemia. The marrow shows replacement of hematopoietic tissue by fat and only residual stromal and lymphoid cells.

or retinal hemorrhage. Symptoms of anemia are also frequent, including lassitude, weakness, shortness of breath, and a pounding sensation in the ears. Infection is an unusual first symptom in aplastic anemia (unlike in agranulocytosis, where pharyngitis, anorectal infection, or frank sepsis occurs early). Patients often feel and look remarkably well despite drastically reduced blood counts. Systemic complaints and weight loss should point to other etiologies of pancytopenia. Prior medical drug use, chemical exposure, and preceding viral illnesses must often be elicited with directed questioning. A family history of hematologic diseases or blood abnormalities, of pulmonary or liver fibrosis, or of early hair graying points to a telomeropathy; a family history of unusual infections and warts to *GATA2* deficiency.

Physical Examination Petechiae and ecchymoses are typical, and retinal hemorrhages may be present. Pelvic and rectal examinations can often be deferred but, when performed, should be undertaken with great gentleness to avoid trauma; these may show bleeding from the cervical os and blood in the stool. Pallor of the skin and mucous membranes is common. Infection on presentation is unusual but may occur if the patient has been symptomatic for a few weeks. Lymphadenopathy and splenomegaly are highly atypical of aplastic anemia. Café au lait spots and short stature suggest Fanconi anemia; peculiar nails and leukoplakia suggest dyskeratosis congenita; early graying (and use of hair dyes to mask it!) suggest a telomerase defect.

LABORATORY STUDIES

Blood The smear shows large erythrocytes and a paucity of platelets and granulocytes. Mean corpuscular volume (MCV) is commonly increased. Reticulocytes are absent or few, and lymphocyte numbers may be normal or reduced. The presence of immature myeloid forms suggests leukemia or MDS; nucleated red blood cells (RBCs) suggest marrow fibrosis or tumor invasion; abnormal platelets suggest either peripheral destruction or MDS.

Bone Marrow The bone marrow is usually readily aspirated but dilute on smear, and the fatty biopsy specimen may be grossly pale on withdrawal; a "dry tap" instead suggests fibrosis or myelophthisis. In severe aplasia, the smear of the aspirated specimen shows only red cells, residual lymphocytes, and stromal cells; the biopsy (which should be >1 cm in length) is superior for determination of cellularity and shows mainly fat under the microscope, with hematopoietic cells occupying <25% of the marrow space; sometimes, the biopsy is virtually all fat. The correlation between marrow cellularity and disease severity is imperfect; patients with moderate disease by blood counts can have empty iliac crest biopsies, whereas "hot spots" of hematopoiesis may be seen in severe cases. Residual hematopoietic cells should have normal morphology, except for mildly megaloblastic erythropoiesis; megakaryocytes are greatly reduced and usually absent. Granulomas may indicate an infectious etiology of the marrow failure.

Ancillary Studies Chromosome breakage studies of peripheral blood using diepoxybutane or mitomycin C should be performed on children and younger adults to exclude Fanconi anemia. Very short telomere length strongly suggests the presence of a telomerase or shelterin mutation, which can be pursued by family studies and nucleotide sequencing. Chromosome studies of bone marrow cells are often revealing in MDS, but should be negative in typical aplastic anemia. Flow cytometry offers a sensitive diagnostic test for PNH. Serologic studies may show evidence of viral infection, such as Epstein-Barr virus and HIV. Posthepatitis aplastic anemia is seronegative. Occasionally MRI may be helpful to assess the fat content of vertebrae in order to distinguish aplasia from MDS.

DIAGNOSIS

The diagnosis of aplastic anemia is usually straightforward, based on the combination of pancytopenia with a fatty bone marrow. Aplastic anemia is a disease of the young and should be a leading diagnosis in the pancytopenic adolescent or young adult. When pancytopenia is secondary, the primary diagnosis is usually obvious from either history or physical examination: the massive spleen of alcoholic cirrhosis, the history of metastatic cancer or SLE, or miliary tuberculosis on chest radiograph (Table 98-1).

Diagnostic problems can occur with atypical presentations and among related hematologic diseases. Patients with bone marrow hypocellularity may have depression of only one or two of three blood lines, with later progression to pancytopenia. The most important differential diagnosis is between acquired and constitutional aplastic anemia, and between aplastic anemia and MDS. The bone marrow in constitutional aplastic anemia is usually morphologically indistinguishable from the aspirate in acquired disease (an exception is *GATA2* deficiency with it characteristic megakaryocyte atypia). The diagnosis can be suggested by family history, abnormal blood counts since childhood, or the presence of associated physical anomalies. Many laboratories now offer genomic sequencing of a panel of etiologic germline genes, allowing for precision diagnosis. Aplastic anemia may be difficult to distinguish from the hypocellular variety of MDS: MDS is favored by finding morphologic abnormalities, particularly of megakaryocytes and myeloid precursor cells, and typical cytogenetic abnormalities. Somatic mutations can be detected on genomic screening of genes recurrently mutated in MDS, acute myeloid leukemia (AML), and myeloproliferative neoplasms (see below).

PROGNOSIS

The natural history of severe aplastic anemia is rapid deterioration and death. Historically, provision first of RBC and later of platelet transfusions and effective antibiotics were of some benefit, but few patients show spontaneous recovery. The major prognostic determinant is the blood count. Severe disease historically has been defined by the presence of two of three parameters: absolute neutrophil count <500/μL, platelet count <20,000/μL, and corrected reticulocyte count <1% (or absolute reticulocyte count <60,000/μL). In the era of effective immunosuppressive therapies, absolute numbers of reticulocytes (>25,000/μL) and lymphocytes (>1000/μL) may be better predictors of response to treatment and long-term outcome.

TREATMENT

Aplastic Anemia

Severe acquired aplastic anemia can be cured by replacement of the absent hematopoietic cells (and the immune system) by stem cell transplant, or it can be ameliorated by suppression of the immune system to allow recovery of the patient's residual bone marrow function. Glucocorticoids are not of value as primary therapy. Suspect exposures to drugs or chemicals should be discontinued; however, spontaneous recovery of severe blood count depression is rare, and a waiting period before beginning treatment may not be advisable unless the blood counts are only modestly depressed.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

This is the best therapy for the younger patient with a fully histocompatible sibling donor **(Chap. 110)**. Human leukocyte antigen (HLA) typing should be ordered as soon as the diagnosis of aplastic anemia is established in a child or younger adult. In transplant candidates, transfusion of blood from family members should be avoided so as to prevent sensitization to histocompatibility antigens. In general, limited numbers of blood products probably do not greatly affect outcome. For allogeneic transplant from fully matched siblings, long-term survival rates for children are ~90%. Transplant morbidity and mortality are increased among adults, due to the higher risk of chronic GVHD and serious infections.

Most patients do not have a suitable sibling donor. Occasionally, a full phenotypic match can be found within the family and serve as well. Far more available are other alternative donors, either unrelated but histocompatible volunteers or closely but not perfectly matched family members. High-resolution matching at HLA and more effective conditioning regimens and GVHD prophylaxis have led to improved survival rates in patients who proceed to alternative donor transplant. Survival is equivalent between matched unrelated and conventional sibling donors, although complication rates (mainly graft-versus-host disease and infection) are higher

using unrelated donors. Cord blood can be a source of stem cells especially for children. Transplantation from an HLA haploidentical family donor is increasingly popular: a donor is almost always quickly available, and post-transplant cyclophosphamide appears to be effective in preventing graft-versus-host disease. Transplant protocols for marrow failure now usually do not include radiation in order to avoid late occurrence of cancer.

IMMUNOSUPPRESSION

The standard regimen of antithymocyte globulin (ATG) in combination with cyclosporine induces hematologic recovery (independence from transfusion and a leukocyte count adequate to prevent infection) in 60–70% of patients. Children do especially well, whereas older adult patients can suffer complications due to the presence of comorbidities. An early robust hematologic response correlates with long-term survival. Improvement in granulocyte number is generally apparent within 2 months of treatment. Most recovered patients continue to have some degree of blood count depression, the MCV remains elevated, and bone marrow cellularity returns toward normal very slowly if at all. Relapse (recurrent pancytopenia) is frequent, often occurring as cyclosporine is discontinued; most, but not all, patients respond to reinstitution of immunosuppression, but some responders become dependent on continued cyclosporine administration. Development of MDS, with typical marrow morphologic, but more often cytogenetic abnormalities, occurs in ~15% of treated patients, usually but not invariably associated with a return of pancytopenia, and some patients develop leukemia. A laboratory diagnosis of PNH can generally be made at the time of presentation of aplastic anemia by flow cytometry; recovered patients may have frank hemolysis if the PNH clone expands. Bone marrow examinations should be performed if there is an unfavorable change in blood counts.

Horse ATG is administered as intravenous infusions over 4 days; rabbit ATG is much less effective, perhaps because it reduces T-regulatory cell numbers in patients. Serum sickness, a flulike illness with a characteristic cutaneous eruption and arthralgia, often develops ~10 days after initiating treatment. Methylprednisolone is administered with ATG to ameliorate the immune consequences of heterologous protein infusion. (Excessive or extended glucocorticoid therapy is associated with avascular joint necrosis.) Cyclosporine is administered orally at an initial high dose, with subsequent adjustment according to blood levels. Its most important side effects are nephrotoxicity, hypertension, and seizures.

Most patients with aplastic anemia lack a suitable marrow donor, and immunosuppression is the treatment of choice. Overall survival is equivalent with transplantation and immunosuppression. However, successful transplant cures marrow failure, whereas patients who recover adequate blood counts after immunosuppression remain at risk of relapse and malignant evolution. Because of excellent results in children and younger adults, allogeneic transplant should be performed if a suitable sibling donor is available. Increasing age and the severity of neutropenia are the most important factors weighing in the decision between transplant and immunosuppression in adults who have a matched family donor: older patients do better with ATG and cyclosporine, whereas transplant is preferred if neutrocytopenia is profound.

ELTROMBOPAG

Hematopoietic growth factors (HGFs) such as erythropoietin (EPO) and granulocyte colony-stimulating factor (G-CSF) are not effective in aplastic anemia, probably because endogenous blood levels in patients are extremely high. Circulating thrombopoietin is also elevated, but a thrombopoietin mimetic has shown unexpected activity, and eltrombopag now is approved for use in patients with refractory aplastic anemia. Robust, trilineage responses suggest action on the stem cell. Eltrombopag added to first-line immunosuppression with horse ATG markedly increased overall and complete response rates.

That outcomes following both stem cell transplant and immunosuppression have improved with time has complicated development of consensus algorithms. Children with histocompatible siblings should be offered transplant, but some have advocated for "upfront" transplants from well-matched unrelated donors. Transplant has also been extended to older patients, including from unrelated matched donors and haploidentical donors. Conversely, immunosuppression combined with stem cell stimulation may lead to responses within a few months in almost all patients and can be instituted at diagnosis. Even heavily transfused and infected patients in whom immunosuppression has failed can be salvaged by stem cell transplant later.

ANDROGENS

The effectiveness of androgens has not been verified in controlled trials, but occasional patients will respond or even demonstrate blood count dependence on continued therapy. Sex hormones upregulate telomerase gene activity in vitro, which is possibly also their mechanism of action in improving marrow function. For patients with moderate disease, especially if a telomere gene defect is present, a 3- to 4-month trial may improve all blood counts **(Chap. 470)**.

SUPPORTIVE CARE

Meticulous medical attention is required so that the patient may survive to benefit from definitive therapy or, having failed treatment, to maintain a reasonable existence in the face of pancytopenia. First and most important, infection in the presence of severe neutropenia must be aggressively treated by prompt institution of parenteral, broad-spectrum antibiotics. Therapy is empirical and must not await results of culture, although specific foci of infection such as oropharyngeal or anorectal abscesses, pneumonia, sinusitis, and typhlitis (necrotizing colitis) should be sought on physical examination and with radiographic studies. When indwelling plastic catheters become contaminated, vancomycin should be added. Persistent or recrudescent fever implies fungal disease: *Candida* and *Aspergillus* are common, especially after several courses of antibacterial antibiotics. A major reason for the improved prognosis in aplastic anemia has been the development of better antifungal drugs and the timely institution of such therapy when infection is suspected. Granulocyte transfusions using G-CSF–mobilized peripheral blood can be effective when infections are overwhelming or refractory. Hand washing, the single best method of preventing the spread of infection, remains a neglected practice. Nonabsorbed antibiotics for gut decontamination are poorly tolerated and not of proven value, nor does reverse isolation reduce mortality from infections.

Both platelet and erythrocyte numbers can be maintained by transfusion. Alloimmunization historically limited the usefulness of platelet transfusions and is now minimized by several strategies, including use of single donors to reduce exposure and physical or chemical methods to diminish leukocytes in the product; HLA-matched platelets are usually effective in patients refractory to random donor products. Inhibitors of fibrinolysis such as aminocaproic acid have not been shown to relieve mucosal oozing; the use of low-dose glucocorticoids to induce "vascular stability" is unproven and not recommended. With prophylactic platelet transfusions, the goal is to maintain the platelet count >10,000/μL (oozing from the gut increases precipitously at counts <5000/μL). Menstruation should be suppressed either by oral estrogens or nasal follicle-stimulating hormone/luteinizing hormone antagonists. Aspirin and other nonsteroidal anti-inflammatory agents must be avoided in the presence of thrombocytopenia.

RBCs should be transfused so as to allow patient a normal level of activity, usually at a hemoglobin value of 70 g/L (90 g/L if there is underlying cardiac or pulmonary disease); a regimen of 2 units every 2 weeks will replace normal losses in a patient without a functioning bone marrow. In chronic anemia, the iron chelators, deferoxamine and deferasirox, should be added at approximately the fiftieth transfusion to avoid secondary hemochromatosis.

PURE RED CELL APLASIA

Other more restricted forms of marrow failure occur, in which only a single circulating cell type is affected and the marrow shows corresponding absence or decreased numbers of specific precursor cells: aregenerative anemia as in PRCA (see below), thrombocytopenia with amegakaryocytosis **(Chap. 111)**, and neutropenia without marrow

myeloid cells in agranulocytosis (Chap. 60). In general, and in contrast to aplastic anemia and MDS, the unaffected lineages appear quantitatively and qualitatively normal. Agranulocytosis, the most frequent of these syndromes, is usually a complication of medical drug use (with agents similar to those related to aplastic anemia), either by a mechanism of direct chemical toxicity or by immune destruction. Agranulocytosis has an incidence similar to aplastic anemia but is especially frequent among older adults and in women. The syndrome should resolve with discontinuation of exposure, but significant mortality is attached to neutropenia in the older and often previously unwell patient. Both pure white cell aplasia (agranulocytosis without incriminating drug exposure) and amegakaryocytic thrombocytopenia are exceedingly rare and, like PRCA, appear to be due to destructive antibodies or lymphocytes and can respond to immunosuppressive therapies. In all of the single-lineage failure syndromes, progression to pancytopenia or leukemia is unusual.

DEFINITION AND DIFFERENTIAL DIAGNOSIS

PRCA is characterized by anemia, reticulocytopenia, and absent or rare erythroid precursor cells in the bone marrow. The classification of PRCA is shown in Table 98-4. In adults, PRCA is acquired. An identical syndrome can occur constitutionally: Diamond-Blackfan anemia, or congenital PRCA, is diagnosed at birth or in early childhood and often responds to glucocorticoid treatment; mutations in ribosome protein genes are etiologic. Temporary red cell failure occurs in transient aplastic crisis of hemolytic anemias due to acute parvovirus infection (Chap. 192) and in transient erythroblastopenia of childhood, which occurs in normal children.

TABLE 98-4 Classification of Pure Red Cell Aplasia

Self-limited
Transient erythroblastopenia of childhood
Transient aplastic crisis of hemolysis (acute B19 parvovirus infection)
Fetal red blood cell aplasia
Nonimmune hydrops fetalis (in utero B19 parvovirus infection)
Hereditary pure red cell aplasia
Congenital pure red cell aplasia (Diamond-Blackfan anemia)
Acquired pure red cell aplasia
Cancer
Thymoma
Lymphoid malignancies (and more rarely other hematologic diseases)
Paraneoplastic to solid tumors
Connective tissue disorders with immunologic abnormalities
Systemic lupus erythematosus, juvenile rheumatoid arthritis, rheumatoid arthritis
Multiple endocrine gland insufficiency
Viruses
Persistent B19 parvovirus, hepatitis, adult T cell leukemia virus, Epstein-Barr virus
Pregnancy
Drugs
Especially phenytoin, azathioprine, chloramphenicol, procainamide, isoniazid
Antibodies to erythropoietin
Idiopathic

CLINICAL ASSOCIATIONS AND ETIOLOGY

PRCA has important associations with immune system diseases. A minority of cases occur with a thymoma. More frequently, red cell aplasia can be the major manifestation of large granular lymphocytosis or complicate chronic lymphocytic leukemia. Some patients may be hypogammaglobulinemic. Occasionally (as compared to agranulocytosis), PRCA can be due to an idiosyncratic drug reaction. Subcutaneous administration of EPO has provoked PRCA mediated by neutralizing antibodies to the hormone.

Antibodies to RBC precursors are frequently present in the blood, but T cell inhibition is probably the more common immune mechanism. Cytotoxic lymphocyte activity restricted by histocompatibility locus or specific for human T-cell leukemia/lymphoma virus I–infected cells and natural killer cell activity inhibitory of erythropoiesis have been demonstrated in particularly well-studied individual cases.

PERSISTENT PARVOVIRUS B19 INFECTION

Chronic parvovirus infection is an important, treatable cause of red cell aplasia. This common virus causes a benign exanthem of childhood (fifth disease) and a polyarthralgia/arthritis syndrome in adults. In patients with underlying hemolysis (or any condition that increases demand for RBC production), parvovirus infection can cause a transient aplastic crisis and an abrupt but temporary worsening of the anemia due to failed erythropoiesis. In normal individuals, acute infection is resolved by production of neutralizing antibodies to the virus, but in the setting of congenital, acquired, or iatrogenic immunodeficiency, persistent viral infection may occur. The bone marrow shows red cell aplasia and the presence of giant pronormoblasts (Fig. 98-2), which is the cytopathic

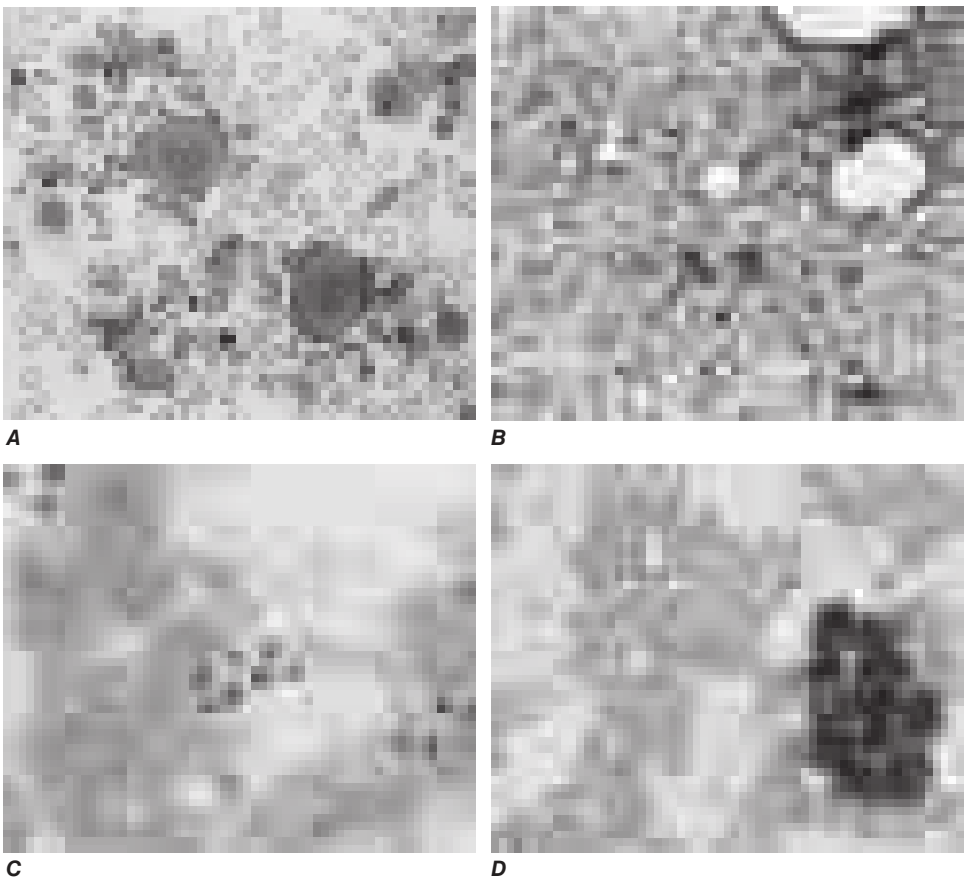

FIGURE 98-2 Pathognomonic cells in marrow failure syndromes. *A.* Giant pronormoblast, the cytopathic effect of B19 parvovirus infection of the erythroid progenitor cell. ***B.*** Uninuclear megakaryocyte and microblastic erythroid precursors typical of the 5q–myelodysplasia syndrome. ***C.*** Ringed sideroblast showing perinuclear iron granules. ***D.*** Tumor cells present on a touch preparation made from the marrow biopsy of a patient with metastatic carcinoma.

sign of B19 parvovirus infection. Viral tropism for human erythroid progenitor cells is due to its use of erythrocyte P antigen as a cellular receptor for entry. Direct cytotoxicity of virus causes anemia if demands on erythrocyte production are high; in normal individuals, the temporary cessation of red cell production is not clinically apparent, and skin and joint symptoms are mediated by immune complex deposition.

TREATMENT

Pure Red Cell Aplasia

History, physical examination, and routine laboratory studies may disclose an underlying disease or a drug exposure. Thymoma should be sought by radiographic procedures; tumor excision is indicated, but anemia does not necessarily improve with surgery. The diagnosis of parvovirus infection requires detection of viral DNA sequences in the blood (IgG and IgM antibodies are commonly absent). The presence of erythroid colonies has been considered predictive of response to immunosuppressive therapy in idiopathic PRCA.

Red cell aplasia is compatible with long-term survival with supportive care alone: a combination of erythrocyte transfusions and iron chelation. For persistent B19 parvovirus infection, almost all patients respond to intravenous immunoglobulin therapy. The majority of patients with idiopathic PRCA respond favorably to immunosuppression: glucocorticoids, cyclosporine, ATG, azathioprine, and cyclophosphamide are effective.

MYELODYSPLASIA

DEFINITION

The MDS are a heterogeneous group of hematologic disorders broadly characterized by both (1) cytopenias due to bone marrow failure and (2) a high risk of development of AML. Anemia, often with thrombocytopenia and neutropenia, occurs with dysmorphic (abnormal appearing) and usually cellular bone marrow, which is evidence of ineffective blood cell production. In patients with "low-risk" MDS, marrow failure dominates the clinical course. In other patients, myeloblasts are present at diagnosis, chromosomes are abnormal, and the "high risk" is due to leukemic progression. MDS may be fatal due, most often, to complications of pancytopenia, or to progression to leukemia, but a large proportion of patients will die of concurrent disease, the comorbidities typical in an elderly population. A useful nosology of these often confusing entities was first developed by the French-American-British Cooperative Group in 1983. Five subtypes were defined then: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML). The World Health Organization (WHO) classification (2002) recognized that the distinction between RAEB-t and AML is arbitrary and grouped them together as acute leukemia, and clarified that CMML behaves as a myeloproliferative disease. The current WHO classification of 2016 is complicated **(Table 98-5)**: blast percentage remains critical in defining MDS categories; erythroid predominant leukemias are now largely regarded as MDS; defining cytogenetic abnormalities are reaffirmed; and a single somatic mutation, in *SF3B1*, is now a feature of sideroblastic anemias. Identification of somatically mutated genes and their correlation with clinical outcomes will be increasingly important in defining classification, prognosis, and targeting therapy.

The diagnosis of MDS can be a challenge, even for the expert, because sometimes subtle clinical and pathologic features must be distinguished, and precise diagnostic categorization requires a hematopathologist knowledgeable in the latest classification scheme. Unfortunately, agreement among pathologists on morphologic features and classification is imperfect; changes in the appearance of megakaryocytes are more reliable than loss of granules in neutrophil precursors or dyserythropoiesis. Further, dysplastic changes can be observed in normal individuals, and they can occur with vitamin deficiencies and as drug effects. Genomic testing is increasingly routine and can be difficult to interpret, as in differences between somatic and germline mutations, pathogenic mutations versus those of unknown significance (clonal hematopoiesis increases in frequency with age and involves genetic changes that may be clinically silent or convey an increased risk of hematologic malignancy), and clone size and changes over time. It is important that the internist and primary care physician be sufficiently familiar with MDS to expedite referral to a hematologist because many new therapies are now available to improve hematopoietic function

TABLE 98-5 World Health Organization (WHO) Classification of Myelodysplastic Syndromes (MDS)/Neoplasms

NAME	RING SIDEROBLASTS	MYELOBLASTS	KARYOTYPE
MDS with single lineage dysplasia (MDS-SLD)	<15% (<5%)[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with multilineage dysplasia (MDS-MLD)	<15% (<5%)[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with ring sideroblasts (MDS-RS)			
MDS-RS with single lineage dysplasia (MDS-RS-SLD)	≥15% / ≥5%[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS-RS with multilineage dysplasia (MDS-RS-MLD)	≥15% / ≥5%[a]	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with isolated del(5q)	None or any	BM <5%, PB <1%, no Auer rods	del(5q) alone or with 1 additional abnormality except –7 or del (7q)
MDS with excess blasts (MDS-EB)			
MDS-EB-1	None or any	BM 5–9% or PB 2–4%, no Auer rods	Any
MDS-EB-2	None or any	BM 10–19% or PB 5–19% or Auer rods	Any
MDS, unclassifiable (MDS-U)			
· with 1% blood blasts	None or any	BM <5%, PB=1%, no Auer rods	Any
· with single lineage dysplasia and pancytopenia	None or any	BM <5%, PB=1%, no Auer rods	Any
· based on defining cytogenetic abnormality	15%	BM <5%, PB=1%, no Auer rods	MDS-defining abnormality
MDS, unclassifiable (MDS-U)			
· with 1% blood blasts	None or any	BM <5%, PB=1%, no Auer rods	Any
· with single lineage dysplasia and pancytopenia	None or any	BM <5%, PB=1%, no Auer rods	Any
· based on defining cytogenetic abnormality	15%	BM <5%, PB=1%, no Auer rods	MDS-defining abnormality
Refractory cytopenia of childhood	None	BM <5%, PB <2%	Any

[a]If *SF3B1* mutation is present.

Abbreviations: BM, bone marrow; PB, peripheral blood.

and the judicious use of supportive care can improve the patient's quality of life.

EPIDEMIOLOGY

MDS is a disease of the elderly; the mean age at onset is older than 70 years. There is a slight male preponderance. MDS is a relatively common form of bone marrow failure, with reported incidence rates of 35 to >100 per million persons in the general population and 120 to >500 per million in older adults. Estimates of incidence in the United States range from 30,000 to 40,000 new cases annually and a prevalence of 60,000–120,000 in the population. MDS is rare in children, in whom it often has an identifiable genetic basis. Secondary or therapy-related MDS is not age related. Rates of MDS have increased over time, due to better recognition of the syndrome by physicians, and an aging population.

ETIOLOGY AND PATHOPHYSIOLOGY

MDS is associated with environmental exposures such as radiation and benzene; other risk factors have been reported inconsistently. Secondary, therapy-related MDS occurs as a late toxicity of cancer treatment, radiation and the radiomimetic alkylating agents such as busulfan, nitrosourea, or procarbazine (with a latent period of 5–7 years), or the DNA topoisomerase inhibitors (2-year latency). Acquired aplastic anemia, Fanconi anemia, and other constitutional marrow failure diseases can evolve into MDS; occasionally, MDS in adults is recognized as due to germline *GATA2, RUNX1,* or telomere repair gene mutations. The typical MDS patient does not have a suggestive environmental exposure history or a preceding hematologic disease. MDS is a disease of aging, suggesting random cumulative intrinsic and environmental damage to marrow cells.

MDS is a clonal hematopoietic stem cell disorder characterized by disordered cell proliferation and impaired differentiation, resulting in cytopenias and risk of progression to leukemia. Both chromosomal and genetic instability have been implicated: both are aging-related. Cytogenetic abnormalities are found in approximately one-half of patients, and some of the same specific lesions are also seen in leukemia; aneuploidy (chromosome loss or gain) is more frequent than translocations. Accelerated telomere attrition may destabilize the genome in marrow failure and predispose to acquisition of chromosomal lesions. Cytogenetic abnormalities are not random (loss of all or part of 5, 7, and 20, trisomy of 8) and may be related to etiology (11q23 following topoisomerase II inhibitors). The type and number of cytogenetic abnormalities strongly correlate with the probability of leukemic transformation and survival.

Genomics has illuminated the role of mutations in the pathophysiology of MDS. Recurrent somatic mutations, acquired in the abnormal marrow cells and absent in the germline, have been identified in about 100 genes. Many of the same genes are also mutated in AML without MDS, whereas others are distinctive in subtypes of MDS. A prominent example of the latter is the discovery of mutations in genes of the RNA splicing machinery, especially *SF3B1*, which strongly associates with sideroblastic anemia. Some mutations correlate with prognosis: spliceosome defects with favorable outcome, and mutations in *EZH2, TP53, RUNX1*, and *ASXL1* with poor outcome. Mutations and cytogenetic abnormalities are not independent: *TP53* mutations associate with complex cytogenetic abnormalities and *TET2* mutations with normal cytogenetics. Correlation and exclusion in the pattern of mutations indicate a functional genomic architecture. Analysis of deep sequencing results in patients whose MDS evolved to AML has shown clonal succession, with founder clones acquiring additional mutations to produce clonal dominance. Furthermore, the prevalence of abnormal cells by morphology underestimates bone marrow involvement by MDS clones, as cells normal in appearance are derived from the abnormal clones. Both presenting and evolving hematologic manifestations result from the accumulation of multiple genetic lesions: loss of tumor-suppressor genes, activating oncogene, epigenetic pathways that affect mRNA processing and methylation status, or other harmful alterations. Pathophysiology has been linked to mutations and chromosome abnormalities in some specific MDS syndromes. The 5q– deletion leads to heterozygous loss of a ribosomal protein gene (ribosomal protein gene mutations cause Diamond-Blackfan anemia, like much MDS characterized by deficient erythropoiesis). An immune pathophysiology may underlie trisomy 8 MDS; selected younger MDS patients can respond to immunosuppressive therapy as administered for aplastic anemia. However, in general for MDS, the role of the immune system and its cells and cytokines; the role of the hematopoietic stem cell niche, the microenvironment, and cell–cell interactions; the fate of normal cells in the Darwinian competitive environment of the dysplastic marrow; and how mutant cells produce marrow failure in MDS are still not completely understood.

CLINICAL FEATURES

Anemia dominates the early course. Most symptomatic patients complain of the gradual onset of fatigue and weakness, dyspnea, and pallor, but at least one-half of patients are asymptomatic, and their MDS is discovered only incidentally on routine blood counts. Previous chemotherapy or radiation exposure is an important historic fact. Fever and weight loss should point to a myeloproliferative rather than myelodysplastic process. MDS in childhood is rare and, when diagnosed, implicates an underlying genetic disease. Children with Down syndrome are susceptible to MDS as well as leukemia. A family history may indicate a hereditary form of sideroblastic anemia, Fanconi anemia, or a telomeropathy. Inherited *GATA2* mutations, as in the MonoMAC syndrome (with increased susceptibility to viral, mycobacteria, and fungal infections, as well as deficient numbers of monocytes, natural killer cells, and B lymphocytes), also can cause MDS in young patients.

The physical examination is remarkable for signs of anemia; approximately 20% of patients have splenomegaly. Some unusual skin lesions, including Sweet's syndrome (febrile neutrophilic dermatosis), occur with MDS. Accompanying autoimmune syndromes are not infrequent. In the younger patient, stereotypical anomalies point to a constitutional syndrome (short stature, abnormal thumbs in Fanconi anemia; early graying in the telomeropathies; cutaneous warts in *GATA2* deficiency).

LABORATORY STUDIES

Blood Anemia is present in most cases, either alone or as part of bi- or pancytopenia; isolated neutropenia or thrombocytopenia is more unusual. Macrocytosis is common, as in most marrow failure disease. Platelets also are large and lack granules. In functional studies, they may show marked abnormalities, and patients may have bleeding symptoms despite seemingly adequate numbers. Neutrophils are hypogranulated; have hyposegmented, ringed, or abnormally segmented nuclei; contain Döhle bodies; and may be functionally deficient. Circulating myeloblasts usually correlate with marrow blast numbers, and their quantity is important for classification and prognosis. The total white blood cell count (WBC) is usually normal or low, except in chronic myelomonocytic leukemia. As in aplastic anemia, MDS can be associated with a clonal population of PNH cells. Genetic testing is commercially available for constitutional syndromes.

Bone Marrow The bone marrow is usually normal or hypercellular, but in about 20% of cases it is sufficiently hypocellular to lead to confusion with aplastic anemia. No single characteristic feature of marrow morphology distinguishes MDS, but the following are commonly observed: dyserythropoietic changes (especially nuclear abnormalities) and ringed sideroblasts in the erythroid lineage; hypogranulation and hyposegmentation in granulocytic precursors, with an increase in myeloblasts; and megakaryocytes showing reduced numbers of or disorganized nuclei. Megaloblastic nuclei and defective hemoglobinization in the erythroid lineage are common. Prognosis strongly correlates with the proportion of marrow blasts. Cytogenetic analysis and fluorescent in situ hybridization can identify chromosomal abnormalities.

DIFFERENTIAL DIAGNOSIS

Deficiencies of vitamin B_{12} or folate should be excluded by appropriate blood tests; vitamin B_6 deficiency can be assessed by a therapeutic trial of pyridoxine if the bone marrow shows ringed sideroblasts. Copper deficiency can lead to cytopenias and dysplastic marrows of varying

TABLE 98-6 International Prognostic Scoring System (IPSS)

1. New marrow blast categories
   ≤2%, >2%–<5%, 5–10%, >10–30%
2. Refined cytogenetic abnormalities and risk groups
   16 (vs 6) specific abnormalities, 5 (vs 3) subgroups[a]
3. Evaluation of depth of cytopenias[b]
   Clinically and statistically relevant cutpoints used
4. Inclusion of differentiating features
   Age, performance status, serum ferritin, LDH; β_2-microglobulin
5. Prognostic model with 5 (vs 4) risk categories
   Improved predictive power

[a]Good, normal, –Y, del(5q), del (20q); poor, complex (≥3 abnormalities) or chromosome 7 abnormalities; intermediate, all other abnormalities. [b]Cytopenias defined as hemoglobin <100 g/L, platelet count <100,000/μL, and absolute neutrophil count <1500/μL.

Abbreviation: LDH, lactate dehydrogenase.

cellularity. Marrow dysplasia can be observed in acute viral infections, drug reactions, or chemical toxicity but should be transient. More difficult are the distinctions between hypocellular MDS and aplasia or between RA with excess blasts and early acute leukemia. The WHO considers 20% blasts in the marrow as the criterion that separates AML from MDS. In young patients, underlying, predisposing genetic diseases should be considered and appropriate genomic testing performed (see above).

PROGNOSIS

The median survival varies greatly from years for patients with 5q– or sideroblastic anemia to a few months in RA with excess blasts or severe pancytopenia associated with monosomy 7. The International Prognostic Scoring System, revised in 2012 (IPSS; **Table 98-6**) assists in making predictions. Even "low-risk" MDS has significant morbidity and mortality. More refined (and also more complicated) prognostic scoring systems can separate out Int-1 risk patients who have relatively poor prognoses. Prognostic systems have been developed based on survival from diagnosis, but prognosis changes over time, and hazards ratios for survival and leukemic transformation converge over time among risk categories, consistent with dynamic changes in clonal architecture.

Most patients die as a result of complications of pancytopenia and not due to leukemic transformation; perhaps one-third succumb to diseases unrelated to their MDS. Precipitous worsening of pancytopenia, acquisition of new chromosomal abnormalities on serial cytogenetic determination, increase in the number of blasts, and marrow fibrosis are all poor prognostic indicators. The outlook in therapy-related MDS, regardless of type, is extremely poor, and most patients will progress within a few months to refractory AML.

TREATMENT

Myelodysplasia

Historically, therapy of MDS has been unsatisfactory, but several drugs may not only improve blood counts but delay onset of leukemia and improve survival. The choice of therapy for an individual patient, administration of treatment, and management of toxicities are complicated and require hematologic expertise.

Only hematopoietic stem cell transplantation offers cure of MDS. The survival rate in selected patient cohorts is ~50% at 3 years but improving. Results using unrelated matched donors are now similar to those with siblings, and patients in their fifties and sixties have been successfully transplanted. Nevertheless, treatment-related mortality and morbidity increase with recipient age. The transplant conundrum is that the high-risk patient (by IPSS score and presence of monosomal karyotype), for whom the procedure is most obviously indicated, has a high probability of a poor outcome from transplant-related mortality or disease relapse, whereas the low-risk patient, who is more likely to tolerate transplant, also may do well for years with less aggressive therapies. In practice, only a small proportion of MDS patients undergo transplantation.

MDS has been regarded as particularly refractory to cytotoxic chemotherapy regimens, and as in AML in the older adult, drug toxicity is frequent and often fatal, and remissions if achieved are brief. Low doses of cytotoxic drugs have been administered for their "differentiation" potential, and from this experience, drug therapies have emerged based on pyrimidine analogues. These drugs are classified as epigenetic modulators, believed to act through a demethylating mechanism to alter gene regulation and allow differentiation to mature blood cells from the abnormal MDS stem cell. The hypomethylating agents azacitidine and decitabine are frequently used in bone marrow failure clinics. Azacitidine improves blood counts and survival in MDS, compared to best supportive care. Azacitidine is usually administered subcutaneously, daily for 7 days, at 4-week intervals, for at least four cycles before assessing for response. Overall, generally improved blood counts with a decrease in transfusion requirements occurred in ~50% of patients in published trials. Response is dependent on continued drug administration, and most patients eventually become refractory to drug intervention and experience recurrent cytopenias or progression to AML. Decitabine is closely related to azacitidine and more potent; 30–50% of patients show responses in blood counts, with a duration of response of almost a year. Decitabine is usually administered by continuous intravenous infusion in regimens of varying doses and durations of 3–10 days in repeating cycles. The major toxicity of azacitidine and decitabine is myelosuppression, leading to worsening blood counts. Hypomethylating agents are frequently used in the high-risk patient who is not a candidate for stem cell transplant. In the lower risk patient, they are also effective, but alternative therapies should be considered.

Lenalidomide, a thalidomide derivative with a more favorable toxicity profile, is particularly effective in reversing anemia in MDS patients with 5q– syndrome; not only do a high proportion of these patients become transfusion independent with normal or near-normal hemoglobin levels, but their cytogenetics also become normal. The drug has many biologic activities, and it is unclear which is critical for clinical efficacy. Lenalidomide is administered orally. Most patients will improve within 3 months of initiating therapy. Toxicities include myelosuppression (worsening thrombocytopenia and neutropenia, necessitating blood count monitoring) and an increased risk of deep vein thrombosis and pulmonary embolism.

Immunosuppression also may produce sustained independence from transfusion and improve survival. ATG, cyclosporine, and the anti-CD52 monoclonal antibody alemtuzumab are especially effective in younger MDS patients (<60 years old) with more favorable IPSS scores and who bear the histocompatibility antigen HLA-DR15.

HGFs can improve blood counts but, as in most other marrow failure states, have been most beneficial to patients with the least severe pancytopenia. EPO alone or in combination with G-CSF can improve hemoglobin levels, particularly in those with low serum EPO levels who have no or a modest need for transfusions. Survival may be enhanced by EPO and amelioration of anemia. G-CSF treatment alone failed to improve survival in a controlled trial. Thrombopoietin mimetics appear to improve platelet counts in some MDS patients, with no clear evidence that they increase the rate of leukemic transformation.

The same principles of supportive care described for aplastic anemia apply to MDS. Many patients will be anemic for years. RBC transfusion support should be accompanied by iron chelation to prevent secondary hemochromatosis.

MYELOPHTHISIC ANEMIAS

Fibrosis of the bone marrow **(see Fig. 96-2)**, usually accompanied by a characteristic blood smear picture called *leukoerythroblastosis*, can occur as a primary hematologic disease, called *myelofibrosis* or *myeloid*

metaplasia **(Chap. 99)**, and as a secondary process, called *myelophthisis*. Myelophthisis, or secondary myelofibrosis, is reactive. Fibrosis can be a response to invading tumor cells, usually an epithelial cancer of breast, lung, or prostate origin or neuroblastoma. Marrow fibrosis may occur with infection of mycobacteria (both *Mycobacterium tuberculosis* and *Mycobacterium avium*), fungi, or HIV and in sarcoidosis. Intracellular lipid deposition in Gaucher disease and obliteration of the marrow space related to absence of osteoclast remodeling in congenital osteopetrosis also can produce fibrosis. Secondary myelofibrosis is a late consequence of radiation therapy or treatment with radiomimetic drugs. Usually the infectious or malignant underlying processes are obvious. Marrow fibrosis can also be a feature of a variety of hematologic syndromes, especially chronic myeloid leukemia, multiple myeloma, lymphomas, myeloma, and hairy cell leukemia.

The pathophysiology has three distinct features: proliferation of fibroblasts in the marrow space (myelofibrosis); the extension of hematopoiesis into the long bones and into extramedullary sites, usually the spleen, liver, and lymph nodes (myeloid metaplasia); and ineffective erythropoiesis. The etiology of the fibrosis is unknown but most likely involves dysregulated production of growth factors: platelet-derived growth factor and transforming growth factor β have been implicated. Abnormal regulation of other hematopoietins would lead to localization of blood-producing cells in nonhematopoietic tissues and uncoupling of the usually balanced processes of stem cell proliferation and differentiation. Myelofibrosis is remarkable for pancytopenia despite very large numbers of circulating hematopoietic progenitor cells.

Anemia is dominant in secondary myelofibrosis, usually normocytic and normochromic. The diagnosis is suggested by the characteristic leukoerythroblastic smear **(see Fig. 96-1)**. Erythrocyte morphology is highly abnormal, with circulating nucleated RBCs, teardrops, and shape distortions. WBC numbers are often elevated, sometimes mimicking a leukemoid reaction, with circulating myelocytes, promyelocytes, and myeloblasts. Platelets may be abundant and are often of giant size. Inability to aspirate the bone marrow, the characteristic "dry tap," can allow a presumptive diagnosis in the appropriate setting before the biopsy is decalcified.

The course of secondary myelofibrosis is determined by its etiology, usually a metastatic tumor or an advanced hematologic malignancy. Treatable causes must be excluded, especially tuberculosis and fungus. Transfusion support can relieve symptoms.

99 Polycythemia Vera and Other Myeloproliferative Neoplasms

Jerry L. Spivak

The World Health Organization (WHO) classification of the chronic myeloproliferative neoplasms (MPNs) includes eight disorders, some of which are rare or poorly characterized **(Table 99-1)** but all of which share an origin in a hematopoietic cell; overproduction of one or more of the formed elements of the blood without significant dysplasia; and a predilection to extramedullary hematopoiesis, myelofibrosis, and transformation at varying rates to acute leukemia. Within this broad classification, however, significant phenotypic heterogeneity exists. Some diseases such as chronic myelogenous leukemia (CML), chronic neutrophilic leukemia (CNL), and chronic eosinophilic leukemia (CEL) express primarily a myeloid phenotype, whereas in other diseases, such as polycythemia vera (PV), primary myelofibrosis (PMF), and essential thrombocytosis (ET), erythroid or megakaryocytic hyperplasia predominates. The latter three disorders, in contrast to the former three, also appear capable of transforming into each other.

Such phenotypic heterogeneity has a genetic basis; CML is the consequence of the balanced translocation between chromosomes 9 and 22 (t[9;22][q34;11]); CNL has been associated with a t(15;19) translocation; and CEL occurs with a deletion or balanced translocations involving the *PDGFRα* gene. By contrast, PV, PMF, and ET are characterized by driver mutations that directly or indirectly constitutively activate JAK2, a tyrosine kinase essential for the function of the erythropoietin and thrombopoietin receptors and also utilized by the granulocyte colony-stimulating factor receptor. This important distinction is reflected in the natural histories of CML, CNL, and CEL, which are usually measured in years, with a high rate of leukemic transformation. The natural histories of PV, PMF, and ET, by contrast, are usually measured in decades, and transformation to acute leukemia is uncommon in the absence of chemotherapy. This chapter focuses only on PV, PMF, and ET because their clinical features and driver mutation overlap are substantial, though their disease duration varies.

The other chronic MPNs will be discussed in Chaps. 101 and 106.

POLYCYTHEMIA VERA

PV is a clonal hematopoietic stem cell disorder in which phenotypically normal red cells, granulocytes, and platelets accumulate in the absence of a recognizable physiologic stimulus. The most common of the MPN, PV occurs in 2.5 per 100,000 persons, sparing no adult age group and increasing with age to rates over 10/100,000. Familial transmission is infrequent, and women predominate among sporadic cases.

ETIOLOGY

Nonrandom chromosome abnormalities such as deletion 20q and deletion 13q or trisomy 9 occur in up to 30% of untreated PV patients, but unlike CML, no consistent cytogenetic abnormality

has been associated with the disorder. However, a mutation in the autoinhibitory pseudokinase domain of the tyrosine kinase JAK2 that replaces valine with phenylalanine (V617F), causing constitutive kinase activation—appears to have a central role in PV pathogenesis.

JAK2 is a member of an evolutionarily well-conserved, nonreceptor tyrosine kinase family and serves as the cognate tyrosine kinase for the erythropoietin and thrombopoietin receptors. It also functions as an obligate chaperone for these receptors in the Golgi apparatus and is responsible for their cell-surface expression. The conformational change induced in the erythropoietin and thrombopoietin receptors following binding to their respective cognate ligands, erythropoietin or thrombopoietin, leads to JAK2 autophosphorylation, receptor phosphorylation, and phosphorylation of proteins involved in cell proliferation, differentiation, and resistance to apoptosis. Transgenic animals lacking *JAK2* die as embryos from severe anemia. Constitutive activation of JAK2, on the other hand, explains the erythropoietin hypersensitivity, erythropoietin-independent erythroid colony formation, rapid terminal differentiation, increased Bcl-X_L expression, and apoptosis resistance in the absence of erythropoietin that characterize the in vitro behavior of PV erythroid progenitor cells.

More than 95% of PV patients express this mutation, as do ~50% of PMF and ET patients. Importantly, the *JAK2* gene is located on the short arm of chromosome 9, and loss of heterozygosity on chromosome 9p involving the segment containing the *JAK2* locus over time due to mitotic recombination (uniparental disomy), is the most common cytogenetic abnormality in PV. Loss of heterozygosity in this region leads to homozygosity for *JAK2* V617F and occurs in ~60% of PV patients and to a lesser extent in PMF but is rare in ET. Most PV patients who do not express *JAK2* V617F express a mutation in exon 12 of the gene and are not clinically different from those who do, with the exception of a higher frequency of isolated erythrocytosis, nor do *JAK2* V617F heterozygotes differ clinically from homozygotes. Importantly, the predisposition to acquire *JAK2* mutations appears to be associated with a specific *JAK2* gene haplotype, GGCC. *JAK2* V617F is the basis for many of the phenotypic and biochemical characteristics of PV such as increased blood cell production and increased inflammatory cytokine production; however, it cannot solely account for the entire PV phenotype and is probably not the initiating lesion in any of the MPN. First, PV patients with the same phenotype and documented clonal disease can have mutations in *LNK*, a JAK2 inhibitor, or rarely, calreticulin (*CALR*), an ER chaperone. Second, ET and PMF patients have the same mutation but different clinical phenotypes. Third, familial PV can occur without the mutation, even when other members of the same family express it. Fourth, not all the cells of the malignant clone express *JAK2* V617F. Fifth, inhibition of *JAK2* V617F-expressing hematopoietic progenitor cells by the nonspecific JAK1/2 kinase inhibitor, ruxolitinib, does not affect the behavior of the involved hematopoietic stem cells. Finally, in some *JAK2* V617F–positive PV or ET patients, acute leukemia can occur in a *JAK2* V617F–negative progenitor cell, suggesting the presence of an ancestral precursor cell.

CLINICAL FEATURES

Isolated thrombocytosis, leukocytosis, or splenomegaly may be the initial presenting manifestation of PV, but most often the disorder is first recognized by the incidental discovery of a high hemoglobin, hematocrit, or red cell count. With the exception of aquagenic pruritus, no symptoms distinguish PV from other causes of erythrocytosis.

Uncontrolled erythrocytosis causes hyperviscosity, leading to neurologic symptoms such as vertigo, tinnitus, headache, visual disturbances, and transient ischemic attacks (TIA). Systolic hypertension is also a feature of the red cell mass elevation. In some patients, venous or arterial thrombosis may be the presenting manifestation of PV. Any vessel can be affected; but cerebral, cardiac, and mesenteric vessels are most commonly involved. Hepatic venous thrombosis (Budd-Chiari syndrome) is particularly common in young women and may be catastrophic if sudden and complete obstruction of the hepatic vein occurs. Indeed, PV should be suspected in any patient who develops hepatic vein thrombosis. Digital ischemia, easy bruising, epistaxis, acid-peptic disease, or gastrointestinal hemorrhage may occur due to vascular stasis or thrombocytosis. In the latter instance, absorption and proteolysis of high molecular weight von Willebrand multimers by the large platelet mass causes acquired von Willebrand disease. Erythema, burning, and pain in the extremities, a symptom complex known as erythromelalgia, is another complication of thrombocytosis in PV due to increased platelet stickiness. Given the large turnover of hematopoietic cells, hyperuricemia with secondary gout, uric acid stones, and symptoms due to hypermetabolism can also complicate the disorder.

DIAGNOSIS

When PV presents with erythrocytosis in combination with leukocytosis, thrombocytosis, or splenomegaly or any combination of these, the diagnosis is apparent. However, when patients present with an elevated hemoglobin, hematocrit, or red cell count alone, the diagnostic evaluation is more complex because of the many diagnostic possibilities **(Table 99-2)**. Furthermore, unless the hemoglobin level is ≥20 g/dL (hematocrit ≥60%), it is not possible to distinguish true erythrocytosis from disorders causing plasma volume contraction. This is because uniquely in PV, in contrast to other causes of true erythrocytosis, there is expansion of the plasma volume, which can mask the elevated red cell mass, particularly in women; thus, red cell mass and plasma volume determinations are necessary to establish the presence of an absolute erythrocytosis and distinguish this from relative erythrocytosis due to a reduction in plasma volume alone (also known as *stress* or *spurious erythrocytosis* or *Gaisböck's syndrome*). **Figure 59-18** illustrates a diagnostic algorithm for the evaluation of suspected erythrocytosis. Assay for *JAK2* mutations in the presence of a normal arterial oxygen saturation provides an alternative diagnostic approach to erythrocytosis when red cell mass and plasma volume determinations are not available; a normal serum erythropoietin level does not exclude the presence of PV, but an elevated erythropoietin level is more consistent with a secondary cause for the erythrocytosis.

Other laboratory studies that may aid in diagnosis include the red cell count, mean corpuscular volume, and red cell distribution width (RDW), particularly when the hematocrit or hemoglobin levels are less than 60% or 20 g/dL, respectively. Only three situations cause microcytic erythrocytosis: β-thalassemia trait, hypoxic erythrocytosis, and PV. With β-thalassemia trait, the RDW is usually normal, whereas with hypoxic erythrocytosis and PV, the RDW may be elevated due to associated iron deficiency. Today, however, the assay for *JAK2* V617F has

superseded other tests for establishing the diagnosis of PV. Of course, in patients with associated acid-peptic disease, occult gastrointestinal bleeding may lead to a presentation with hypochromic, microcytic anemia, masking the presence of PV.

A bone marrow aspirate and biopsy provide no specific diagnostic information because these may be normal or indistinguishable from ET or PMF. Similarly, no specific cytogenetic abnormality is associated with the disease, and the absence of a cytogenetic marker does not exclude the diagnosis.

COMPLICATIONS

Many of the clinical complications of PV relate directly to the increase in blood viscosity associated with red cell mass elevation and indirectly to the increased turnover of red cells, leukocytes, and platelets with the attendant increase in uric acid and inflammatory cytokine production. The latter appears to be responsible for constitutional symptoms. Peptic ulcer disease can also be due to *Helicobacter pylori* infection, the incidence of which is increased in PV, while the pruritus associated with this disorder may be a consequence of mast cell activation by JAK2 V617F. A sudden increase in spleen size can be associated with painful splenic infarction. Myelofibrosis appears to be part of the natural history of the disease but is a reactive, reversible process that does not itself impede hematopoiesis and by itself has no prognostic significance. In ~15% of patients, however, myelofibrosis is associated with hematopoietic stem cell failure, manifested by substantial extramedullary hematopoiesis in the liver and spleen and transfusion-dependent anemia. The organomegaly can cause significant mechanical discomfort, portal hypertension, and progressive cachexia. Although the incidence of acute myeloid leukemia is increased in PV, the incidence of acute leukemia in patients not exposed to chemotherapy or radiation therapy is low. Interestingly, chemotherapy, including hydroxyurea, has been associated with acute leukemia in *JAK2* V617F–negative stem cells in some PV patients. *Erythromelalgia* is a curious syndrome of unknown etiology associated with thrombocytosis, primarily involving the lower extremities and usually manifested by erythema, warmth, and pain of the affected appendage and occasionally digital infarction. It occurs with a variable frequency and is usually responsive to salicylates. Some of the central nervous system symptoms observed in patients with PV, such as ocular migraine, appear to represent a variant of erythromelalgia.

Left uncontrolled, erythrocytosis can lead to thrombosis involving vital organs such as the liver, heart, brain, or lungs. Patients with massive splenomegaly are particularly prone to thrombotic events because the associated increase in plasma volume masks the true extent of the red cell mass elevation measured by the hematocrit or hemoglobin level. A "normal" hematocrit or hemoglobin level in a PV patient with massive splenomegaly should be considered indicative of an elevated red cell mass until proven otherwise.

TREATMENT

Polycythemia Vera

PV is generally an indolent disorder, the clinical course of which is measured in decades, and its management should reflect its tempo. Thrombosis due to erythrocytosis is the most significant complication and often the presenting manifestation; maintenance of the hemoglobin level at ≤140 g/L (14 g/dL; hematocrit <45%) in men and ≤120 g/L (12 g/dL; hematocrit <42%) in women is mandatory to avoid thrombotic complications. Phlebotomy serves initially to reduce hyperviscosity by reducing the red cell mass to normal while further expanding the plasma volume. Periodic phlebotomies thereafter serve to maintain the red cell mass within the normal range and induce a state of iron deficiency that prevents accelerated reexpansion of the red cell mass. In most PV patients, once an iron-deficient state is achieved, phlebotomy is usually only required at 3-month intervals. Neither phlebotomy nor iron deficiency increases the platelet count relative to the effect of the disease itself, and neither thrombocytosis nor leukocytosis are correlated with thrombosis in PV, in contrast to the strong correlation between erythrocytosis and thrombosis. The use of salicylates to prevent thrombosis in PV patients is not only potentially harmful if the red cell mass is not controlled by phlebotomy, but is also an unproven remedy. Anticoagulants are indicated when a thrombosis has occurred and can be difficult to monitor if the red cell mass is substantially elevated owing to the artifactual imbalance between the test tube anticoagulant and plasma that occurs when blood from these patients is assayed for prothrombin or partial thromboplastin activity. Asymptomatic hyperuricemia (<10 mg/dL) requires no therapy, but allopurinol should be administered to avoid further elevation of the uric acid when chemotherapy is used to reduce splenomegaly or leukocytosis or to treat pruritus. Generalized pruritus intractable to antihistamines or antidepressants such as doxepin can be a major problem in PV; the JAK1/2 inhibitor, ruxolitinib, pegylated interferon α (IFN-α), psoralens with ultraviolet light in the A range (PUVA) therapy, and hydroxyurea are other methods of palliation. Asymptomatic thrombocytosis requires no therapy unless the platelet count is sufficiently high to cause bleeding due to acquired von Willebrand's disease, but bleeding in this situation is not usually spontaneous and is responsive to ε-aminocaproic acid. Symptomatic splenomegaly can be treated with either ruxolitinib or pegylated IFN-α. Pegylated IFN-α has the advantage over recombinant IFN-α of being better tolerated and requiring only weekly administration and produced complete hematologic and molecular remissions in ~20% of PV patients; its role in this disorder is currently under investigation. Anagrelide, a phosphodiesterase inhibitor, can reduce the platelet count and, if tolerated, is preferable to hydroxyurea because it lacks marrow toxicity and is also protective against venous thrombosis while hydroxyurea is not. A reduction in platelet number may be necessary for the treatment of erythromelalgia or ocular migraine if salicylates are not effective or if the platelet count is sufficiently high to increase the risk of hemorrhage, but only to the degree that symptoms are alleviated. Alkylating agents and radioactive sodium phosphate (^{32}P) are leukemogenic in PV, and their use should be avoided. If a cytotoxic agent must be used, hydroxyurea is preferred, but this drug does not prevent either thrombosis or myelofibrosis in PV, is itself leukemogenic, and should be used for as short a time as possible. Previously, PV patients with massive splenomegaly unresponsive to reduction by chemotherapy or interferon required splenectomy. However, with the introduction of the nonspecific JAK2 inhibitor ruxolitinib, it has been possible in the majority of patients with PV complicated by myelofibrosis and myeloid metaplasia to reduce spleen size while at the same time alleviating constitutional symptoms and pruritus due to cytokine release and reducing the phlebotomy requirement. Ruxolitinib has also been demonstrated in a phase three clinical trial to be effective in PV patients without myelofibrosis who are intolerant or refractory to hydroxyurea or best available supportive therapy. In some patients with end-stage disease, pulmonary hypertension may develop due to fibrosis or extramedullary hematopoiesis. A role for bone marrow transplantation, either allogeneic or haploidentical, in PV has not been defined.

Most patients with PV can live long lives without functional impairment when their red cell mass is effectively managed with phlebotomy alone. Chemotherapy is never indicated to control the red cell mass unless venous access is inadequate.

PRIMARY MYELOFIBROSIS

Chronic PMF (other designations include *idiopathic myelofibrosis*, *agnogenic myeloid metaplasia*, or *myelofibrosis with myeloid metaplasia*) is a clonal hematopoietic stem cell disorder associated with mutations in *JAK2*, *MPL* or *CALR* and characterized by marrow fibrosis, extramedullary hematopoiesis, and splenomegaly. PMF is the least common MPN, and establishing its diagnosis in the absence of a specific clonal marker is difficult because myelofibrosis and splenomegaly are also features of both PV and CML. Furthermore, myelofibrosis and splenomegaly also occur in a variety of benign and malignant disorders **(Table 99-3)**, many of which are amenable to specific therapies not effective in PMF. In contrast to the other MPN and so-called acute or malignant

TABLE 99-3 Disorders Causing Myelofibrosis

MALIGNANT	NONMALIGNANT
Acute leukemia (lymphocytic, myelogenous, megakaryocytic)	HIV infection

Polycythemia vera	
Systemic mastocytosis	

myelofibrosis, which can occur at any age, PMF primarily afflicts men in their sixth decade or later.

ETIOLOGY

Nonrandom chromosome abnormalities such as 9p, 20q−, 13q−, trisomy 8 or 9, or partial trisomy 1q are common in PMF, but no cytogenetic abnormality specific to the disease has been identified. *JAK2* V617F is present in ~50% of PMF patients, and mutations in the thrombopoietin receptor, *MPL*, occur in about 8%. Most of the rest have mutations in the calreticulin gene (*CALR*) that alter the carboxy-terminal portion of the protein, permitting it to bind and activate MPL. The degree of myelofibrosis and the extent of extramedullary hematopoiesis are not related. Fibrosis in this disorder is associated with overproduction of transforming growth factor β and tissue inhibitors of metalloproteinases, while osteosclerosis is associated with overproduction of osteoprotegerin, an osteoclast inhibitor. Marrow angiogenesis occurs due to increased production of vascular endothelial growth factor. Importantly, fibroblasts in PMF are polyclonal and not part of the neoplastic clone but can be induced by it to produce inflammatory cytokines.

CLINICAL FEATURES

No signs or symptoms are specific for PMF. Many patients are asymptomatic at presentation, and the disease is usually detected by the discovery of splenic enlargement and/or abnormal blood counts during a routine examination. In contrast to its companion MPN, night sweats, fatigue, and weight loss are common presenting complaints. A blood smear will show the characteristic features of extramedullary hematopoiesis: teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes; myeloblasts may also be present **(Fig. 99-1)**.

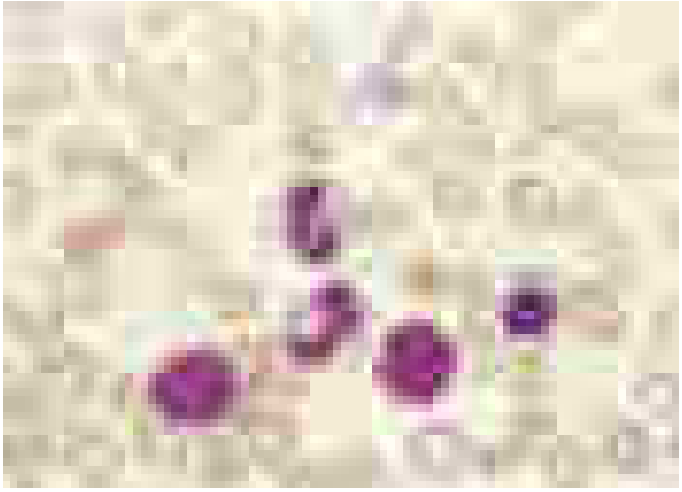

FIGURE 99-1 Teardrop-shaped red blood cells indicative of membrane damage from passage through the spleen, a nucleated red blood cell, and immature myeloid cells indicative of extramedullary hematopoiesis are noted. This peripheral blood smear is related to any cause of extramedullary hematopoiesis.

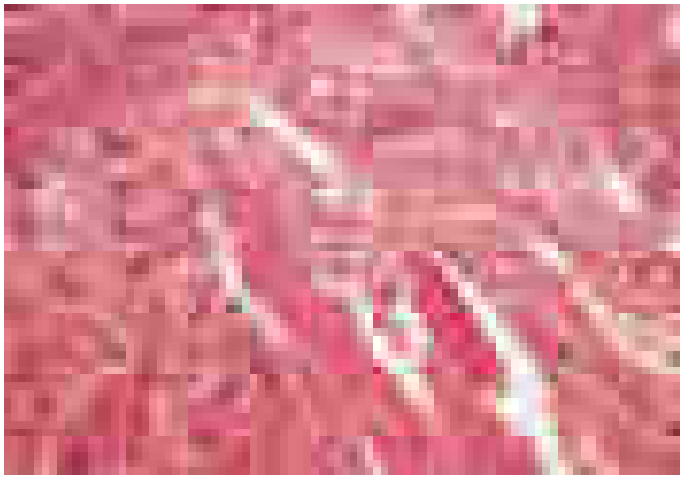

FIGURE 99-2 This marrow section shows the marrow cavity replaced by fibrous tissue composed of reticulin fibers and collagen. When this fibrosis is due to a primary hematologic process, it is called *myelofibrosis*. When the fibrosis is secondary to a tumor or a granulomatous process, it is called *myelophthisis*.

Anemia, usually mild initially, is common, whereas the leukocyte and platelet counts are either normal or increased, but either can be depressed. Mild hepatomegaly may accompany the splenomegaly but is unusual in its absence; isolated lymphadenopathy should suggest another diagnosis. Both serum lactate dehydrogenase and alkaline phosphatase levels can be elevated. Marrow is usually inaspirable due to the myelofibrosis **(Fig. 99-2)**, and bone x-rays may reveal osteosclerosis. Exuberant extramedullary hematopoiesis can cause ascites; portal, pulmonary, or intracranial hypertension; intestinal or ureteral obstruction; pericardial tamponade; spinal cord compression; or skin nodules. Splenic enlargement can be sufficiently rapid to cause splenic infarction with fever and pleuritic chest pain. Hyperuricemia and secondary gout may ensue.

DIAGNOSIS

While the clinical picture described above is characteristic of PMF, all of these clinical features can be observed in PV or CML. Massive splenomegaly commonly masks erythrocytosis in PV, and reports of intraabdominal thrombosis in PMF most likely represent instances of unrecognized PV. In some PMF patients, erythrocytosis has developed during the course of the disease. Furthermore, because many other disorders have features that overlap with PMF but respond to distinctly different therapies, the diagnosis of PMF is one of exclusion, which requires that the disorders listed in Table 99-3 be ruled out.

The presence of teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes establishes the presence of extramedullary hematopoiesis, while the presence of leukocytosis, thrombocytosis with large and bizarre platelets, and circulating myelocytes suggests the presence of an MPN as opposed to a secondary form of myelofibrosis (Table 99-3). Marrow is usually inaspirable due to increased marrow reticulin, but marrow biopsy will reveal a hypercellular marrow with trilineage hyperplasia and, in particular, increased numbers of megakaryocytes in clusters and with large, dysplastic nuclei. However, there are no characteristic bone marrow morphologic abnormalities that distinguish PMF from the other MPN. Splenomegaly due to extramedullary hematopoiesis may be sufficiently massive to cause portal hypertension and variceal formation. In some patients, exuberant extramedullary hematopoiesis can dominate the clinical picture. An intriguing feature of PMF is the occurrence of autoimmune abnormalities such as immune complexes, antinuclear antibodies, rheumatoid factor, or a positive Coombs' test. Whether these represent a host reaction to the disorder or are involved in its pathogenesis is unknown. Cytogenetic analysis of the blood is useful both to exclude CML and for prognostic purposes because the development of complex karyotype abnormalities portends a poor prognosis in PMF. For unknown reasons, the number of circulating CD34+ cells is markedly

TABLE 99-4 Three Current Scoring Systems for Estimating Prognosis in PMF Patients

[a]Blood 113:2895, 2009. [b]Blood 115:1703, 2010. [c]J Clin Oncol 29:392, 2011.

Note: The Dynamic International Prognostic Scoring System (DIPSS) was developed to determine if the International Prognostic Scoring System (IPSS) risk factors identified as important for survival at the time of primary myelofibrosis (PMF) diagnosis could also be used for risk stratification following their acquisition during the course of the disease. One point is assigned to each risk factor for IPSS scoring. For DIPSS, the same is true, but anemia is assigned 2 points. The DIPSS Plus scoring system represents recognition that the addition of unfavorable karyotype, thrombocytopenia, and transfusion dependence improved the DIPSS risk stratification system for which additional points are assigned (Table 99-5). More recent studies suggest that mutational analysis of the *ASXL1, EZH2, SRSF2*, and *IDH1/2* genes further improves risk stratification for survival and leukemic transformation (Leukemia 27:1861, 2013). These prognostic scoring systems are not accurate for risk assessment in PV or ET patients who have developed myelofibrosis (Haematologica 99:e55, 2014).

increased in PMF (>15,000/μL) compared to the other MPN, unless they too develop extramedullary hematopoiesis.

Importantly, ~50% of PMF patients, like patients with its companion MPN, express the *JAK2* V617F mutation, often as homozygotes. Such patients are usually older and have higher hematocrits than patients with *MPL* (8%) or *CALR* (30%) mutations; PMF patients expressing an *MPL* mutation tend to be more anemic and have lower leukocyte counts than *JAK2* V617F-positive patients. Somatic mutations (due to deletions [type 1] or insertions [type 2]) in exon 9 of *CALR* have been found in a majority of patients with PMF who lack mutations in either *JAK2* or *MPL*. In some studies, type 1 mutations, the most common CALR mutation in PMF, had a survival advantage compared to *JAK2* or *MPL* mutations but not with respect to leukemic transformation. PMF patients who lack a known driver mutation have the worst prognosis.

COMPLICATIONS

Survival in PMF varies according to specific risk factors at diagnosis **(Tables 99-4 and 99-5)** but is shorter than in PV and ET patients. The natural history of PMF is one of increasing marrow failure with transfusion-dependent anemia and increasing organomegaly due to extramedullary hematopoiesis. As with CML, PMF can evolve from a chronic to an accelerated phase with constitutional symptoms and increasing marrow failure. About 10% of patients spontaneously transform to an aggressive form of acute leukemia for which therapy is usually ineffective. Additional important prognostic factors for disease acceleration during the course of PMF include the presence of complex cytogenetic abnormalities, thrombocytopenia, and transfusion-dependent anemia. Mutations in the *ASXL1*, *EZH2*, *SRSF2*, and *IDH1/2* genes have been identified as risk factors for early death or transformation to acute leukemia and may prove to be more useful for PMF risk assessment than clinical scoring systems.

TABLE 99-5 IPSS and DIPSS Risk Stratification Systems

	NUMBER OF RISK FACTORS		
RISK CATEGORIES[a]	IPSS	DIPSS	DIPSS PLUS
Low	0	0	0
Intermediate-1	1	1–2	1
Intermediate-2	2	3–4	2–3
High	≥3	>4	4–6

[a]The corresponding survival curves for each risk category can be found in the references cited in the footnotes of Table 99-4.

TREATMENT

Primary Myelofibrosis

No specific therapy exists for PMF. The causes for anemia are multifarious and include ineffective erythropoiesis uncompensated by splenic extramedullary hematopoiesis, hemodilution due to splenomegaly, splenic sequestration, blood loss secondary to thrombocytopenia or portal hypertension, folic acid deficiency, systemic inflammation, and autoimmune hemolysis. Neither recombinant erythropoietin nor androgens such as danazol have proven to be consistently effective as therapy for anemia. Erythropoietin may worsen splenomegaly and will be ineffective if the serum erythropoietin level is >125 mU/L. Given the inflammatory milieu that characterizes PMF, glucocorticoids can ameliorate anemia as well as constitutional symptoms such as fever, chills, night sweats, anorexia, and weight loss, and combining these with low-dose thalidomide has proved effective as well. Thrombocytopenia can be due to impaired marrow function, splenic sequestration, or autoimmune destruction and may also respond to low-dose thalidomide and prednisone.

Splenomegaly is by far the most distressing and intractable problem for PMF patients, causing abdominal pain, portal hypertension, easy satiety, and cachexia, whereas surgical removal of a massive spleen is associated with significant postoperative complications including mesenteric venous thrombosis, hemorrhage, rebound leukocytosis and thrombocytosis, and hepatic extramedullary hematopoiesis with no amelioration of either anemia or thrombocytopenia when present. For unexplained reasons, splenectomy also increases the risk of blastic transformation. Splenic irradiation is, at best, temporarily palliative and associated with a significant risk of neutropenia, infection, and subsequent operative hemorrhage if splenectomy is attempted. Allopurinol can control significant hyperuricemia, and bone pain can be alleviated by local irradiation. Pegylated IFN-α can ameliorate fibrosis in early PMF, but in advanced disease, it may exacerbate the bone marrow failure. The JAK2 inhibitor, ruxolitinib, has proved effective in reducing splenomegaly and alleviating constitutional symptoms in a majority of advanced PMF patients while also prolonging survival, although it does not significantly influence the *JAK2* V617F neutrophil allele burden. Although anemia and thrombocytopenia are its major side effects, these are dose-dependent, and with time, anemia stabilizes and thrombocytopenia may improve. Allogeneic bone marrow transplantation is the only curative treatment for PMF and should be considered in younger patients and older patients with high risk disease; nonmyeloablative conditioning regimens may permit hematopoietic cell transplantation to be extended to older individuals, and is currently under investigation.

ESSENTIAL THROMBOCYTOSIS

ET (other designations include *essential thrombocythemia*, *idiopathic thrombocytosis*, *primary thrombocytosis*, and *hemorrhagic thrombocythemia*) is a clonal hematopoietic stem cell disorder associated with mutations in *JAK2* (V617F), *MPL*, and *CALR* and manifested clinically by overproduction of platelets without a definable cause. ET has an incidence of 1–2/100,000 and a distinct female predominance in association with *JAK2* V617F, *CALR*, and *MPL* mutations. Canonical MPN driver mutations distinguish 90% of ET patients from the more common nonclonal, reactive forms of thrombocytosis **(Table 99-6)**; mutation-negative ET patients may have an hereditary form of thrombocytosis. Once considered a disease of the elderly and responsible for significant morbidity due to hemorrhage or thrombosis, it is now clear that ET can occur at any age in adults and often without symptoms or disturbances of hemostasis. There is an unexplained female predominance in contrast to PMF or the reactive forms of thrombocytosis where no sex difference

TABLE 99-6 Causes of Thrombocytosis

Tissue inflammation: collagen vascular disease, inflammatory bowel disease	Hemorrhage
Malignancy	Iron-deficiency anemia
Infection	Surgery
Myeloproliferative disorders: polycythemia vera, primary myelofibrosis, essential thrombocytosis, chronic myelogenous leukemia	Rebound: Correction of vitamin B_{12} or folate deficiency, post-ethanol abuse
Myelodysplastic disorders: 5q–syndrome, idiopathic refractory sideroblastic anemia	Hemolysis
Postsplenectomy or hyposplenism	Familial: Thrombopoietin overproduction, *JAK2* or *MPL* mutations

exists. Because no specific clonal marker is available, clinical and laboratory criteria have been proposed to distinguish ET from other MPN, which may also present with initially with isolated thrombocytosis but have differing prognoses and therapies (Table 99-6). These criteria are useful in identifying disorders such as CML, PV, PMF, or myelodysplasia, which can masquerade as ET. Furthermore, as with "idiopathic" erythrocytosis, nonclonal benign forms of thrombocytosis exist (such as hereditary overproduction of thrombopoietin and those with noncanonical *JAK2* driver mutations) that are not widely recognized because we currently lack diagnostic assays. Approximately 55% of ET patients express *JAK2* V617F, 36% *CALR* (both type 1 and type 2) and 4% *MPL* mutations. ET patients lacking a canonical MPN driver mutation usually have a benign prognosis.

ETIOLOGY

Megakaryocytopoiesis and platelet production depend on thrombopoietin and its receptor MPL. As in the case of early erythroid and myeloid progenitor cells, early megakaryocytic progenitors require the presence of interleukin 3 (IL-3) and stem cell factor for optimal proliferation in addition to thrombopoietin. Their subsequent terminal development is also enhanced by the chemokine stromal cell-derived factor 1 (SDF-1). Interestingly, terminal megakaryocyte maturation and platelet production do not require thrombopoietin.

Megakaryocytes are unique amongst hematopoietic progenitor cells because reduplication of their genome is endomitotic rather than mitotic and promoted by thrombopoietin. Unlike erythropoietin, thrombopoietin is produced primarily in the liver and to a lesser extent in other organs, most importantly the bone marrow where it functions to maintain hematopoietic stem cells quiescent in the endosteal niche; once released, thrombopoietin promotes the proliferation of these cells in the sinusoidal niche. An inverse correlation exists between the platelet count and plasma thrombopoietin. However, again unlike erythropoietin, thrombopoietin is only constitutively produced and the plasma thrombopoietin level is controlled by the size of the megakaryocyte progenitor cell pool. Also, in contrast to erythropoietin, but like its myeloid counterparts, granulocyte and granulocyte-macrophage colony-stimulating factors, thrombopoietin not only enhances the proliferation of its target cells but also enhances the reactivity of their end-stage product, the platelet.

The clonal nature of ET was established by analysis of glucose-6-phosphate dehydrogenase isoenzyme expression in patients hemizygous for this gene. Although thrombocytosis is its principal manifestation, like the other MPN, a hematopoietic stem cell is involved in ET. Furthermore, a number of families have been described in which ET was inherited, in one instance as an autosomal dominant trait. In addition to ET, PMF and PV have also been observed in such kindreds.

CLINICAL FEATURES

Clinically, ET is most often identified incidentally when a platelet count is obtained during the course of a routine medical evaluation. Occasionally, review of previous blood counts will reveal that an elevated platelet count was present but overlooked for many years. No symptoms or signs are specific for ET, but these patients can have hemorrhagic and thrombotic tendencies expressed as easy bruising for the former and microvascular occlusive events for the latter such as erythromelalgia, ocular migraine, or a TIA. Physical examination is generally unremarkable except occasionally for mild splenomegaly. Significant splenomegaly is indicative of another MPN, in particular PV, PMF, or CML.

Anemia is unusual, but a mild neutrophilic leukocytosis is not. The blood smear is most remarkable for the number of platelets present, some of which may be very large. The large mass of circulating platelets may prevent the accurate measurement of serum potassium due to release of platelet potassium upon blood clotting. This type of hyperkalemia is a test tube artifact and not associated with electrocardiographic abnormalities. Similarly, arterial oxygen measurements can be inaccurate unless thrombocythemic blood is collected on ice. The prothrombin and partial thromboplastin times are normal, whereas abnormalities of platelet function such as a prolonged bleeding time and impaired platelet aggregation can be present. However, despite much study, no platelet function abnormality is characteristic of ET, and no platelet function test predicts the risk of clinically significant bleeding or thrombosis.

The elevated platelet count may hinder marrow aspiration, but marrow biopsy usually reveals megakaryocyte hypertrophy and hyperplasia, as well as an overall increase in marrow cellularity. If marrow reticulin is increased, another diagnosis should be considered. The absence of stainable iron demands an explanation because iron deficiency alone can cause thrombocytosis, and absent marrow iron in the presence of marrow hypercellularity is a feature of PV.

Nonrandom cytogenetic abnormalities occur in ET but are uncommon, and no specific or consistent abnormality is notable, even those involving chromosomes 3 and 1, where the genes for thrombopoietin and its receptor, MPL, respectively, are located.

DIAGNOSIS

Thrombocytosis is encountered in a broad variety of clinical disorders (Table 99-6), in many of which inflammatory cytokine production is increased. The absolute level of the platelet count is not a useful diagnostic aid for distinguishing between benign and clonal causes of thrombocytosis. About 55% of ET patients express the *JAK2* V617F mutation. When *JAK2* V617F is absent, cytogenetic evaluation is mandatory to determine if the thrombocytosis is due to CML or a myelodysplastic disorder such as the 5q– syndrome. Because the bcr-abl translocation can be present in the absence of the Ph chromosome, and because bcr-abl reverse transcriptase polymerase chain reaction is associated with false-positive results, fluorescence in situ hybridization (FISH) analysis for bcr-abl is the preferred assay in patients with thrombocytosis in whom a cytogenetic study for the Ph chromosome is negative. *CALR* (type 1 or type 2) are present in 36%, and *MPL* mutations are present in 4% respectively, of ET patients who do not have a *JAK2* mutation. Anemia and ringed sideroblasts are not features of ET, but they are features of idiopathic refractory sideroblastic anemia, and in some of these patients, the thrombocytosis occurs in association with expression of *JAK2* V617F, *CALR*, or an *MPL* mutation. Significant splenomegaly should suggest the presence of another MPN, and in this setting, a red cell mass determination should be performed because splenomegaly can mask the presence of erythrocytosis. Importantly, what appears to be ET can evolve into PV (usually in women with *JAK2* V617F) or PMF (usually in men with type 1 CALR mutations) after a period of many years due to clonal evolution or succession. There is sufficient overlap of the *JAK2* V617F neutrophil allele burden between ET and PV that this cannot be used as a distinguishing diagnostic feature; only a red cell mass and plasma volume determination can distinguish PV from ET, and importantly in this regard, 64% of *JAK2* V617F–positive ET patients in one study actually were found to have PV when red cell mass and plasma volume determinations were performed. Claims that ET and PV form a biological continuum are unfounded as these disorders have different gene expression profiles and different natural histories.

COMPLICATIONS

Perhaps no other condition in clinical medicine has caused otherwise astute physicians to intervene inappropriately more often than thrombocytosis, particularly if the platelet count is >1 × 10^6/μL. It is commonly believed that a high platelet count causes thrombosis; however, no controlled clinical study has ever established this association, and in patients younger than age 60 years, the incidence of thrombosis was not greater in patients with thrombocytosis than in age-matched controls, and tobacco use appears to be the most important risk factor for thrombosis in ET patients.

To the contrary, very high platelet counts are associated primarily with hemorrhage due to acquired von Willebrand's disease. This is not meant to imply that an elevated platelet count cannot cause symptoms in an ET patient, but rather that the focus should be on the patient, not the platelet count. For example, some of the most dramatic neurologic problems in ET are migraine-related and respond only to lowering of the platelet count, whereas other symptoms such as erythromelalgia respond simply to platelet cyclooxygenase-1 inhibitors such as aspirin or ibuprofen, without a reduction in platelet number. Still others may represent an interaction between an atherosclerotic vascular system and a high platelet count, and others may have no relationship to the platelet count whatsoever. Recognition that PV can present with thrombocytosis alone as well as the discovery of previously unrecognized causes of hypercoagulability **(Chap. 113)** make the older literature on the complications of thrombocytosis unreliable.

TREATMENT

Essential Thrombocytosis

Survival of ET patients is not different than the general population regardless of their driver mutation. An elevated platelet count in an asymptomatic patient without cardiovascular risk factors or tobacco use requires no therapy. Indeed, before any therapy is initiated in a patient with thrombocytosis, the cause of symptoms must be clearly identified as due to the elevated platelet count. When the platelet count rises above 1 × 10^6/μL, a substantial quantity of high-molecular-weight von Willebrand multimers are removed from the circulation and destroyed by the enlarged platelet mass, resulting in an acquired form of von Willebrand's disease. This can be identified by a reduction in ristocetin cofactor activity. In this situation, aspirin could promote hemorrhage. Bleeding in this situation is rarely spontaneous and usually responds to ε-aminocaproic acid, which can be given prophylactically before and after elective surgery. Plateletpheresis is at best a temporary and inefficient remedy that is rarely required. Importantly, ET patients treated with ^{32}P or alkylating agents are at risk of developing acute leukemia without any proof of benefit; combining either therapy with hydroxyurea increases this risk. If platelet reduction is deemed necessary on the basis of symptoms refractory to salicylates alone, pegylated IFN-α, the quinazoline derivative, anagrelide, or hydroxyurea can be used to reduce the platelet count, but none of these is uniformly effective or without significant side effects. Hydroxyurea and aspirin are more effective than anagrelide and aspirin for prevention of TIA because hydroxyurea is an NO donor, but not more effective for the prevention of other types of arterial thrombosis and actually less effective for venous thrombosis. The risk of gastrointestinal bleeding is also higher when aspirin is combined with anagrelide. Normalizing the platelet count does not prevent either arterial or venous thrombosis. Pegylated interferon can produce a complete molecular remission in some ET patients, but a role for it or ruxolitinib in ET management has not yet been established.

As more clinical experience is acquired, ET appears more benign than previously thought. Evolution to acute leukemia is more likely to be a consequence of therapy than of the disease itself. In managing patients with thrombocytosis, the physician's first obligation is to do no harm.

100 Acute Myeloid Leukemia

William Blum, Clara D. Bloomfield

INCIDENCE

Acute myeloid leukemia (AML) is a neoplasm characterized by infiltration of the blood, bone marrow, and other tissues by proliferative, clonal, poorly differentiated cells of the hematopoietic system. These leukemias comprise a spectrum of malignancies that, untreated, are uniformly fatal. In 2016, the estimated number of new AML cases in the United States was 19,950, comprising ~1.2% of all cancer cases. AML is the most common acute leukemia in older patients, with a median age at diagnosis of 67 years. Long-term survival is infrequent; U.S. registry data report that only 27% of patients survive 5 years.

ETIOLOGY

Most cases of AML are idiopathic. Genetic predisposition, radiation, chemical/other occupational exposures, and drugs have been implicated in the development of AML, but AML cases with established etiology are relatively rare. No direct evidence suggests a viral etiology. Genome sequencing studies suggest that most cases of AML arise from a limited number of mutations that accumulate with advancing age. Indeed, genome sequencing is providing paradigm-shifting advances in our understanding of leukemogenesis. The Cancer Genome Atlas (TCGA) and other databases demonstrate that blood cells from up to 5–6% of normal individuals aged >70 years contain potentially "premalignant" mutations that are associated with clonal expansion. The additional insults that subsequently direct "premalignant" blood cells to leukemia are quite heterogeneous and still poorly understood.

Genetic Predisposition Myeloid neoplasms typically occur sporadically in adults; inherited predisposition is rare. Yet, it is clear that myeloid neoplasms with germline predisposition represent an important and growing subset of disease. Germline mutations associated with increased risk of developing a myeloid neoplasm include *CEBPA*, *DDX41*, *RUNX1*, *ANKRD26*, *ETV6*, and *GATA2* **(Table 100-1)**. Likewise, myeloid neoplasms with germline predisposition are a feature of several well-described clinical syndromes, including bone marrow failure disorders (e.g., Fanconi anemia, Shwachman-Diamond syndrome, Diamond-Blackfan anemia), and telomere biology disorders (e.g., dyskeratosis congenita). As new mutations and associations are added to a rapidly growing list, it is increasingly clear that genetic predisposition plays a larger role than has been previously understood.

Several genetic syndromes with somatic cell chromosome aneuploidy, such as Down syndrome with trisomy 21, are associated with an increased incidence of AML. Down syndrome–associated AML in young children (<4 years) is typically of the acute megakaryocytic subtype and is associated with mutation in the *GATA1* gene. Such patients have excellent clinical outcomes but require dose modification of chemotherapy due to high treatment-related toxicities. Inherited

TABLE 100-1 WHO 2016 Classification of Myeloid Neoplasms with Germline Predisposition

CLASSIFICATION[a]
Myeloid neoplasms with germline predisposition without a preexisting disorder or organ dysfunction
Acute myeloid leukemia with germline *CEBPA* mutation
Myeloid neoplasms with germline *DDX41* mutation[b]
Myeloid neoplasms with germline predisposition and preexisting platelet disorders
Myeloid neoplasms with germline *RUNX1* mutation[b]
Myeloid neoplasms with germline *ANKRD26* mutation[b]
Myeloid neoplasms with germline *ETV6* mutation[b]
Myeloid neoplasms with germline predisposition and other organ dysfunction
Myeloid neoplasms with germline *GATA2* mutation
Myeloid neoplasms associated with bone marrow failure syndromes
Myeloid neoplasms associated with telomere biology disorders
Myeloid neoplasms associated with Noonan syndrome
Myeloid neoplasms associated with Down syndrome[b]

[a]Recognition of familial myeloid neoplasms requires that physicians take a thorough patient and family history to assess for typical signs and symptoms of known syndromes, including data on malignancies and previous bleeding episodes. Molecular genetic diagnostics is guided by a detailed patient and family history. Diagnostics should be performed in close collaboration with a genetic counselor; patients with a suspected heritable myeloid neoplasm, who test negative for known predisposition genes, should ideally be entered on a research study to facilitate new syndrome discovery. [b]Lymphoid neoplasms also reported.

TABLE 100-2 WHO 2016 Classification of Acute Myeloid Leukemia and Related Neoplasms

Acute myeloid leukemia (AML) with recurrent genetic abnormalities
AML with t(8;21)(q22;q22); RUNX1-RUNX1T1
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
Acute promyelocytic leukemia with *PML-RARA*
AML with t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*
AML with t(6;9)(p23;q34.1); *DEK-NUP214*
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2, MECOM*
AML (megakaryoblastic) with t(1;22)(p13.3;q13.3); *RBM15-MKL1*
Provisional entity: AML with BCR-ABL1
AML with mutated *NPM1*
AML with biallelic mutations of *CEBPA*
Provisional entity: AML with mutated RUNX1
AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML, not otherwise specified (NOS)
AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis (TAM)
Myeloid leukemia associated with Down syndrome

Note: Marrow blast count of ≥20% is required, except for AML with the recurrent genetic abnormalities t(15;17), t(8;21), inv(16), or t(16;16).

Source: Adapted from Arber DA et al: Acute myeloid leukaemia (AML) with recurrent genetic abnormalities, in *World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues*, update to 4th ed. IARC, 2017.

diseases with defective DNA repair (e.g., Fanconi anemia, Bloom syndrome, and ataxia-telangiectasia) are also associated with AML. Each syndrome is associated with unique clinical features and atypical toxicities with chemotherapy, requiring expert care. Congenital neutropenia (Kostmann syndrome), due to mutations in the genes encoding the granulocyte colony-stimulating factor receptor and neutrophil elastase, is another disorder that may evolve into AML.

Chemical, Radiation, and Other Exposures Anticancer drugs are the leading cause of therapy-associated AML. Alkylating agent–associated leukemias occur on average 4–6 years after exposure, and affected individuals often have multilineage dysplasia and monosomy/aberrations in chromosomes 5 and 7. Topoisomerase II inhibitor–associated leukemias occur 1–3 years after exposure, and affected individuals often have AML with monocytic features and aberrations involving chromosome 11q23. Exposure to ionizing radiation, benzene, chloramphenicol, phenylbutazone, and other drugs can uncommonly result in bone marrow failure that may evolve into AML.

CLASSIFICATION

The current categorization of AML uses the World Health Organization (WHO) classification **(Table 100-2)**, which defines biologically distinct groups based on cytogenetic and molecular abnormalities in addition to clinical features and light microscope morphology. Myeloid neoplasms with germline predisposition, as introduced above, are included as a new and important feature of this classification (Table 100-1). The WHO classification enables the identification of subsets of disease that may now (or in the future) be treated differently and advances the care of AML patients by enhancing recognition of the molecular basis of the disease from the time of diagnosis. Marrow (or blood) blast count of ≥20% is required to establish the diagnosis of AML, except for AML with the recurrent genetic abnormalities t(15;17), t(8;21), inv(16), or t(16;16).

Clinical Features Even with advances in molecular biology, recognizing clinical features remains important in understanding AML. For example, therapy-related AML is a distinct entity that develops following prior chemotherapy (e.g., alkylating agents, topoisomerase II inhibitors) or ionizing radiation. AML with myelodysplasia-related changes is recognized based in part on morphology but also on a medical history of an antecedent myelodysplastic syndrome (MDS) or myelodysplastic/myeloproliferative neoplasm. These clinical features contribute to AML prognosis and have therefore been included in the WHO classification.

Genetic Findings Subtypes of AML are recognized based on the presence or absence of specific, recurrent cytogenetic, and/or genetic abnormalities. For example, the diagnosis of *acute promyelocytic leukemia* (APL) is based on the presence of either the t(15;17)(q22;q12) cytogenetic rearrangement or the *PML-RARA* fusion product of the translocation. Similarly, core binding factor (CBF) AML is designated based on the presence of t(8;21)(q22;q22), inv(16)(p13.1q22), or t(16;16)(p13.1;q22) or the respective fusion products *RUNX1-RUNX1T1* and *CBFB-MYH11*. Each of these groups identifies patients with favorable clinical outcomes when appropriately treated.

Several cytogenetic or genetic AML subtypes often associate with a specific morphologic appearance, such as a complex karyotype and AML with myelodysplasia-related changes. Patients with such changes typically fare poorly with standard treatments. However, only one cytogenetic abnormality is invariably associated with specific morphologic features: t(15;17)(q22;q12) with APL. Other cytogenetic and genetic findings may be commonly but not invariably associated with a morphological description, highlighting the necessity of genetic and cytogenetic testing beyond simple morphology to most accurately diagnose AML. Several chromosomal abnormalities often associate primarily with one morphologic/immunophenotypic group. Examples include inv(16)(p13.1q22) with AML with abnormal bone marrow eosinophils; t(8;21)(q22;q22) with slender Auer rods, expression of CD19, and increased normal eosinophils; and t(9;11)(p22;q23), and other

translocations involving 11q23, with monocytic features. Recurring chromosomal abnormalities in AML may also be loosely associated with specific clinical characteristics. More commonly associated with younger age are t(8;21) and t(15;17), and with older age, del(5q) and del(7q). Myeloid sarcomas are associated with t(8;21); disseminated intravascular coagulation (DIC) is associated with t(15;17). 11q23 aberrations and monocytic leukemia are associated with extramedullary sites of involvement at presentation, especially gingival hypertrophy.

The WHO classification also incorporates molecular abnormalities by recognizing fusion genes or specific genetic mutations with a role in leukemogenesis. As a classic example, t(15;17) results in the fusion gene *PML-RARA* that encodes a chimeric protein, promyelocytic leukemia (Pml)–retinoic acid receptor α (Rarα), which is formed by the fusion of the retinoic acid receptor α (*RARA*) gene from chromosome 17 and the promyelocytic leukemia (*PML*) gene from chromosome 15. The *RARA* gene encodes a member of the nuclear hormone receptor family of transcription factors. *PML* is important in many cellular processes, including cell growth control, apoptosis, and senescence; its effects are mediated at least in part by nuclear bodies that store a myriad of proteins/enzymes that are involved in these functions. The PML-RARA fusion protein suppresses gene transcription and blocks differentiation beyond the promyelocyte stage. Pharmacologic concentrations of the Rarα ligand, achieved with the drug all-*trans*-retinoic acid (tretinoin, ATRA), relieve the block and promote hematopoietic cell differentiation. However, the effects of ATRA are not primarily from direct restoration of gene transactivation via RA signaling. Rather, drug treatment induces degradation of the fusion protein. Mechanistic work has demonstrated that the RARA fusion partner PML is far more important in the pathobiology than was initially understood. PML-RARA disturbs nuclear body assembly. This impairs many PML functions, culminating in enhanced self-renewal of leukemic cells. ATRA and arsenic trioxide (ATO) both induce PML-RARA degradation (by different mechanisms), leading to reformation of PML nuclear bodies (or enhanced nuclear body activity). Restored PML functions include the activation of p53 which triggers senescence in leukemic cells. Clinical therapy with ATRA and ATO has revolutionized the care of APL patients (see "Treatment of Acute Promyelocytic Leukemia" section).

Similar examples of molecular subtypes included in the category of AML with recurrent genetic abnormalities are those characterized by the leukemogenic fusion genes *RUNX1-RUNX1T1*, *CBFB-MYH11*, *MLLT3-KMT2A*, and *DEK-NUP214*, resulting, respectively, from t(8;21), inv(16) or t(16;16), t(9;11), and t(6;9)(p23;q34).

The WHO classification of AML continues to expand as knowledge of specific genetic or cytogenetic aberrations grows. Several AML subtypes are defined by the presence of genetic mutations rather than chromosomal aberrations including, for example, *AML with mutated nucleophosmin (nucleolar phosphoprotein B23, numatrin)* (*NPM1*) and *AML with biallelic mutated CEBPA*, respectively. Both entities are associated with more favorable clinical outcomes, though the *NPM1* prognostic impact is affected by coexisting mutation in fms-related tyrosine kinase 3 (*FLT3*). Activating mutations of *FLT3* are present in ~30% of adult AML patients, primarily due to internal tandem duplications (ITD) in the juxtamembrane domain that have negative prognostic impact. In contrast, point mutations of the activating loop of the kinase (called tyrosine kinase domain [TKD] mutations) have uncertain prognostic impact. Aberrant activation of the *FLT3*-encoded protein provides increased proliferation and antiapoptotic signals to the myeloid progenitor cell. *FLT3*-ITD, the more common of the *FLT3* mutations, occurs preferentially in patients with cytogenetically normal AML (CN-AML). The importance of identifying *FLT3*-ITD at diagnosis relates to the fact that is it useful not only as a prognosticator but also may predict response to specific treatment such as a tyrosine kinase inhibitor (TKI); several TKI are currently in clinical investigation (e.g., midostaurin, quizartinib, gilteritinib, crenolanib, sorafenib). The *FLT3* allelic ratio (of the number of mutated alleles to wild type alleles) provides information beyond the mere presence or absence of the mutation. The ratio is affected by several mutational scenarios such as one mutated gene and one wild type gene, or one mutated gene with no (deleted) wild type gene, and the ratio of malignant to nonmalignant cells in the sample.

TABLE 100-3 2017 European LeukemiaNet Risk Stratification by Genetics for Acute Myeloid Leukemia[a]

RISK CATEGORY[b]	GENETIC ABNORMALITY
Favorable	t(8;21)(q22;q22); *RUNX1-RUNX1T1*
	inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
	Mutated *NPM1* without *FLT3*-ITD or with *FLT3*-ITD$^{low(c)}$
	Biallelic mutated *CEBPA*
Intermediate	Mutated *NPM1* and *FLT3*-ITD$^{high(c)}$
	Wild type *NPM1* without *FLT3*-ITD or with *FLT3*-ITD$^{low(c)}$ (w/o adverse-risk genetic lesions)
	t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*[d]
	Cytogenetic abnormalities not classified as favorable or adverse
Adverse	t(6;9)(p23;q34.1); *DEK-NUP214*
	t(v;11q23.3); *KMT2A* rearranged
	t(9;22)(q34.1;q11.2); *BCR-ABL1*
	inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); *GATA2, MECOM(EVI1)*
	–5 or del(5q); –7; –17/abn(17p)
	Complex karyotype,[e] monosomal karyotype[f]
	Wild type *NPM1* and *FLT3*-ITD$^{high(c)}$
	Mutated *RUNX1*[g]
	Mutated *ASXL1*[g]
	Mutated *TP53*[h]

[a]This table excludes acute promyelocytic leukemia. Frequencies, response rates, and outcome measures should be reported by risk category, and, if sufficient numbers are available, by specific genetic lesions indicated. [b]Prognostic impact of a marker is treatment-dependent and may change with new therapies. [c]Low, low allelic ratio (<0.5); high, high allelic ratio (≥0.5); semiquantitative assessment of *FLT3*-ITD allelic ratio (using DNA fragment analysis) is determined as ratio of the area under the curve (AUC) "*FLT3*-ITD" divided by AUC "*FLT3*-wild type"; recent studies indicate that acute myeloid leukemia with *NPM1* mutation and *FLT3*-ITD low allelic ratio may also have a more favorable prognosis and patients should not routinely be assigned to allogeneic hematopoietic-cell transplantation. [d]The presence of t(9;11)(p21.3;q23.3) takes precedence over rare, concurrent adverse-risk gene mutations. [e]Three or more unrelated chromosome abnormalities in the absence of one of the World Health Organization-designated recurring translocations or inversions, i.e., t(8;21), inv(16) or t(16;16), t(9;11), t(v;11)(v;q23.3), t(6;9), inv(3) or t(3;3); AML with *BCR-ABL1*. [f]Defined by the presence of one single monosomy (excluding loss of X or Y) in association with at least one additional monosomy or structural chromosome abnormality (excluding core-binding factor AML). [g]These markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes. [h]*TP53* mutations are significantly associated with AML with complex and monosomal karyotype.

Source: Adapted from Döhner H et al: Diagnosis and management of acute myeloid leukemia in adults: 2017 recommendations from an international expert panel, on behalf of the European LeukemiaNet. Blood 129:424, 2017.

The allelic ratio affects the prognostic impact of the *FLT3*-ITD mutation; patients with *FLT3*-ITD "low" allelic ratio (<0.5) fare better. Accordingly, mutated *NPM1* without *FLT3*-ITD or with *FLT3*-ITD^{low} are both viewed as favorable-risk by the European LeukemiaNet (ELN) risk stratification schema **(Table 100-3)**. Conversely, *FLT3*-ITD^{high} is known to have an adverse prognostic impact; patients with mutated *NPM1* and *FLT3*-ITD with an allelic ratio >0.5 are thus intermediate-risk by ELN stratification. Involving a different tyrosine kinase, AML with *BCR-ABL1* fusion is a new WHO provisional entity, to recognize rare cases that may benefit from *BCR-ABL* TKI therapy (Table 100-2).

Immunophenotypic Findings The immunophenotype of human leukemia cells can be studied by multiparameter flow cytometry after the cells are labeled with monoclonal antibodies to cell-surface antigens. This can be important in quickly distinguishing AML from acute lymphoblastic leukemia and for identifying some subtypes of AML. For example, AML with minimal differentiation, characterized by immature morphology and no lineage-specific cytochemical reactions, may be diagnosed by flow-cytometric demonstration of the myeloid-specific antigens cluster designation (CD) 13 and/or 117. Similarly, acute megakaryoblastic leukemia can often be diagnosed only by expression of the platelet-specific antigens CD41 and/or CD61.

Although flow cytometry is widely used, and in some cases essential for the diagnosis of AML, it has only a supportive role in establishing the different subtypes of AML through the WHO classification. Increasingly, multiparameter flow cytometry is used for the measurement of minimal residual disease (MRD) after remission is achieved.

PROGNOSTIC FACTORS

Several factors predict outcome of AML patients treated with chemotherapy; they should be used for risk stratification and treatment guidance.

Chromosome findings at diagnosis currently provide the most important independent prognostic information. Several reports have categorized patients as having favorable, intermediate, or adverse cytogenetic risk based on the presence of structural and/or numerical aberrations. Patients with t(15;17) have a very good prognosis (~85% cured), and those with t(8;21) and inv(16) have a good prognosis (~55% cured), whereas those with no cytogenetic abnormality have an intermediate outcome risk (~40% cured). Patients with a complex karyotype, t(6;9), inv(3), or –7 have a very poor prognosis. Another cytogenetic subgroup, the monosomal karyotype, has been suggested to adversely impact the outcome of AML patients other than those with t(15;17), t(8;21), or inv(16) or t(16;16). The monosomal karyotype subgroup is defined by the presence of at least two autosomal monosomies (loss of chromosomes other than Y or X) or a single autosomal monosomy with additional structural abnormalities.

For patients lacking prognostic cytogenetic abnormalities, such as those with CN-AML, testing for several mutated genes can help to risk-stratify. In addition to the *NPM1* mutation and/or *FLT3*-ITD as described above, biallelic *CEBPA* mutations have prognostic value. Such mutations predict favorable outcome. Given the proven prognostic importance of *NPM1*, *CEBPA*, and *FLT3*, molecular assessment of these genes at diagnosis has been incorporated into AML management guidelines by the National Comprehensive Cancer Network (NCCN) and the ELN. The same markers help to define genetic groups in the ELN standardized reporting system, which is based on both cytogenetic and molecular abnormalities and is used for comparing clinical features/treatment response among subsets of patients reported across different clinical studies (Table 100-3). These genetic groups should be used for risk stratification and treatment guidance.

In addition to *NPM1* and *CEBPA* mutations and *FLT3*-ITD, molecular aberrations in other genes may be routinely used for prognostication in the future **(Table 100-4)**. Among these mutated genes are those encoding receptor tyrosine kinases (e.g., v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog [*KIT*]), transcription factors (i.e., *RUNX1* and Wilms tumor 1 [*WT1*]), and epigenetic modifiers (i.e., additional sex combs like transcriptional regulator 1 [*ASXL1*], DNA (cytosine-5-)-methyltransferase 3 alpha [*DNMT3A*], isocitrate dehydrogenase 1 [NADP+], soluble [*IDH1*], isocitrate dehydrogenase 2 (NADP+), mitochondrial [*IDH2*], lysine (K)–specific methyltransferase 2A [*KMT2A*, also known as *MLL*], and tet methylcytosine dioxygenase 2 [*TET2*]). Although *KIT* mutations are almost exclusively present in CBF AML and impact adversely the outcome, the remaining markers have been reported primarily in CN-AML. These gene mutations have been shown to be associated with outcome in multivariable analyses independent of other prognostic factors. However, for some of them, data remain unclear on the prognostic impact due to conflicting reports (e.g., *TET2*, *IDH1*, *IDH2*). Increasingly, novel drugs that inhibit/modulate aberrant pathways activated by some of these genes (e.g., *IDH1*, *IDH2*, *KMT2A*, among others) are being incorporated into clinical trials to treat AML.

In addition to gene mutations, deregulation of the expression levels of coding genes and of short noncoding RNAs (microRNAs) also provide prognostic information (Table 100-4). Overexpression of genes such as brain and acute leukemia, cytoplasmic (*BAALC*), v-ets avian erythroblastosis virus E26 oncogene homologue (avian) (*ERG*), meningioma (disrupted in balanced translocation) 1 (*MN1*), and MDS1 and EVI1 complex locus (*MECOM*, also known as *EVI1*) predict poor outcome, especially in CN-AML. Similarly, deregulated expression levels of microRNAs, naturally occurring noncoding RNAs that regulate the expression of proteins via degradation or translational inhibition of their target coding RNAs, have also been associated with prognosis in AML. Overexpression of *miR-155* and *miR-3151* predicts unfavorable outcome in CN-AML, whereas overexpression of *miR-181a* predicts favorable outcome both in CN-AML and cytogenetically abnormal AML.

Because prognostic molecular markers in AML are not mutually exclusive and often occur concurrently (>80% patients have at least two or more prognostic gene mutations), the likelihood that distinct marker combinations may be more informative than single markers is increasingly clear.

Epigenetic changes (e.g., DNA methylation and/or post-translational histone modification) and microRNAs are often involved in deregulation of genes involved in hematopoiesis, contribute to leukemogenesis and may associate with the previously discussed prognostic gene mutations. These changes have been shown to provide biologic insights into leukemogenic mechanisms and also independent prognostic information. Indeed, it is anticipated that with the enormous progress made in DNA and RNA sequencing technology, additional genetic and epigenetic aberrations will soon be discovered, further improving classification and risk-stratification in AML patients.

In addition to cytogenetics and molecular aberrations, several other factors are associated with outcome in AML. Age at diagnosis is one of the most important risk factors. Advancing age is associated with a poor prognosis for two reasons: (1) its influence on the ability to survive induction therapy due to coexisting medical comorbidities, and (2) with each successive decade of age, a greater proportion of patients have intrinsically more resistant disease. A prolonged symptomatic interval with cytopenias preceding AML diagnosis, or a history of antecedent

TABLE 100-4 Molecular Prognostic Markers in AML[a]

GENE SYMBOL	GENE LOCATION	PROGNOSTIC IMPACT
Genes Included in the WHO Classification and ELN Reporting System		
NPM1 mutations	5q35.1	Favorable
CEBPA mutations	19q13.1	Favorable
FLT3-ITD	13q12	Depends on allelic ratio and *NPM1* mutational status
Genes Encoding Receptor Tyrosine Kinases		
KIT mutation	4q12	Adverse
FLT3-TKD	13q12	Unclear
Genes Encoding Transcription Factors		
RUNX1 mutations	21q22.12	Adverse
WT1 mutations	11p13	Adverse
Genes Encoding Epigenetic Modifiers		
ASXL1 mutations	20q11.21	Adverse
DNMT3A mutations	2p23.3	Adverse
IDH mutations (*IDH1* and *IDH2*)	2q34 & 15q26.1	Adverse
KMT2A-PTD	11q23	Adverse
TET2 mutations	4q24	Adverse
Deregulated Genes		
BAALC overexpression	8q22.3	Adverse
ERG overexpression	21q22.3	Adverse
MN1 overexpression	22q12.1	Adverse
EVI1 overexpression	3q26.2	Adverse
Deregulated MicroRNAs		
miR-155 overexpression	21q21.3	Adverse
miR-3151 overexpression	8q22.3	Adverse
miR-181a overexpression	1q32.1 and 9q33.3	Favorable

[a]This table excludes acute promyelocytic leukemia.

Abbreviations: AML, acute myeloid leukemia; ELN, European LeukemiaNet; ITD, internal tandem duplication; PTD, partial tandem duplication; TKD, tyrosine kinase domain; WHO, World Health Organization.

hematologic disorders including MDS or myeloproliferative neoplasms, is often found in older patients. Cytopenia is a clinical feature associated with a lower complete remission (CR) rate and shorter survival time. The CR rate is lower in patients who have had anemia, leukopenia, and/or thrombocytopenia for >3 months before the diagnosis of AML, when compared to those without such a history. Responsiveness to chemotherapy declines as the duration of the antecedent disorder increases. Likewise, AML developing after treatment with cytotoxic agents for other malignancies is usually difficult to treat successfully. In addition, older patients less frequently harbor favorable cytogenetic abnormalities (i.e., t[8;21], inv[16], and t[16;16]) and more frequently harbor adverse cytogenetic (e.g., complex and monosomal karyotypes) and/or molecular (e.g., *ASXL1*, *p53*) abnormalities.

Other factors independently associated with worse outcome are a poor performance status that influences ability to survive induction therapy and a high presenting leukocyte count that in some series is an adverse prognostic factor for attaining a CR. Among patients with hyperleukocytosis (>100,000/μL), early central nervous system bleeding and pulmonary leukostasis contribute to poor outcomes.

Following administration of therapy, achievement of CR is associated with better outcome and longer survival. CR is defined after examination of both blood and bone marrow and essentially represents both eradication of detectable leukemia and restoration of normal hematopoiesis. The blood neutrophil count must be ≥1000/μL and the platelet count ≥100,000/μL. Hemoglobin concentration is not considered in determining CR. Circulating blasts should be absent. Although rare blasts may be detected in the blood during marrow regeneration, they should disappear on successive studies. At CR, the bone marrow should contain <5% blasts, and Auer rods should be absent. Extramedullary leukemia should not be present.

CLINICAL PRESENTATION

Symptoms Patients with AML usually present with nonspecific symptoms that begin gradually, or abruptly, and are the consequence of anemia, leukocytosis, leukopenia/leukocyte dysfunction, or thrombocytopenia. Nearly half have symptoms for ≤3 months before the leukemia is diagnosed.

Fatigue is a frequent first symptom among AML patients. Anorexia and weight loss are common. Fever with or without an identifiable infection is the initial symptom in ~10% of patients. Signs of abnormal hemostasis (bleeding, easy bruising) are common. Bone pain, lymphadenopathy, nonspecific cough, headache, or diaphoresis may also occur.

Rarely, patients may present with symptoms from a myeloid sarcoma (a tumor mass consisting of myeloid blasts occurring at anatomic sites other than bone marrow). Sites involved are most commonly the skin, lymph node, gastrointestinal tract, soft tissue, and testis. This rare presentation, often characterized by chromosome aberrations (e.g., monosomy 7, trisomy 8, 11q23 rearrangement, inv[16], trisomy 4, t[8;21]), may precede or coincide with blood and/or marrow involvement by AML. Patients who present with isolated myeloid sarcoma typically develop blood and/or marrow involvement quickly thereafter and cannot be cured with local therapy (radiation or surgery) alone.

Physical Findings Fever, infection, and hemorrhage are often found at the time of diagnosis; splenomegaly, hepatomegaly, lymphadenopathy, and "bone pain" may also be present less commonly. Hemorrhagic complications are most commonly and, classically, found in APL. APL patients often present with DIC-associated minor hemorrhage but may have significant gastrointestinal bleeding, intrapulmonary hemorrhage, or intracranial hemorrhage. Likewise, thrombosis is another less frequent but well recognized clinical feature of DIC in APL. Bleeding associated with coagulopathy may also occur in monocytic AML and with extreme degrees of leukocytosis or thrombocytopenia in other morphologic subtypes. Retinal hemorrhages are detected in 15% of patients. Infiltration of the gingiva, skin, soft tissues, or meninges with leukemic blasts at diagnosis is characteristic of the monocytic subtypes and those with 11q23 chromosomal abnormalities.

Hematologic Findings Anemia is usually present at diagnosis though it is not typically severe. The anemia is usually normocytic normochromic. Decreased erythropoiesis in the setting of AML often results in a reduced reticulocyte count, and red blood cell (RBC) survival is decreased by accelerated destruction. Active blood loss may rarely contribute to the anemia.

The median presenting leukocyte count is ~15,000/μL. Lower presenting leukocyte counts are more typical of older patients and those with antecedent hematologic disorders. Between 25 and 40% of patients have counts <5000/μL, and 20% have counts >100,000/μL. Fewer than 5% have no detectable leukemic cells in the blood. In AML, the cytoplasm often contains primary (nonspecific) granules, and the nucleus shows fine, lacy chromatin with one or more nucleoli characteristic of immature cells. Abnormal rod-shaped granules called Auer rods are not uniformly present, but when they are, AML is virtually certain **(Fig. 100-1)**.

Platelet counts <100,000/μL are found at diagnosis in ~75% of patients, and ~25% have counts <25,000/μL. Both morphologic and functional platelet abnormalities can be observed, including large and bizarre shapes with abnormal granulation and inability of platelets to aggregate or adhere normally to one another.

Pretreatment Evaluation Once the diagnosis of AML is suspected, thorough evaluation and initiation of appropriate therapy should follow. In addition to clarifying the subtype of leukemia, initial studies should evaluate the overall functional integrity of the major organ systems, including the cardiovascular, pulmonary, hepatic, and renal systems **(Table 100-5)**. Factors that have prognostic significance, either for achieving CR or for predicting CR duration, should also be assessed before initiating treatment, including cytogenetics and molecular markers. Leukemic cells should be obtained from all patients and cryopreserved for future investigational testing as well as potential future use as new diagnostics and therapeutics become available. All patients should be evaluated for infection.

Most patients are anemic and thrombocytopenic at presentation. Replacement of the appropriate blood components, if necessary, should begin promptly. Because qualitative platelet dysfunction or the presence of an infection may increase the likelihood of bleeding, evidence of hemorrhage justifies the immediate use of platelet transfusion, even if the platelet count is only moderately decreased.

About 50% of patients have a mild to moderate elevation of serum uric acid at presentation. Only 10% have marked elevations, but renal precipitation of uric acid and the nephropathy that may result is a serious but uncommon complication. The initiation of chemotherapy may aggravate hyperuricemia, and patients are usually started immediately on allopurinol and hydration at diagnosis. Rasburicase (recombinant uric oxidase) is also useful for treating uric acid nephropathy and often can normalize the serum uric acid level within hours with a single dose of treatment, although its expense suggests that limiting its use to patients with severe hyperuricemia and/or kidney injury may be prudent. The presence of high concentrations of lysozyme, a marker for monocytic differentiation, may be etiologic in renal tubular dysfunction for a minority of patients.

TREATMENT

Acute Myeloid Leukemia

Treatment of the newly diagnosed patient with AML is usually divided into two phases, induction and postremission management (consolidation) **(Fig. 100-2)**. The initial goal is to induce CR. Once CR is obtained, further therapy must be given to prolong survival and achieve cure. The initial induction treatment and subsequent postremission therapy are chosen based on the patient's age, overall fitness, and cytogenetic/molecular risk. Intensive therapy with cytarabine and anthracyclines in younger patients (<60 years) increases the cure rate of AML. In older patients, the benefit of intensive therapy is controversial in all but favorable-risk patients; novel approaches for selecting patients predicted to be responsive to treatment and new therapies are being pursued.

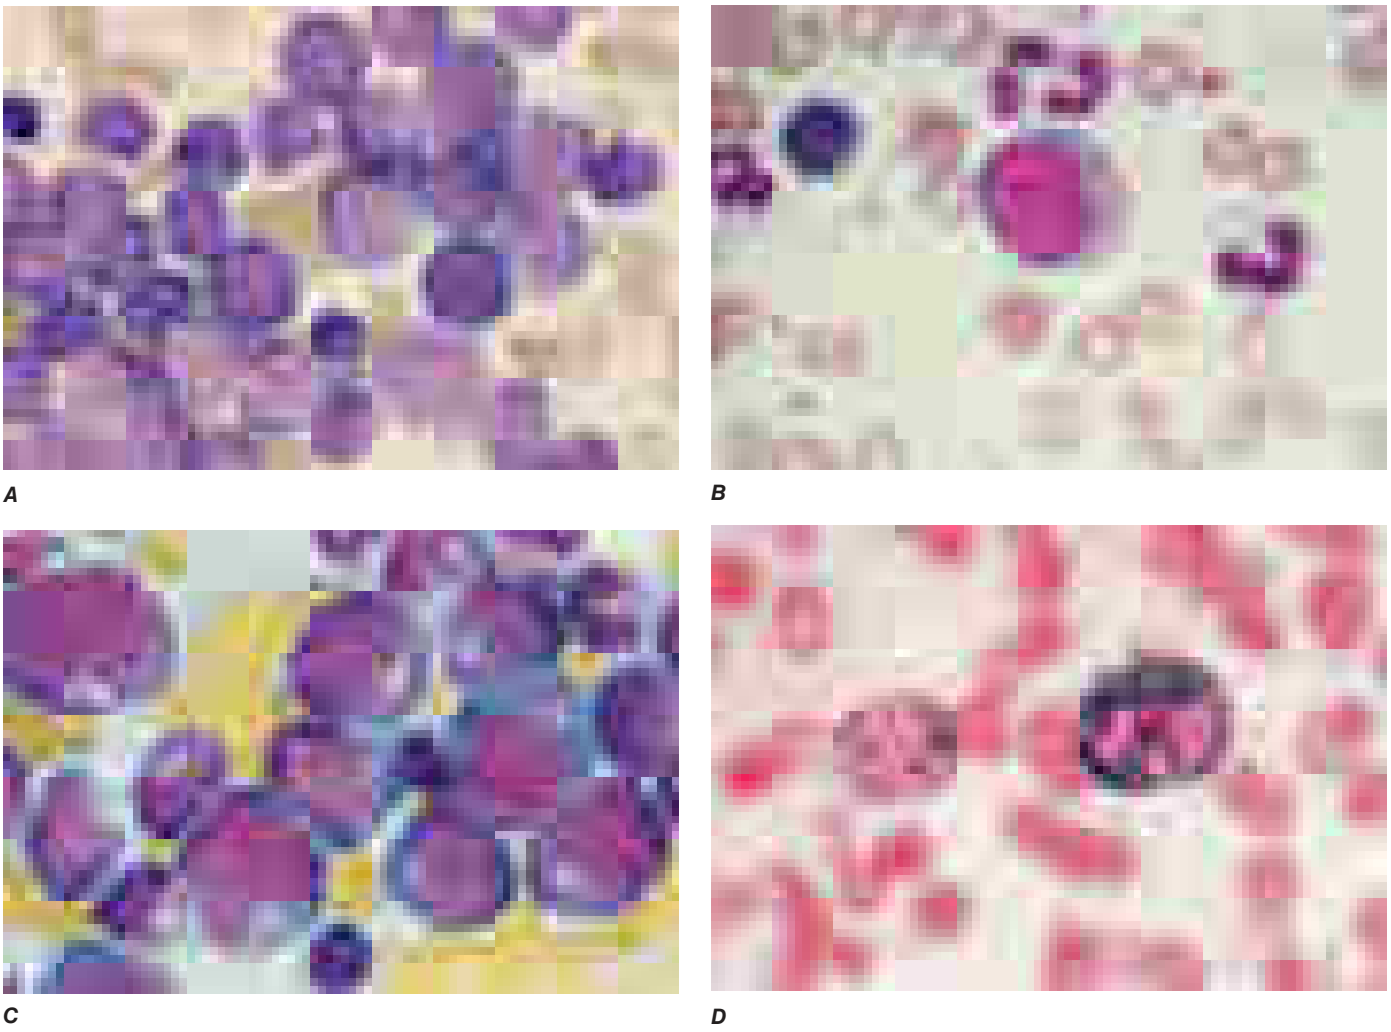

FIGURE 100-1 Morphology of acute myeloid leukemia (AML) cells. ***A.*** Uniform population of primitive myeloblasts with immature chromatin, nucleoli in some cells, and primary cytoplasmic granules. ***B.*** Leukemic myeloblast containing an Auer rod. ***C.*** Promyelocytic leukemia cells with prominent cytoplasmic primary granules. ***D.*** Peroxidase stain shows dark blue color characteristic of peroxidase in granules in AML.

INDUCTION CHEMOTHERAPY

The most commonly used induction regimens (for patients other than those with APL) consist of combination chemotherapy with cytarabine and an anthracycline (e.g., daunorubicin, idarubicin). Cytarabine is a cell cycle S-phase–specific antimetabolite that becomes phosphorylated intracellularly to an active triphosphate form that interferes with DNA synthesis. Anthracyclines are DNA intercalators. Their primary mode of action is thought to be inhibition of topoisomerase II, leading to DNA breaks.

In adults, cytarabine used at standard dose (100–200 mg/m^2) is administered as a continuous intravenous infusion for 7 days. With cytarabine, anthracycline therapy generally consists of daunorubicin (60–90 mg/m^2) or idarubicin (12 mg/m^2) intravenously on days 1, 2, and 3 (the 7 and 3 regimen). Other agents can be added (e.g., cladribine) when 60 mg/m^2 of daunorubicin is used. With the 7 and 3 regimen, it is now clearly established that 45 mg/m^2 dosing of daunorubicin results in inferior outcomes; patients should receive higher doses as described. Patients failing remission after one induction are offered reinduction with the same (or slightly modified) therapy.

In older patients (age ≥60–65 years), the outcome is generally poor due to a higher frequency of resistant disease and increased rate of treatment-related mortality. This is especially true in patients with prior hematologic disorders (MDS or myeloproliferative neoplasms), therapy-related AML, or cytogenetic and genetic abnormalities that adversely impact on clinical outcome. All older patients should be considered for clinical trials, but in particular older patients in the adverse-risk groups delineated above should be offered investigational approaches when possible. Conventional therapy for older patients is similar to that for younger: the 7 and 3 regimen with standard-dose cytarabine and idarubicin (12 mg/m^2), or daunorubicin (60 mg/m^2, or 90 mg/m^2 for those <65 years). For patients aged >65 years, high-dose daunorubicin (90 mg/m^2) has increased toxicity and is not recommended. Older patients and those with adverse-risk genetics may receive lower intensity therapy with a hypomethylating agent (decitabine or azacitidine), clofarabine, or preferably investigational therapy **(Table 100-6)**.

With the 7 and 3 regimen, 60–80% of younger and 33–60% of older patients (among those who are candidates for intensive therapy) with primary AML achieve CR. Of patients who do not achieve CR, most have drug-resistant leukemia, although induction death is more frequent with advancing age and medical comorbidity. Patients with refractory disease after induction should be considered for salvage treatments, preferentially on clinical trials, before receiving allogeneic hematopoietic stem cell transplantation (HCT) that is usually reserved for patients in or near CR. However, fit younger patients with primary refractory disease have ~15–20% cure rates with allogeneic HCT (after myeloablative conditioning); for this reason early consideration of future allogeneic HCT feasibility (including HLA typing, donor search, etc.) should be part of the initial induction approach for most AML patients.

TABLE 100-5 Initial Diagnostic Evaluation and Management of Adult Patients with AML

History
Increasing fatigue or decreased exercise tolerance (anemia)
Excess bleeding or bleeding from unusual sites (DIC, thrombocytopenia)
Fevers or recurrent infections (neutropenia)
Headache, vision changes, nonfocal neurologic abnormalities (CNS leukemia or bleed)
Early satiety (splenomegaly)
Family history of AML (Fanconi, Bloom, or Kostmann syndromes or ataxia-telangiectasia)
History of cancer (exposure to alkylating agents, radiation, topoisomerase II inhibitors)
Occupational exposures (radiation, benzene, petroleum products, paint, smoking, pesticides)
Physical Examination
Performance status (prognostic factor)
Ecchymosis and oozing from IV sites (DIC, possible acute promyelocytic leukemia)
Fever and tachycardia (signs of infection)
Papilledema, retinal infiltrates, cranial nerve abnormalities (CNS leukemia)
Poor dentition, dental abscesses
Gum hypertrophy (leukemic infiltration, most common in monocytic leukemia)
Skin infiltration or nodules (leukemia infiltration, most common in monocytic leukemia)
Lymphadenopathy, splenomegaly, hepatomegaly
Back pain, lower extremity weakness (spinal granulocytic sarcoma, most likely in t[8;21] patients)
Laboratory and Radiologic Studies
CBC with manual differential cell count
Chemistry tests (electrolytes, creatinine, BUN, calcium, phosphorus, uric acid, hepatic enzymes, bilirubin, LDH, amylase, lipase)
Clotting studies (prothrombin time, partial thromboplastin time, fibrinogen, D-dimer)
Viral serologies (CMV, HSV-1, varicella-zoster)
RBC type and screen
HLA typing for potential allogeneic HCT
Bone marrow aspirate and biopsy (morphology, cytogenetics, flow cytometry, molecular studies for NPM1 and CEBPA mutations and FLT3-ITD)
Cryopreservation of viable leukemia cells
Myocardial function (echocardiogram or MUGA scan)
PA and lateral chest radiograph
Placement of central venous access device
Interventions for Specific Patients
Dental evaluation (for those with poor dentition)
Lumbar puncture (for those with symptoms of CNS involvement)
Screening spine MRI (for patients with back pain, lower extremity weakness, paresthesias)
Social work referral for patient and family psychosocial support
Counseling for All Patients
Provide patients with information regarding their disease and genetic risks, sperm banking or menstrual suppression, financial counseling, and support group contact

Abbreviations: AML, acute myeloid leukemia; BUN, blood urea nitrogen; CBC, complete blood count; CMV, cytomegalovirus; CNS, central nervous system; DIC, disseminated intravascular coagulation; HLA, human leukocyte antigen; HCT, hematopoietic stem cell transplantation; HSV, herpes simplex virus; IV, intravenous; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; MUGA, multigated acquisition; PA, posteroanterior; RBC, red blood (cell) count.

POSTREMISSION THERAPY

Induction of a durable first CR (CR1) is critical to long-term survival in AML. However, without further therapy virtually all patients relapse. Thus, postremission therapy is designed to eradicate residual (typically undetectable) leukemic cells to prevent relapse and prolong survival. As for induction, the type of postremission therapy in AML is selected for each individual patient based on age, fitness, and cytogenetic/molecular risk.

The choice between consolidation with chemotherapy or transplantation is complex and based on age, risk, and practical considerations. In younger patients receiving chemotherapy, postremission therapy with intermediate/high-dose cytarabine for two to four cycles is standard practice. Higher doses of cytarabine during post remission therapy appear more effective than standard doses (as are used in induction), at least for those who do not have adverse-risk genetics. Recent studies suggest that the long-standing practice of high-dose cytarabine (3 g/m^2, every 12 h on days 1, 3, and 5) may not improve survival over intermediate-dose cytarabine (IDAC, 1-1.5 g/m^2) for such patients. Thus, the ELN has recommended IDAC at 1–1.5 g/m^2, every 12 h, on days 1–3, as the optimal postremission chemotherapy approach for favorable and intermediate-risk younger patients, for two to four cycles. While high-dose cytarabine may not be necessary, it is important to note that younger favorable-risk patients have worse outcomes when doses below $1g/m^2$ are used. In contrast to favorable-risk, intermediate- and adverse-risk patients should be considered for allogeneic HCT CR1 when feasible (see transplant discussion below). As older patients have increased toxicities with higher doses of cytarabine, ELN recommends relatively attenuated cytarabine doses (0.5–$1g/m^2$, every 12 h, on days 1–3) in favorable-risk older patients. There is no clear value for intensive postremission therapy in non–favorable-risk older patients; allogeneic HCT in CR1 (up to age 75 years) or investigational therapy is recommended. Indeed, postremission therapy is an appropriate setting for introduction of new agents in both older and younger patients (Table 100-6).

Allogeneic HCT is the best relapse-prevention strategy currently available for AML. Allogeneic HCT is probably best understood as an opportunity for immunotherapy; residual leukemia cells potentially elicit an immunologic response from donor immune cells, the so-called graft-versus-leukemia (GVL) effect. The benefit of GVL in relapse risk reduction, unfortunately, is offset somewhat by increased morbidity and mortality from complications of allogeneic HCT including graft-versus-host disease (GVHD). Given that relapsed AML is typically resistant to chemotherapy, allogeneic HCT in CR1 is a favored strategy. It is recommended in patients age <75 years who do not have favorable-risk disease and who have a human leukocyte antigen (HLA)–matched donor (related or unrelated). We recommend allogeneic HCT in CR1 for patients with intermediate-risk disease (Table 100-3). However, considerable debate exists regarding whether allogeneic HCT in CR1 is a requirement for younger patients with intermediate-risk AML, as one large series from the Medical Research Council reported that such patients have similar outcomes if transplanted only after relapse (and achievement of CR2), sparing some the long-term morbidity of transplantation. That said, allogeneic HCT is generally recommended as soon as possible after CR1 is achieved unless the patient is in a favorable-risk group. Selected adverse-risk patients without HLA-matched donors are considered for alternative donor transplants (e.g., HLA-mismatched unrelated, haploidentical related, and umbilical cord blood) even in CR1. Notably, more effective methods of in vivo T cell depletion (i.e., post-transplant cyclophosphamide following haploidentical transplantation) have broadened the availability of potential allogeneic HCT donors. Now, virtually any patient with a healthy parent or child (i.e., haploidentical) has an available donor suitable for allogeneic HCT if desired. Long-term outcomes with conventional chemotherapy for older patients are dismal; transplantation for such patients is expanding. For older patients, nonrandomized data demonstrate benefit for older patients in CR1 treated with reduced-intensity conditioning regimens and allogeneic HCT. Prospective data suggest that 40% of older patients in CR1 who are candidates for allogeneic HCT may be cured.

Trials comparing allogeneic HCT with intensive chemotherapy or autologous HCT have shown improved duration of remission with allogeneic HCT. However, the relapse risk reduction that is observed with allogeneic HCT is partially offset by the increase in fatal

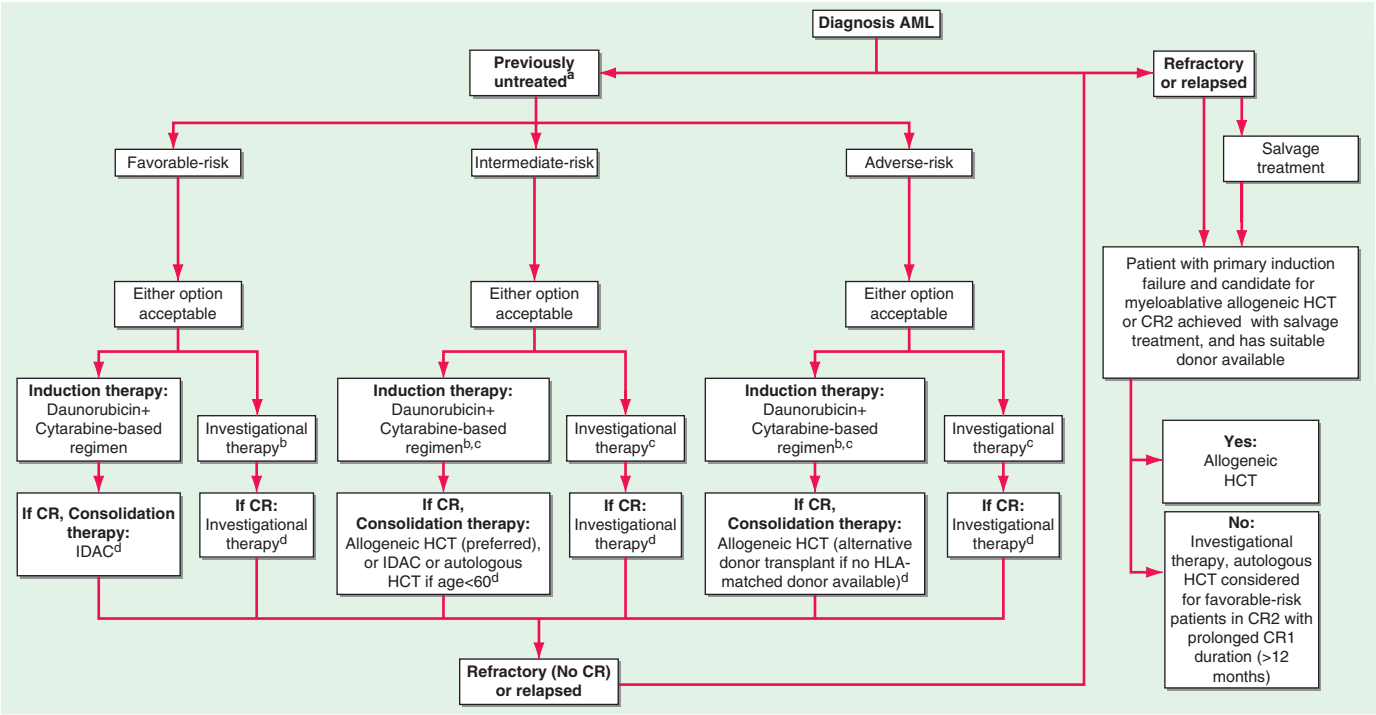

FIGURE 100-2 Flowchart for the therapy of newly diagnosed acute myeloid leukemia (AML). [a]Risk stratification according to the European LeukemiaNet (see Table 100-3). [b]Younger patients (<60–65 years) should routinely be offered investigational therapy on a backbone of standard chemotherapy for induction and consolidation. [c]Older patients, especially those >65 years or with adverse-risk disease, or those who are unfit for intensive daunorubicin + cytarabine regimens, may be considered for investigational therapy alone or in combination with lower intensity chemotherapy regimens (azacitidine, decitabine). [d]Investigational therapy as maintenance should be considered if available (after consolidation for younger patients and older patients with favorable-risk disease, and for all other older patients after induction).

For all forms of AML except acute promyelocytic leukemia (APL), standard induction therapy includes a regimen based on a 7-day continuous infusion of cytarabine (100–200 mg/m^2/d) and a 3-day course of daunorubicin (60–90 mg/m^2/d) with or without additional drugs. Idarubicin (12 mg/m^2/d) could be used in place of daunorubicin (not shown). The value of postremission/consolidation therapy for older patients (>60 years) who do not have favorable-risk disease is uncertain. Patients who achieve complete remission (CR) undergo postremission consolidation therapy, including sequential courses of intermediate-risk cytarabine, allogeneic HCT, autologous HCT, or novel therapies, based on their predicted risk of relapse (i.e., risk-stratified therapy). Patients with APL (see text for treatment) usually receive tretinoin and arsenic trioxide–based regimens with or without anthracycline-based chemotherapy and possibly maintenance with tretinoin. HCT, hematopoietic cell transplantation; HLA, human leukocyte antigen; IDAC, intermediate dose cytarabine.

treatment-related toxicity (GVHD, organ toxicity). Despite this, there is no debate that patients with adverse-risk AML have improved long-term survival with early allogeneic HCT. Alternatively, high-dose chemotherapy with autologous HCT rescue is another post-remission approach in non-adverse risk subsets. Autologous HCT patients receive their own stem cells (collected during remission and cryopreserved), following administration of myeloablative chemotherapy. The toxicity is relatively low with autologous HCT (5% mortality rate), but the relapse rate is higher than with allogeneic HCT, due to the absence of the GVL effect. Favorable and intermediate-risk patients may benefit from autologous HCT more so than adverse-risk patients. Practically speaking, however, autologous HCT in AML patients is less frequently employed currently due to enhanced relapse risk reduction seen with allogeneic HCT and the growing use of HLA mismatched donors (in novel transplantation approaches).

Prognostic factors help to select the appropriate postremission therapy in patients in CR1. Our approach includes allogeneic HCT in first CR for patients without favorable cytogenetics or genotype (e.g., patients who do not have CEBPA biallelic mutations or NPM1 mutations without FLT3-ITD/with *FLT3*-ITD^{low}). Patients with adverse-risk disease should proceed to allogeneic HCT at CR1 if possible. The decision for allogeneic HCT for younger intermediate-risk patients is complex and individualized as described above; we recommend it when an HLA-matched donor is available. Subsets of patients may benefit from targeted therapy given during remission; emerging data demonstrate survival benefit from incorporation of the FLT3 inhibitor midostaurin, for example, into induction and postremission therapies for patients with *FLT3* mutated AML. On April 28, 2017, the U.S. Food and Drug Administration (FDA) approved midostaurin (RYDAPT, Novartis Pharmaceuticals Corp.) for the treatment of adult patients with newly diagnosed AML who are *FLT3* mutation-positive (either ITD or TKD+), in combination with standard cytarabine and daunorubicin induction and cytarabine consolidation. Allogeneic transplantation in CR1 is still recommended for these patients.

For patients in morphologic CR, measurement of MRD remains a very important and challenging research area. Cytogenetics are a mainstay of disease assessment, and persistence of abnormal karyotype (in spite of morphologic CR) is clearly associated with poor clinical outcomes. Immunophenotyping to detect minute populations of blasts or sensitive molecular assays (e.g., reverse transcriptase polymerase chain reaction [RT-PCR]) to detect AML-associated molecular abnormalities (e.g., NPM1 mutation, the CBF AML RUNX1/RUNX1T1 and CBFB/MYH11 transcripts, the APL PML/RARA transcript) can be performed to assess whether MRD is present at sequential time points during or after treatment. Whether emerging next-generation sequencing or serial quantitative assessment using flow or RT-PCR, performed during remission, can effectively direct successful subsequent therapy and improve clinical outcome remains to be determined. Currently, no consensus exists for the optimal MRD measurement technique, or its application. Data suggest that MRD measurement can in some settings be a reliable discriminator between patients who will continue in CR or relapse, but whether subsequent therapy (i.e., allogeneic HCT or additional chemotherapy) can effectively eradicate disease in such patients is not yet clear. In the subset of patients with APL, serial RT-PCR (for the *PML/RARA* transcript) is a very useful and reliable tool to detect

TABLE 100-6 Novel Therapies in Clinical Development in Acute Myeloid Leukemia

Protein kinase inhibitors	• FLT3 inhibitors (midostaurin, quizartinib, gilteritinib, crenolanib, sorafenib) • KIT inhibitors • PI3K/AKT/mTOR inhibitors • Aurora and polo-like kinase inhibitors, CDK4/6 inhibitors, CHK1, WEE1, and MPS1 inhibitors • SRC and HCK inhibitors • Syk inhibitors
Epigenetic modulators	• New DNA methyltransferase inhibitors (SGI-110) • Histone deacetylase (HDAC) inhibitors • IDH1 and IDH2 inhibitors • DOT1L inhibitors • BET-bromodomain inhibitors
Chemotherapeutic agents	• CPX-351 (especially in secondary AML) • Vosaroxin • Nucleoside analogues
Mitochondrial inhibitors	• Bcl-2, Bcl-xL, and Mcl-1 inhibitors • Caseinolytic protease inhibitors
Therapies targeting oncogenic proteins	• Fusion transcripts targeting • EVI1 targeting • NPM1 targeting • Hedgehog inhibitors (glasdegib)
Antibodies and immunotherapies	• Monoclonal antibodies against CD33, CD44, CD47, CD123, CLEC12A • Immunoconjugates (e.g., gemtuzumab ozogamicin, SGN33A) • Bispecific T-cell engagers (BiTEs) and dual affinity re-targeting molecules (DARTs) • Chimeric antigen-receptor (CAR) T cells or genetically engineered T-cell receptor (TCR) T cells • Immune checkpoint inhibitors (PD-1/PD-L1, CTLA-4) • Anti-KIR antibody (lirilumab) • Vaccines (e.g., WT1)
Therapies targeting AML environment	• CXCR4 and CXCL12 antagonists • Anti-angiogenic therapies

early relapse and direct initiation of reinduction therapy prior to onset of overt relapse.

SUPPORTIVE CARE

Measures geared to supporting patients through several weeks of neutropenia and thrombocytopenia are critical to successful AML therapy. Patients with AML should be treated in centers expert in providing supportive care. Multilumen central venous catheters should be inserted as soon as newly diagnosed AML patients have been stabilized. They should be used thereafter for administration of intravenous medications/chemotherapy and transfusions, as well as for blood drawing instead of venipuncture.

Adequate and prompt blood bank support is critical to therapy of AML. Platelet transfusions should be given as needed to maintain a platelet count ≥10,000/μL. The platelet count should be kept at higher levels in febrile patients and during episodes of active bleeding or DIC. Patients with poor posttransfusion platelet count increments may benefit from administration of platelets from HLA-matched donors. RBC transfusions should be administered to keep the hemoglobin level >70–80 g/L (7–8 g/dL) in the absence of active bleeding, DIC, or congestive heart failure, which require higher hemoglobin levels. Blood products leukodepleted by filtration should be used to avert or delay alloimmunization as well as febrile reactions. Blood products may also be irradiated to prevent transfusion-associated GVHD. Cytomegalovirus (CMV)–negative blood products should be used for CMV-seronegative patients who are potential candidates for allogeneic HCT; fortunately white blood cell filtration is quite effective at reducing CMV exposure as well.

Neutropenia (neutrophils <500/μL or <1000/μL and predicted to decline to <500/μL over the next 48 h) can be part of the initial presentation and/or a side effect of the chemotherapy treatment in AML patients. Thus, infectious complications remain the major cause of morbidity and death during induction and postremission chemotherapy for AML. Antibacterial (i.e., quinolones) and antifungal (i.e., posaconazole) prophylaxis, especially in conjunction with regimens that cause mucositis, is beneficial. For patients who are herpes simplex virus or varicella-zoster seropositive, antiviral prophylaxis should be initiated (e.g., acyclovir, valacyclovir).

Fever develops in most patients with AML, but infections are documented in only half of febrile patients. Early initiation of empirical broad-spectrum antibacterial and antifungal antibiotics has significantly reduced the number of patients dying of infectious complications **(Chap. 70)**. An antibiotic regimen adequate to treat gram-negative organisms should be instituted at the onset of fever in a neutropenic patient after clinical evaluation, including a detailed physical examination with inspection of the indwelling catheter exit site and a perirectal examination (for perirectal abscess), as well as procurement of cultures and radiographs aimed at documenting the source of fever. Specific antibiotic regimens should be based on institutional antibiotic sensitivity data obtained from where the patient is being treated. Acceptable regimens for empiric antibiotic therapy include monotherapy with imipenem-cilastatin, meropenem, piperacillin/tazobactam, or an extended-spectrum antipseudomonal cephalosporin (cefepime or ceftazidime). The combination of an aminoglycoside with an antipseudomonal penicillin (e.g., piperacillin) or an aminoglycoside in combination with an extended-spectrum antipseudomonal cephalosporin should be considered in complicated or resistant cases. Aminoglycosides should be avoided, if possible, in patients with renal insufficiency. Empirical vancomycin should be added in neutropenic patients with catheter-related infections, blood cultures positive for gram-positive bacteria before final identification and susceptibility testing, hypotension or shock, or known colonization with penicillin/cephalosporin-resistant pneumococci or methicillin-resistant *Staphylococcus aureus*. In special situations where decreased susceptibility to vancomycin, vancomycin-resistant organisms, or vancomycin toxicity is documented, other options including linezolid, daptomycin, and quinupristin/dalfopristin need to be considered.

Caspofungin (or a similar echinocandin), voriconazole, isavuconazonium, or liposomal amphotericin B should be considered for antifungal treatment if fever persists for 4–7 days following initiation of empiric antibiotic therapy. Amphotericin B has long been used for antifungal therapy. Although liposomal formulations have improved the toxicity profile of this agent, its use has been limited to situations with high risk of or documented mold infections. Caspofungin has been approved for empiric antifungal treatment. Voriconazole has also been shown to be equivalent in efficacy and less toxic than amphotericin B; isavuconazonium may also be effective with fewer drug-drug interactions. Antibacterial and antifungal antibiotics should be continued until patients are no longer neutropenic, regardless of whether a specific source has been found for the fever. Unfortunately, this practice likely contributes to development of resistance and increased incidence of nosocomial infections such as *Clostridium difficile* colitis, so great care should be taken preferably in hospital-wide antibiotic surveillance and isolation strategies to reduce these complications. Recombinant hematopoietic growth factors have a limited role in AML; myeloid growth factors may be useful in the postremission setting but are not recommended in induction or for "palliative" care for patients not in remission.

TREATMENT FOR REFRACTORY OR RELAPSED AML

In patients who relapse after achieving CR, the length of first CR is predictive of response to salvage chemotherapy treatment; patients with longer first CR (>12 months) generally relapse with

drug-sensitive disease and have a higher chance of attaining a CR, even with the same chemotherapeutic agents used for first remission induction. Whether initial CR was achieved with one or two courses of chemotherapy and the type of postremission therapy may also predict achievement of second CR. Similar to patients with refractory disease, patients with relapsed disease are rarely cured by salvage chemotherapy treatments. Therefore, patients who eventually achieve a second CR and are eligible for allogeneic HCT should be transplanted. However, there is no consensus on optimal treatment for patients who relapse after allogeneic HCT; outcomes in this setting are very poor.

Because achievement of a second CR with routine salvage therapies is relatively uncommon, especially in patients who relapse rapidly after achievement of first CR (<12 months), these patients and those lacking HLA-compatible donors or who are not candidates for allogeneic HCT should be considered for innovative approaches on clinical trials. Many new agents are in current testing (Table 100-6). The discovery of novel gene mutations and mechanisms of leukemogenesis that might represent actionable therapeutic targets has prompted the development of many new targeting agents. In addition to kinase inhibitors for *FLT3*-mutated AML, other compounds targeting the aberrant activity of mutant proteins (e.g., IDH1/2 inhibitors) and numerous other biologic mechanisms are being tested in clinical trials. Furthermore, approaches with antibodies targeting markers commonly expressed on leukemia blasts (e.g., CD33) or leukemia-initiating cells (e.g., CD123) are also under investigation. Once these compounds have demonstrated safety and activity as single agents, investigation of combinations with other molecular targeting compounds and/or chemotherapy should be pursued.

TREATMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

APL is a highly curable AML subtype, and ~85% of these patients achieve long-term survival with current approaches. APL has long been shown to be responsive to cytarabine and daunorubicin, but in the past patients who were treated with these drugs alone frequently died from DIC induced by the release of granule components by the chemotherapy-treated leukemia cells. However, the prognosis of APL patients has changed dramatically with the introduction of tretinoin (ATRA), an oral drug that induces the differentiation of leukemic cells bearing the t(15;17), where disruption of the *RARA* gene encoding a retinoid acid receptor occurs. ATRA decreases the frequency of DIC but often produces another complication called the APL (differentiation) syndrome. Occurring within the first 3 weeks of treatment, it is characterized by fever, fluid retention, dyspnea, chest pain, pulmonary infiltrates, pleural and pericardial effusions, and hypoxemia. The syndrome is related to adhesion of differentiated neoplastic cells to the pulmonary vasculature endothelium. Glucocorticoids, chemotherapy, and/or supportive measures can be effective for management of the APL syndrome. Temporary discontinuation of ATRA is necessary in cases of severe APL syndrome (i.e., patients developing renal failure or requiring admission to the intensive care unit due to respiratory distress). The mortality rate of this syndrome is ~10%. APL syndrome may also occur, less commonly, with ATO in APL.

In low-risk APL (low leukocyte count at presentation), ATRA (45 mg/m^2/d) plus ATO (0.15 mg/kg/d) was recently compared to ATRA plus concurrent idarubicin chemotherapy. ATRA/ATO was superior and is the new standard of care for such patients. CR rates in low-risk disease approach 100%, with excellent long-term survival. Notably, patients with high-risk APL (high leukocyte count) must be uniquely treated, as they require immediate cytoreduction with chemotherapy due to life-threatening APL syndrome often with rapidly rising leukocyte count after initiation of ATRA. High-risk patients are at increased risk for induction death due to this syndrome as well as increased frequency of hemorrhagic complications (related to DIC).

Assessment of residual disease by RT-PCR amplification of the t(15;17) chimeric gene product PML-RARA following the final cycle of treatment is important. Disappearance of the signal is associated with long-term disease-free survival; its persistence or reemergence invariably predicts relapse. Sequential monitoring of RT-PCR for PML-RARA is now considered standard for postremission monitoring of APL, at least in high-risk patients.

Patients in molecular, cytogenetic, or clinical relapse should be salvaged with ATO with or without ATRA; in patients who were treated with ATRA plus chemotherapy in the frontline setting, ATO-based therapy at relapse produces meaningful responses in up to 85% of patients. Though experience with relapsed APL in patients who received ATO during initial induction is limited (given that few relapses occur in low-risk patients, and widespread use of ATO during first-line therapy is relatively new), ATO remains the preferred reinduction therapy for patients who relapse. Achievement of CR2 should be followed by consolidation with autologous HCT (for patients who achieve RT-PCR negative status). In the minority who do not achieve negative RT-PCR or who relapse again, allogeneic HCT may still be potentially curative.

101 Chronic Myeloid Leukemia

Hagop Kantarjian, Jorge Cortes

Chronic myeloid leukemia (CML) is a clonal hematopoietic stem cell disorder. The disease is driven by the *BCR-ABL1* chimeric gene product, that codes for a constitutively active tyrosine kinase, resulting from a reciprocal balanced translocation between the long arms of chromosomes 9 and 22, t(9;22)(q34.1;q11.2), known as the Philadelphia chromosome (Ph) **(Fig. 101-1)**. Untreated, the course of CML is typically biphasic or triphasic, with an early indolent or chronic phase, followed often by an accelerated phase and a terminal blastic phase. Before the era of selective BCR-ABL1 tyrosine kinase inhibitors (TKIs),

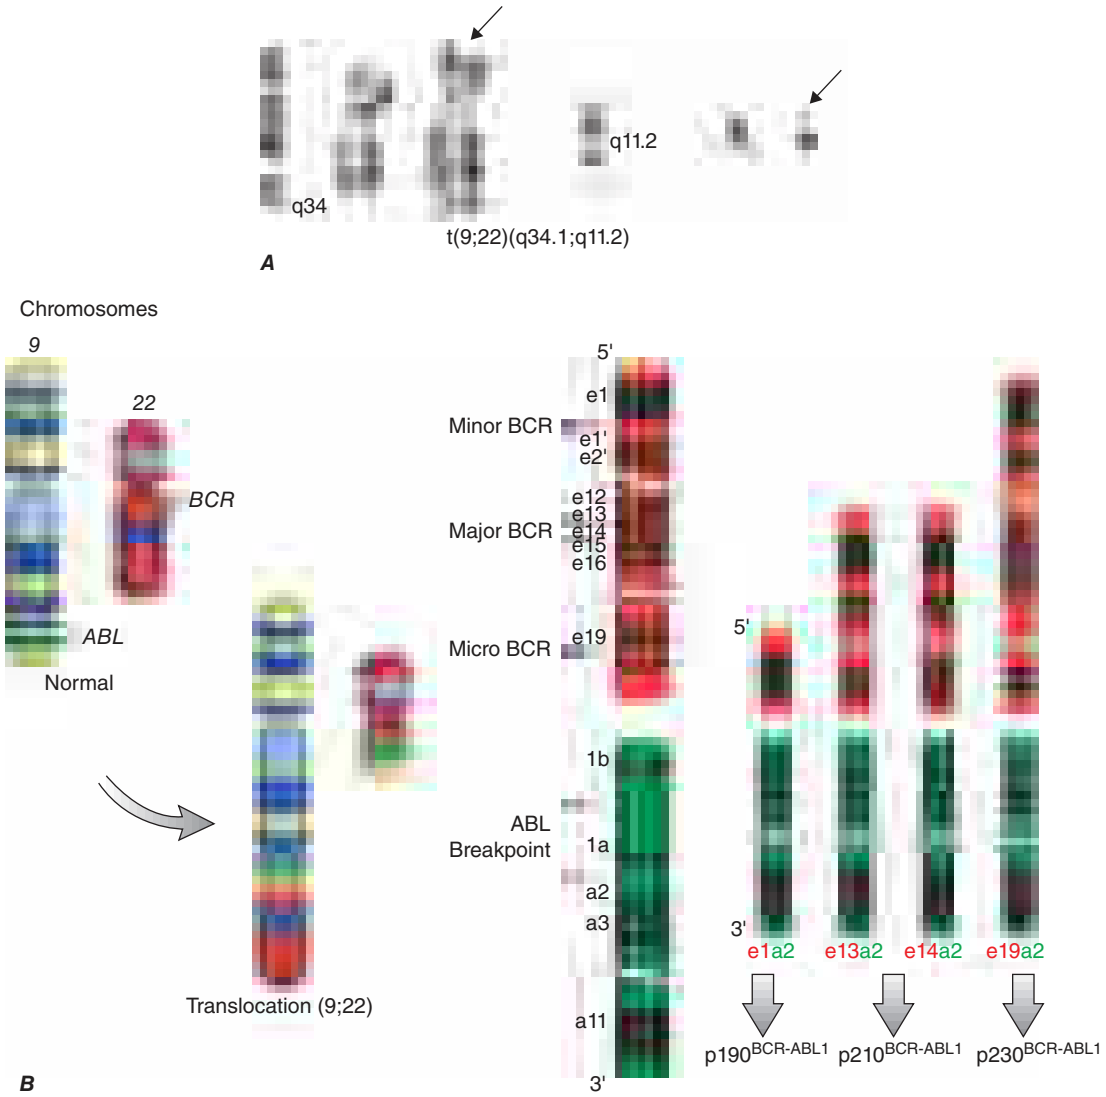

FIGURE 101-1 ***A.*** The Philadelphia (Ph) chromosome cytogenetic abnormality. ***B.*** Breakpoints in the long arms of chromosome 9 (*ABL* locus) and chromosome 22 (*BCR* regions) result in at least three different BCR-ABL1 oncoprotein messages, $p210^{BCR\text{-}ABL1}$ (most common message in chronic myeloid leukemia [CML]), $p190^{BCR\text{-}ABL1}$ (present in two-thirds of patients with Ph-positive acute lymphocytic leukemia; rare in CML), and $p230^{BCR\text{-}ABL1}$ (rare in CML and associated with an indolent course). Other rearrangements (e.g., b14a3) are less common. *(© 2013 The University of Texas MD Anderson Cancer Center.)*

the median survival in CML was 3–7 years, and the 10-year survival rate was 30% or less. Introduced into standard CML therapy in 2000, TKIs have revolutionized the treatment, natural history, and prognosis of CML. Today, the estimated 10-year survival rate with imatinib mesylate, the first BCR-ABL1 TKI approved, is 85%. Allogeneic stem cell transplantation (SCT), a curative approach but one that involves more risks, is now more often offered as second- or third-line therapy after failure of TKIs.

INCIDENCE AND EPIDEMIOLOGY

CML accounts for ~15% of all cases of leukemia. There is a slight male preponderance (male:female ratio 1.6:1). The median age at diagnosis is 55–65 years. It is uncommon in children; only 3% of patients with CML are younger than 20 years although in recent years a higher proportion of young patients seem to be diagnosed. CML incidence increases slowly with age, with a steeper increase after the age of 40–50 years. The annual incidence of CML is 1.5 cases per 100,000 individuals. In the United States this translates into about 8000 new cases per year. The incidence of CML has not changed over several decades. By extrapolation, the worldwide annual incidence of CML is about 100,000–120,000 cases. With a median survival of 6 years before 2000, the disease prevalence in the United States was 25,000–30,000 cases. With TKI therapy, the annual mortality has been reduced from 10–20% to about 2%. Therefore, the prevalence of CML in the United States is expected to continue to increase (approximately 100,000 in 2016). The worldwide prevalence will depend on the treatment penetration of TKIs and their effect on reduction of worldwide annual mortality. Ideally, with full TKI treatment penetration, the worldwide prevalence should plateau at 35 times the incidence, or around 3–4 million patients.

ETIOLOGY

There are no familial associations in CML. The risk of developing CML is not increased in monozygotic twins or in relatives of patients. No etiologic agents are incriminated, and no associations exist with exposures to benzene or other toxins, fertilizers, insecticides, or viruses. CML is not a frequent secondary leukemia following therapy of other cancers with alkylating agents and/or radiation. Exposure to ionizing radiation (e.g., nuclear accidents, radiation treatment for ankylosing spondylitis or cervical cancer) has increased the risk of CML, which peaks at 5–10 years after exposure and is dose-related. The median time to development of CML among atomic bomb survivors was 6.3 years. Following the Chernobyl accident, the incidence of CML did not increase, suggesting that larger dose exposures of radiation are required to cause CML. Because of adequate protection, the risk of CML is not increased in individuals working in the nuclear industry or among radiologists in recent times.

PATHOPHYSIOLOGY

The t(9;22)(q34.1;q11.2) is present in >90% of classical CML cases. It results from a balanced reciprocal translocation between the long arms of chromosomes 9 and 22. It is present in hematopoietic cells (myeloid, erythroid, megakaryocytes, and monocytes; less often mature B lymphocytes; rarely mature T lymphocytes, but not stromal cells), but not in other cells in the human body. As a result of the translocation, DNA sequences from the cellular oncogene *ABL1* are translocated next to the major breakpoint cluster region (*BCR*) gene on chromosome 22, generating a hybrid oncogene, *BCR-ABL1*. This fusion gene typically encodes for a novel oncoprotein of molecular weight 210 kDa, referred to as $p210^{BCR\text{-}ABL1}$ (Fig. 101-1*B*). This BCR-ABL1 oncoprotein exhibits constitutive kinase activity that leads to excessive proliferation and reduced apoptosis of CML cells, endowing them with a growth advantage over their normal counterparts. Over time, normal hematopoiesis is suppressed, but normal stem cells can persist and reemerge following effective therapy, for example with TKIs. In most instances of Ph-positive acute lymphoblastic leukemia (ALL) and in rare cases of CML, the breakpoint in *BCR* is more centromeric, in a region called the minor *BCR* region (*mBCR*). As a result, a shorter sequence of *BCR* is fused to *ABL1*, with a consequent smaller BCR-ABL1 oncoprotein, $p190^{BCR\text{-}ABL1}$. When occurring in Ph-positive CML, this translocation may predict for a worse outcome. A third rarer breakpoint in *BCR* occurs telomeric to the major *BCR* region and is called *micro-BCR* (μ-BCR). It juxtaposes a larger fragment of the *BCR* gene to *ABL1* and produces a larger $p230^{BCR\text{-}ABL1}$ oncoprotein, which is associated with a more indolent CML course. Other rearrangements, such as b14a3, occur much less frequently.

The constitutive activation of *BCR-ABL1* results in autophosphorylation and activation of multiple downstream pathways that affect gene transcription, apoptosis, stromal adherence, skeletal organization, and degradation of inhibitory proteins. These transduction pathways may involve RAS, mitogen-activated protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidylinositol-3-kinase (PI3k), MYC, and others. These interactions are mostly mediated through tyrosine phosphorylation and require binding of BCR-ABL1 to adapter proteins such as GRB-2, CRK, CRK-like (CRK-L) protein, and Src homology containing proteins (SHC). Most BCR-ABL1 TKIs bind to the *BCR-ABL1* ATP-binding domain, preventing the activation of transformation pathways and inhibiting downstream signaling. As a result, proliferation of CML cells is inhibited and apoptosis induced, allowing the reemergence of normal hematopoiesis. A plethora of signaling pathways have been implicated in BCR-ABL1-mediated cellular transformation. The emerging picture is a complex and redundant transformation network. An additional layer of complexity is related to differences in signal transduction between CML-differentiated cells and early progenitors. Beta-catenin, Wnt1, Foxo3a, transforming growth factor β, interleukin-6, PP2A, SIRT1, and others have been implicated in CML stem cell survival.

Experimental models have established the causal relationship between the *BCR-ABL1* rearrangement and the development of CML. In animal models, expression of *BCR-ABL1* in normal hematopoietic cells produced CML-like disorders or lymphoid leukemia, demonstrating the leukemogenic potential of *BCR-ABL1* as a single oncogenic abnormality. Other models however suggest the need for a "second hit."

The cause of the *BCR-ABL1* molecular rearrangement is unknown. Molecular techniques that detect *BCR-ABL1* at a level of 1 in 10^8 identify this molecular abnormality in the blood of up to 25% of normal adults and 5% of infants, but 0% of cord blood samples. This suggests that *BCR-ABL1* is not sufficient to cause overt CML in the overwhelming majority of individuals in whom it occurs. Because CML develops in only 1.5 of 100,000 individuals annually, it is evident that additional molecular events or poor immune recognition of the rearranged cells are needed to cause overt CML.

CML is defined by the presence of *BCR-ABL1* fusion gene in a patient with a myeloproliferative neoplasm. In some patients with a typical morphologic picture of CML, the Ph chromosome is not detectable by standard G-banding karyotype, but fluorescence in situ hybridization (FISH) and/or molecular studies (polymerase chain reaction [PCR]) detect *BCR-ABL1*. These patients have a course similar to Ph-positive CML and respond to TKI therapy. Many of the remaining patients have atypical morphologic or clinical features and belong to other diagnostic groups, such as atypical CML, chronic myelomonocytic leukemia, and myelodysplastic-myeloproliferative neoplasms (MDS-MPN). These individuals do not respond to TKI therapy and have a poor prognosis with a median survival of about 2–3 years. Detection of mutations in the granulocyte colony-stimulating factor receptor (*CSF3R*) in chronic neutrophilic leukemia (90% of cases) and in some cases of atypical CML, of mutations in *SETBP1* in atypical CML (25% of cases), and of mutations in *SF3B1* in MDS-MPN with ringed sideroblasts and marked thrombocytosis (MDS-MPD-RST; 50–70% of cases, associated with longer median survival of 7 years vs 3.3 years with wild-type *SF3B1*), confirmed that they are distinct molecular and biologic entities.

The events associated with the transition of CML from a chronic to accelerated-blastic phase are poorly understood. They are often associated with characteristic chromosomal abnormalities such as a double Ph, trisomy 8, isochromosome 17 or deletion of 17p (loss of *TP53*), 20q–, and others. Molecular events associated with transformation include mutations in *TP53*, retinoblastoma 1 (*RB1*), myeloid transcriptions factors like *RUNX1*, and cell cycle regulators like *p16*. A plethora of other mutations or functional abnormalities have been implicated in blastic transformation, but no unifying theme has emerged other than the fact that *BCR-ABL1* itself induces genetic instability that favors the acquisition of additional molecular events and eventually to blastic transformation. In this frame of thinking, one critical effect of TKIs is their ability to stabilize the CML genome, leading to a much reduced transformation rate. In particular, the previously observed sudden blastic transformations (i.e., abrupt transformation to blastic phase in a patient who had been in cytogenetic response) have become uncommon, occurring rarely in younger patients in the first 1–2 years of TKI therapy (usually sudden lymphoid blastic transformations). Sudden transformations beyond the third year of TKI therapy are rare in patients who continue on TKI therapy. Moreover, initial experience suggests that the course of CML has become significantly more indolent, even without cytogenetic responses, in patients on TKI-based therapy compared to previous experience with hydroxyurea/busulfan.

Among patients developing resistance to TKIs, several resistance mechanisms have been observed. The most clinically relevant one is the development of different *ABL1* kinase domain mutations that may prevent the binding of TKIs to the catalytic site (ATP-binding site) of the kinase or maintain the kinase activity despite the presence of a TKI. More than 100 *BCR-ABL1* mutations have now been described, many of which confer relative or absolute resistance to imatinib. This has resulted in the development of second-generation TKIs (i.e., dasatinib, nilotinib, bosutinib) and of a third-generation TKI (ponatinib) with significant efficacy against T315I, a "gatekeeper" mutation that prevents binding of and causes resistance to all other TKIs.

CLINICAL PRESENTATION

The presenting signs and symptoms in CML depend on the availability of and access to health care, including physical examinations and screening tests. In the United States, because of the wider access to health care screening and physical examinations, 50–60% of patients are diagnosed on routine blood tests and have minimal symptoms at presentation, such as fatigue. In geographic locations where access to health care is more limited, patients often present with high CML burden including splenomegaly, anemia, and related symptoms (abdominal pain, weight loss, fatigue), which translate into a higher frequency of high-risk CML. Presenting findings in patients diagnosed in the United States are shown in **Table 101-1**.

Symptoms Most patients with CML (90%) present in the indolent or chronic phase. Depending on the timing of diagnosis, patients are often asymptomatic (if the diagnosis is discovered during health care screening tests). Common symptoms, when present, are manifestations of anemia and splenomegaly. These may include fatigue, malaise, weight loss (if high leukemia burden), or early satiety and left upper quadrant pain or masses (from splenomegaly). Less common presenting findings

TABLE 101-1 Presenting Signs and Symptoms of Newly Diagnosed Philadelphia Chromosome–Positive Chronic Myeloid Leukemia in Chronic Phase

PARAMETER	PERCENTAGE
Age ≥60 years (median)	40–50 (55–65)
Female gender	35–45
Splenomegaly	30
Hepatomegaly	5–10
Lymphadenopathy	5
Other extramedullary disease	2
Hemoglobin <10 g/dL	10–15
Platelets	
>450 × 10^9 cells/L	30–35
<100 × 10^9 cells/L	3–5
White blood cells ≥50 × 10^9 cells/L	35–40
Marrow	
≥5% blasts	5
≥5% basophils	10–15
Peripheral blood	
≥3% blasts	8–10
≥7% basophils	10
Cytogenetic clonal evolution other than the Philadelphia chromosome	4–5
Sokal risk	
Low	60–65
Intermediate	25–30
High	10

include thrombotic or hyperviscosity-related events (from severe leukocytosis or thrombocytosis). These include priapism, cardiovascular complications, myocardial infarction, venous thrombosis, visual disturbances, dyspnea and pulmonary insufficiency, drowsiness, loss of coordination, confusion, or cerebrovascular accidents. Manifestations of bleeding diatheses include retinal hemorrhages, gastrointestinal bleeding, and others. Patients who present with, or progress to, the accelerated or blastic phases frequently have additional symptoms including unexplained fever, significant weight loss, severe fatigue, bone and joint pain, bleeding and thrombotic events, and infections.

Physical Findings Splenomegaly is the most common physical finding, occurring in 20–70% of patients depending on health care screening frequency. Other less common findings include hepatomegaly (5–10%), lymphadenopathy (5–10%), and extramedullary disease (skin or subcutaneous lesions). The latter indicates CML transformation if a biopsy confirms predominance of blasts. Other physical findings are manifestations of complications of high tumor burden described earlier (e.g., cardiovascular, cerebrovascular, bleeding). High basophil counts may be associated with histamine overproduction causing pruritus, diarrhea, flushing, and even gastrointestinal ulcers.

Hematologic and Marrow Findings In untreated CML, leukocytosis ranging from 10–500 × 10^9/L is common. The peripheral blood differential shows left-shifted hematopoiesis with predominance of neutrophils and the presence of bands, myelocytes, metamyelocytes, promyelocytes, and blasts (usually ≤5%). Basophils and/or eosinophils are frequently increased. Thrombocytosis is common, but thrombocytopenia is rare and, when present, suggests a worse prognosis, disease acceleration, or an unrelated etiology. Anemia is present in one-third of patients. Cyclic oscillations of counts are noted in 10–20% of patients without treatment. Biochemical abnormalities include a low leukocyte alkaline phosphatase score and high levels of vitamin B_{12}, uric acid, lactic dehydrogenase, and lysozyme. The presence of unexplained and sustained leukocytosis, with or without splenomegaly, should lead to a marrow examination and cytogenetic analysis.

The bone marrow is hypercellular with marked myeloid hyperplasia and a high myeloid-to-erythroid ratio of 15–20:1. Marrow blasts are 5% or less; when higher, they carry a worse prognosis or represent transformation to accelerated phase (if they are ≥15%). Increased reticulin fibrosis (by Snook's silver stain) is common, with 30–40% of patients demonstrating grade 3–4 reticulin fibrosis. This was considered adverse in the pre-TKI era. With TKI therapy, reticulin fibrosis resolves in most patients and is not an indicator of poor prognosis. Collagen fibrosis (Wright-Giemsa stain) is rare at diagnosis. Disease progression with a "spent phase" of myelofibrosis (myelophthisis, or burnt-out marrow) was common with busulfan therapy (20–30%) but is rare with TKI therapy.

Cytogenetic and Molecular Findings The diagnosis of CML is straightforward and depends on documenting the t(9;22)(q34.1;q11.2), which is identified by G-banding in 90% of cases. This is known as the Philadelphia chromosome (initially identified in Philadelphia as a minute chromosome), later identified to be chromosome 22 (Fig. 101-1). Some patients may have complex translocations (variant Ph) involving three or more chromosomes including chromosomes 9 and 22 and one or more additional chromosomes. Others may have a "masked Ph," involving translocations between chromosome 9 and a chromosome other than 22 (but molecularly showing the *BCR-ABL1* rearrangement). The prognosis of these patients and their response to TKI therapy are similar to those in patients with Ph. About 5–10% of patients may have additional chromosomal abnormalities in the Ph-positive cells. These usually involve trisomy 8, a double Ph, isochromosome 17 or 17p deletion, 20q–, or others. This is referred to as cytogenetic clonal evolution and was historically a sign of adverse prognosis, particularly when trisomy 8, double Ph, or chromosome 17 abnormalities were noted. A less common abnormality involving chromosome 3q26.2 also carries a poor prognosis.

Techniques such as FISH and PCR are now used to aid in the diagnosis of CML. They are more sensitive approaches to estimate the CML burden in patients on TKI therapy. They can be done on peripheral blood, and thus are more convenient to patients. Patients with CML at diagnosis should have a FISH analysis to quantify the percentage of Ph-positive cells, if FISH is used to replace marrow cytogenetic analysis in monitoring response to therapy. FISH will not detect additional chromosomal abnormalities (clonal evolution); thus, a cytogenetic analysis is usually recommended at the time of diagnosis. The *BCR-ABL1* rearrangement is usually one of two variants: e13a2 (formerly b2a2) and e14a2 (formerly b3a2). About 2–5% of patients may have other RNA fusion types (e.g., e1a2, e13a3, or e14a3). In these patients, the routine real-time PCR primers may not amplify the *BCR-ABL1* transcripts, thus leading to false-negative results. Therefore, molecular studies at diagnosis are important to document the type and presence of *BCR-ABL1* transcripts to avoid erroneously "undetectable" *BCR-ABL1* transcripts on follow-up studies, with the false impression of a complete molecular response. The presence of the Philadelphia chromosome with "negative" PCR with standard methodology should prompt investigation of atypical transcripts.

Both FISH and PCR studies can be falsely positive at low levels or falsely negative because of technical issues. Therefore, a diagnosis of CML must always rely on a marrow analysis with routine cytogenetics. The diagnostic bone marrow confirms the presence of the Ph chromosome, detects clonal evolution, that is, chromosomal abnormalities in the Ph-positive cells (which may be prognostic), and also quantifies the percentage of marrow blasts and basophils. In 10% of patients, the percentage of marrow blasts and basophils can be significantly higher than in the peripheral blood, conferring poorer prognosis or even representing disease transformation.

Monitoring patients on TKI therapy by cytogenetics, FISH, and molecular studies has become an important standard practice to assess response to therapy, emphasize compliance, evaluate possible treatment resistance, identify the need to change TKI therapy, and determine the need to assess for kinase domain mutations. It is thus important to recognize the comparability of these measures in monitoring response. A partial cytogenetic response is defined as the presence of 35% or less Ph-positive metaphases by routine cytogenetic analysis. This is roughly equivalent to *BCR-ABL1* transcripts by the

International Scale (IS) of 10% or less. A complete cytogenetic response refers to the absence of Ph-positive metaphases (0% Ph positivity). This is approximately equivalent to *BCR-ABL1* transcripts (IS) of 1% or less. A major molecular response refers to *BCR-ABL1* transcripts (IS) ≤0.1%, or roughly a 3-log or greater reduction of *BCR-ABL1* transcripts from a standardized basline. A molecular response MR4.5 refers to *BCR-ABL1* transcripts (IS) ≤0.0032%, roughly equivalent to a 4.5-log reduction or greater of transcripts.

Findings in CML Transformation Progression of CML is usually associated with leukocytosis resistant to therapy, increasing anemia, fever and constitutional symptoms, and increased blasts and basophils in the peripheral blood or marrow. Criteria of accelerated-phase CML, historically associated with median survival of <1.5 years, include the presence of 15% or more peripheral blasts, 30% or more peripheral blasts plus promyelocytes, 20% or more peripheral basophils, cytogenetic clonal evolution (presence of chromosomal abnormalities in addition to Ph), and thrombocytopenia <100 × 10^9/L (unrelated to therapy). About 5–10% of patients present with de novo accelerated phase or blastic phase. The prognosis of de novo accelerated phase with TKI therapy has improved significantly, with an estimated 8-year survival rate of 75%. The median survival of accelerated phase evolving from chronic phase has also improved from a historical median survival of 18 months to an estimated 4-year survival rate of 70% on TKI therapy. Therefore, the criteria for accelerated-phase CML should be revisited because most clinical criteria defining accelerated phase have lost much of their prognostic significance. Blastic-phase CML is defined by the presence of 30% or more peripheral or marrow blasts or the presence of sheets of blasts in extramedullary disease (usually skin, soft tissues, or lytic bone lesions). Blastic-phase CML is commonly myeloid (60%) but can present uncommonly as erythroid, promyelocytic, monocytic, or megakaryocytic. Lymphoid blastic phase occurs in about 25% of patients. Lymphoblasts are terminal deoxynucleotide transferase positive and peroxidase negative (although occasionally with low positivity up to 3–5%) and express lymphoid markers (CD10, CD19, CD20, CD22). However, they also often express myeloid markers (50–80%), resulting in diagnostic challenges. This is important because, unlike other morphologic blastic phases, lymphoid blastic-phase CML is quite responsive to anti-ALL-type chemotherapy (e.g., hyper-CVAD [cyclophosphamide, vincristine, doxorubicin, and dexamethasone]) in combination with TKIs (complete response rates 60–70%; median survival 2–3 years).

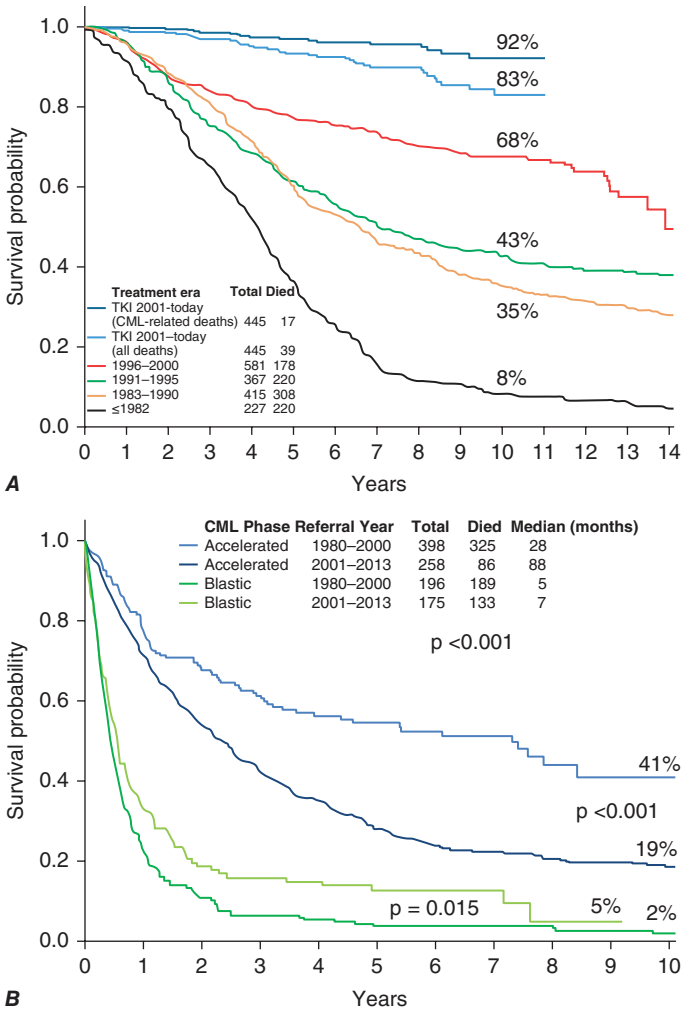

FIGURE 101-2 ***A.*** Survival in newly diagnosed chronic-phase chronic myeloid leukemia (CML) by era of therapy (MD Anderson Cancer Center experience from 1965 to present). Causes of non-CML deaths in 22 patients were other cancers (n = 7), postsurgical complications (n = 3), car accident (n = 2), suicide (n = 1), neurologic events (n = 3), cardiac (n = 3), pneumonia (n = 1), and unknown (n = 2). ***B.*** Survival in patients with accelerated- and blastic-phase CML referred to MD Anderson Cancer Center by era of therapy, demonstrating the significant survival benefit in the tyrosine kinase inhibitor (TKI) era in accelerated-phase CML but the modest benefit in blastic-phase CML. Referred cases included de novo and post-chronic-phase transformations.

PROGNOSIS AND CML COURSE

Before the imatinib era, the annual mortality in CML was 10% in the first 2 years and 15–20% thereafter. The median survival time in CML was 3–7 years (with hydroxyurea-busulfan and interferon α). Without a curative option of allogeneic SCT, the course of CML was toward transformation to, and death from, accelerated or blastic phases for most patients as the rate of complete cytogenetic response with interferon was low. Even apparent disease stability was unpredictable, with some patients demonstrating sudden transformation to a blastic phase. With imatinib therapy, the annual mortality in CML has decreased to 2% in the first 16 years of observation. More than half of the deaths are from factors other than CML, such as aging-related comorbidities, accidents, suicides, other cancers, and other medical conditions (e.g., infections, surgical procedures). The estimated 10-year survival rate is 85%, or 93% if only CML-related deaths are considered **(Fig. 101-2)**. The course of CML has also become quite predictable. In the first 2 years of TKI therapy, rare sudden transformations are still reported (1–2%), usually lymphoid blastic transformations that respond to combinations of chemotherapy and TKIs followed by allogeneic SCT. These may be explained by the intrinsic mechanisms of sudden transformation already existing in the CML clones before the start of therapy that were not amenable to TKI inhibition, in particular imatinib. Second-generation TKIs (nilotinib, dasatinib) used as frontline therapy have reduced the incidence of transformation in the first 2–3 years from 6–8% with imatinib to 2–5% with nilotinib or dasatinib. Disease transformation to accelerated or blastic phase is rare with continued TKI therapy, estimated at <1% annually in years 4–10 of follow-up on the original imatinib trials. Patients usually develop resistance in the form of cytogenetic resistance or relapse, followed by hematologic relapse and subsequent transformation, rather than the previously feared sudden transformations without the warning signals of cytogenetic-hematologic relapse.

Before the imatinib era, several pretreatment prognostic factors predicted for worse outcome in CML and have been incorporated into prognostic models and staging systems. These have included older age, significant splenomegaly, anemia, thrombocytopenia or thrombocytosis, high percentages of blasts and basophils (and/or eosinophils), marrow fibrosis, deletions in the long arm of chromosome 9, clonal evolution, and others. Different risk models and staging systems, derived from multivariate analyses, were proposed to define different risk groups. As with the introduction of cisplatin into testicular cancer therapy, the introduction of TKIs into CML therapy has decreased or, in some instances, eliminated the prognostic impact of most of these prognostic factors and the significance of the CML models (e.g., Sokal, Hasford, European Treatment and Outcome Study [EUTOS]). Treatment-related prognostic factors have emerged as the most important prognostic factors in the era of imatinib therapy. Achievement of complete cytogenetic response has become the major therapeutic endpoint and is the only endpoint associated with improvement in

survival. Achievement of a major molecular response is associated with decreased risk of events (relapse) and CML transformation, but has not been associated with survival prolongation among patients with complete cytogenetic response. This may be due to the efficacy of salvage TKI therapies, which are and should be implemented at the first evidence of cytogenetic relapse. Achievement of undetectable *BCR-ABL1* transcripts, particularly when sustained (>2–3 years), may offer the possibility of treatment-free remission (molecular cure rather than functional cure) in the context of investigational trials, and may allow temporary therapy interruption in women pursuing pregnancy. The lack of achievement of major or "complete" molecular responses should not be considered as "failure" of a particular TKI therapy and/or an indication to change the TKI or to consider allogeneic SCT.

Long-term updates of randomized trials suggest that second generation TKIs and imatinib are more similarly effective in lower-risk CML, but second generation TKIs may offer a greater therapeutic advantage for patients with high-risk CML.

TREATMENT

Chronic Myeloid Leukemia

With TKI therapy, the estimated 10-year survival in CML is 85%. Since 2001, six agents have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of CML. These include five oral TKIs: imatinib (Gleevec, Glivec), nilotinib (Tasigna), dasatinib (Sprycel), bosutinib (Bosulif), and ponatinib (Iclusig). Imatinib 400 mg orally daily, nilotinib 300 mg orally twice a day (on an empty stomach), dasatinib 100 mg orally daily, and bosutinib 400 mg orally daily are approved for frontline therapy of CML. All four are also approved for salvage therapy (nilotinib 400 mg twice daily; bosutinib 500 mg daily), in addition to ponatinib (45 mg daily). Because of concerns of arterio-occlusive events with ponatinib, the dose is often reduced to 15–30 mg daily after a response is achieved. Imatinib, dasatinib (140 mg daily), bosutinib, and ponatinib are also approved for the treatment of CML in transformation (accelerated and blastic phase), whereas nilotinib is only approved for chronic and accelerated phase. Dasatinib, nilotinib, and bosutinib are referred to as second-generation TKIs; ponatinib is referred to as a third-generation TKI as it is the only currently approved TKI that has clinical activity in the setting of T315I mutation (in addition to unmutated BCR-ABL1 and BCR-ABL1 with other common mutations). Nilotinib is similar in structure to imatinib but 30 times more potent. Dasatinib and bosutinib inhibit SRC family of kinases in addition to ABL1, with dasatinib reported to be 300 times more potent and bosutinib 30–50 times more potent than imatinib. In contrast to all other TKI, bosutinib has no activity against c-Kit or PDGFR. Ponatinib is effective against wild-type, and mutant *BCR-ABL1* clones. It is currently the only available BCR-ABL1 TKI active against T315I, a gatekeeper mutation resistant to the other four TKIs **(Table 101-2)**. Ponatinib also inhibits VEGFR which may be related to the high incidence of hypertension observed with this agent (Table 101-2). The sixth approved agent is omacetaxine (Synribo), a protein synthesis inhibitor with presumed more selective inhibition of the synthesis of the BCR-ABL1 oncoprotein. It is approved for the treatment of chronic and accelerated phase CML after failure of two or more TKIs, at 1.25 mg/m^2 subcutaneously twice a day for 14 days for induction and for 7 days for consolidation-maintenance. The main adverse event of omacetaxine is prolonged myelosuppression: omacetaxine 5–7 days induction and 2–5 days maintenance, perhaps combined with a TKI, may be equally effective and less toxic (Table 101-2).

Imatinib, nilotinib, and dasatinib are all acceptable frontline therapies in CML. The long-term results of imatinib are very favorable. The 8-year follow-up results show a cumulative complete cytogenetic response rate (occurring at least once) of 83%, with 60–65% of patients being in complete cytogenetic response at 5-year follow-up. The estimated 10-year survival rate is 85%. Among patients continuing on imatinib, the annual rate of transformation to accelerated -blastic phase in years 4–8 is <1%. In two randomized studies, one comparing nilotinib 300 mg twice daily or 400 mg twice daily with imatinib (ENESTnd) and the other comparing dasatinib 100 mg daily with imatinib (DASISION), the second-generation TKIs were associated with better outcomes in early surrogate endpoints, including higher rates of complete cytogenetic responses (85–87% vs 77–82%), major molecular responses (5-year rates 76–77% vs 60–64%), and MR4.5 (5-year rates 42–53% vs 31–33%), with lower rates of transformation to accelerated and blastic phase (2–5% vs 7%). However, neither study has shown a survival benefit with second-generation TKIs (with a minimum follow-up times of 5–6 years). This may be because the rate of complete cytogenetic response is ultimately similarly high with either agent, and also because sequential therapy with TKIs (following close observation and treatment change at progression) provides highly effective therapy for most patients that allows adequate long-term outcome despite relapse or intolerance after initial therapy.

Salvage therapy in chronic phase with dasatinib, nilotinib, bosutinib, or ponatinib is associated with complete cytogenetic response rates of 30–60%, depending on the salvage status (cytogenetic vs hematologic relapse), prior response to other TKIs, and the mutations at the time of relapse. Complete cytogenetic responses are generally durable, particularly in the absence of clonal evolution and mutations. Ponatinib is the only TKI active in the setting of T315I mutation, with complete cytogenetic response rates of 50–70% among patients who have received 2 or more TKI. The estimated 5-year survival rates with new TKIs as salvage are 70–75% (compared with <50% before their availability). For example, with dasatinib salvage after imatinib failure in chronic-phase CML, the estimated 7-year rate of major molecular was 46%, the estimated 7-year survival rate was 65%, and progression-free survival rate was 42%. Thus, TKIs in the salvage setting have already reduced the annual mortality from the historical rate of 10–15% to ≤5%.

TABLE 101-2 Medical Therapeutic Options in Chronic Myeloid Leukemia

AGENT (BRAND NAME)	APPROVED INDICATIONS	DOSE SCHEDULE	NOTABLE TOXICITIES
Imatinib mesylate (Gleevec)	All phases	400 mg daily	See text
Dasatinib (Sprycel)	All phases	First-line: 100 mg daily Salvage: 100 mg daily in chronic phase; 140 mg daily in transformation	Myelosuppression; pleural and pericardial effusions; pulmonary hypertension
Nilotinib (Tasigna)	All phases except blastic phase	First-line: 300 mg twice daily Salvage: 400 mg twice daily	Diabetes; arterio-occlusive disease; pancreatitis
Bosutinib (Bosulif)	All phases except frontline	500 mg daily	Diarrhea, liver toxicity
Ponatinib (Iclusig)	Optimal TKI if T315I mutation Failure of ≥2 tyrosine kinase inhibitors	45 mg daily (may consider lower starting doses in the future, e.g., 30 mg daily)	Skin rashes (10–20%); pancreatitis (5%); arterio-occlusive disease (10–20%); systemic hypertension (10–15%)
Omacetaxine mepesuccinate (Synribo)	Failure ≥2 tyrosine kinase inhibitors	1.25 mg/m^2 subcutaneously twice daily for 14 days of induction; 7 days of maintenance every month (may consider shorter dose schedules, 7 days of induction, 2–5 days of maintenance)	Myelosuppression

The goal of CML therapy is viewed differently in the context of research versus standard practice. In current practice, functional cure, which can be considered when the relative survival is similar to that of the general population, is the current goal of therapy. CML is now considered an indolent disease, which, with appropriate continuous TKI therapy, treatment compliance, careful monitoring, and early change to other TKIs as indicated, can be associated with close to normal survival. Therefore, in standard practice, achievement and maintenance of a complete cytogenetic response are the aims of therapy because complete cytogenetic response is the only outcome associated with survival prolongation. Lack of achievement of a major molecular response (protects against events; associated with longer event-free survival) or of negative *BCR-ABL1* transcripts (offers the potential of TKI interruption on investigational studies) should not be considered indications to change TKI therapy or to consider allogeneic SCT. A general practice rule is to continue the particular TKI chosen at the most tolerable dose schedule not associated with grade 3–4 side effects or with bothersome chronic side effects, for as long as possible, until either cytogenetic relapse or the persistence of unacceptable side effects. These two factors (i.e., cytogenetic relapse and intolerable side effects as judged by the patient and treating physician) are the indicators of "failure" of a particular TKI therapy. A second emerging general practice rule is that patients with CML should always receive daily TKI therapy throughout their lifetime (chronic, transformation), either alone (chronic) or in combinations (possibly for those in transformation although combinations not formally approved), except perhaps in situations of "molecular cure" (elective discontinuation of TKI with close observation if *BCR-ABL* transcripts undetectable are sustained for >2–3 years) or after allogeneic SCT with undetectable disease.

Because of the increasing prevalence of CML (cost of TKI therapy) and the emerging evidence of possible organ toxicities with long-term use (e.g., renal with imatinib, arterio-occlussive with nilotinib, dasatinib, and ponatinib), a goal of therapy of increasing interest in CML is to achieve eradication of the disease (molecular cure) that is prolonged and durable, with recovery of non-neoplastic, non-clonal hematopoiesis off TKI therapy. The first step toward this aim is to obtain the highest rates of undetectable *BCR-ABL1* transcripts lasting for at least 2 or more years. This is currently achievable in about 25–30% of patients treated with imatinib and in 40–45% of patients treated with second-generation TKIs. As a result, molecular cures (off TKI therapy) are estimated to be about 15% post-imatinib therapy and 20–25% post–second-generation TKIs.

Recommendations provided by the National Comprehensive Cancer Network (NCCN) and by the European LeukemiaNet (ELN) propose optimal/expected, suboptimal/warning, and failure response scenarios at different time points of TKI treatment duration. Unfortunately, they may have been misinterpreted in current practice, because oncologists often report that their aim of treatment is the achievement of major molecular response and disease eradication. Significantly, a substantial proportion of oncologists consider a change of TKI therapy in a patient in complete cytogenetic response if they note "loss of major molecular response" (increase of *BCR-ABL1* transcripts ([IS] from ≤0.1 to >0.1%). This perception may be the result of confusion regarding the aims of the NCCN and ELN guidelines, which have been updated often as a result of maturing data and have multiple treatment endpoint considerations. Although such endpoints may have been suggested as possible criteria for failure or suboptimal response, it is important to emphasize that no randomized study has yet shown that a change of TKI treatment in patients with complete cytogenetic response because of a loss of major molecular response, versus changing at the time of cytogenetic relapse, has been shown to improve survival or other long-term outcome. This is likely because of the high efficacy of salvage TKI therapy at the time of cytogenetic relapse.

Side effects of TKIs are generally mild to moderate, although with long-term TKI therapy, they could affect the patient's quality of life. Serious side effects occur in <5–10% of patients. With imatinib therapy, common mild to moderate side effects include fluid retention, weight gain, nausea, diarrhea, skin rashes, periorbital edema, bone or muscle aches, fatigue, and others (rates of 10–20%). In general, second-generation TKIs are associated with lower rates of these bothersome adverse events. However, dasatinib 100 mg daily is associated with higher rates of myelosuppression (20–30%), particularly thrombocytopenia, with pleural (10–25%) or pericardial effusions (≤5%), and with pulmonary hypertension (<5%). Nilotinib is associated with higher rates of hyperglycemia (10–20%), pruritus and skin rashes, hyperbilirubinemia (typically among patients with Gilbert's syndrome and mostly of no clinical consequences), and headaches. Nilotinib is also associated with occasional instances of pancreatitis (<5%). Bosutinib is associated with higher rates of liver toxicity and of early and self-limited gastrointestinal adverse events, particularly diarrhea (70–85%). Ponatinib is associated with higher rates of skin rashes (10–15%), pancreatitis (10%), elevations of amylase/lipase (10%), and systemic hypertension (50–60%; severe in 20%). Arterio-occlusive events (cardiovascular, cerebrovascular, and peripheral arterial) have been reported with most TKI. The incidence appears to be highest with ponatinib, but both nilotinib and dasatinib are associated with these events at an incidence significantly higher than imatinib. Nilotinib and dasatinib may cause prolongation of the QTc interval; therefore, they should be evaluated cautiously in patients with prolonged QTc interval on electrocardiogram (>470–480 ms), and drugs given for other medical conditions should have relatively smaller or no effects on QTc. These side effects can often be dose-dependent and are generally reversible with treatment interruptions and dose reductions. Dose reductions can be individualized. However, the lowest estimated effective doses of TKIs (from different studies and treatment practices) are imatinib 200–300 mg daily; nilotinib 150–200 mg twice daily; dasatinib 20 mg daily; bosutinib 300 mg daily; and ponatinib 15 mg daily.

With long-term follow-up, rare but clinically relevant serious toxicities are emerging. Renal dysfunction and occasionally renal failure (creatinine elevations >2–3 mg/dL) are observed in 2–3% of patients, more frequently with imatinib and bosutinib than other TKI, and usually reverse with TKI discontinuation and/or dose reduction. Rarely, patients may develop TKI-related peripheral neuropathy or even central neurotoxicities that are misdiagnosed as dementia or Alzheimer's disease; they may reverse slowly after TKI discontinuation. Pulmonary hypertension has been reported with dasatinib (<1–2%) and should be considered in a patient with shortness of breath and a normal chest x-ray (echocardiogram with emphasis on measurement of pulmonary artery pressure). This may be reversible with dasatinib discontinuation and occasionally the use of sildenafil citrate. Systemic hypertension has been observed more often with ponatinib. Hyperglycemia and occasionally diabetes have been noted more frequently with nilotinib. Finally, mid- and small-vessel arterio-occlusive and vasospastic events have been reported at low but significant rates with nilotinib and ponatinib and should be considered possibly TKI-related and represent indications to interrupt or reduce the dose of the TKI. These events include angina, coronary artery disease, myocardial infarction, peripheral arterial occlusive disease, transient ischemic attacks, cerebral vascular accidents, Raynaud's phenomenon, and accelerated atherosclerosis. Although these events are uncommon (<5%) (10-year cumulative rates 10% with nilotinib 300 mg BID, 16% with 400 mg BID, compared with 2.5% with imatinib), they are clinically significant for the patient's long-term prognosis and occur at significantly higher rates than in the general population. Serious arterio-occlusive and vasospastic events are more common with ponatinib 45 mg daily (5-year rates 20%).

Discontinuation of TKIs and Treatment-Free Remissions or "Molecular Cures" Several studies have confirmed that TKI discontinuation among patients who achieve undetectable *BCR-ABL1* transcripts for longer than 2–3 years can result in treatment-free remission rates of 40–60%. Since the incidence of durable undetectable *BCR-ABL1* transcripts is 20–45%, about 13–22% of all patients with CML on TKI therapy may achieve treatment-free remission status or molecular cure. This approach is still considered investigational, but may be ready for community practice provided it is done under optimal

conditions. These include the following: patients must have low Sokal-risk CML in first chronic phase (no evidence of transformation), with history of quantifiable *BCR-ABL1* transcripts (e13a2, e14a2), on long-term TKI therapy (5 to 8+ years), with documented undetectable *BCR-ABL1* transcripts for >2–3 years (assessed every 6 months during this timespan and with a PCR with adequate sensitivity), and should be monitored at referral centers that offer rigorous testing of residual CML disease. Patients must also be compliant to frequent monitoring (PCR studies every 1–2 months for the first 6 months, then every 2 months until 2 years and every 3–6 months thereafter).

ALLOGENEIC STEM CELL TRANSPLANT

Allogeneic SCT, a curative modality in CML, is associated with long-term survival rates of 40–60% when implemented in the chronic phase. It is associated with early (1-year) mortality rates of 5–30%. Although the 5- to 10-year survival rates were reported to be around 50–60% (and considered as cure rates), about 10–15% of patients die in the subsequent 1–2 decades from subtle long-term complications of the transplant (rather than from CML relapse). These are related to chronic graft-versus-host disease (GVHD), organ dysfunction, development of second cancers, and hazard ratios for mortality higher than in the normal population. Other significant morbidities include infertility, chronic immune-mediated complications, cataracts, hip necrosis, and other morbidities affecting quality of life. The cure and early mortality rates in chronic-phase CML are also associated with several factors: patient age, duration of chronic phase, whether the donor is related or unrelated, degree of matching, preparative regimen, and others. In accelerated-phase CML, the cure rates with allogeneic SCT are 20–40%, depending on the definition of accelerated disease. Patients with clonal evolution as the only criterion have cure rates of up to 40–50%. Patients undergoing allogeneic SCT in second chronic phase have cure rates of 40–50%. The cure rates with allogeneic SCT in blastic phase CML are ≤15%. Post–allogeneic SCT strategies are now implemented in the setting of molecular or cytogenetic relapse or in hematologic relapse/transformation. These include the use of TKIs for prevention or treatment of relapse, donor lymphocyte infusions, and second allogeneic SCTs, among others. TKIs appear to be highly successful at reinducing cytogenetic/molecular remissions in the setting of cytogenetic or molecular relapse after allogeneic SCT.

Choice and Timing of Allogeneic SCT Allogeneic SCT was considered first-line CML therapy before 2000. The maturing positive experience with TKIs has now relegated its use to after first-line TKI failures. An important question is the optimal timing and sequence of TKIs and allogeneic SCT (whether allogeneic SCT should be used as second- or third-line therapy). Among patients who present with or evolve to blastic phase, combinations of chemotherapy and TKIs should be used to induce remission, followed by allogeneic SCT as soon as possible. The same applies to patients who evolve from chronic to accelerated phase. Patients with de novo accelerated-phase CML may do well with long-term TKI therapy (estimated 8-year survival rate 75%); the timing of allogeneic SCT depends on their optimal response to TKI (achievement of complete cytogenetic response). Among patients who relapse in chronic phase, the treatment sequence depends on several factors: (1) patient age and availability of appropriate donors; (2) risk of allogeneic SCT; (3) presence or absence of clonal evolution and mutations; (4) patient's prior history and comorbidities; and (5) patient and physician preferences **(Table 101-3)**. Patients with T315I mutations at relapse should be offered ponatinib and considered for allogeneic SCT particularly in blastic phase and perhaps also in accelerated phase (because of the short follow-up with ponatinib). Patients with mutations involving Y253H, E255K/V, and F359V/C/I respond better to dasatinib or bosutinib. Patients with mutations involving V299L, T315A, and F317L/F/I/C respond better to nilotinib. Comorbidities such as diabetes, hypertension, pulmonary hypertension, chronic lung disease, cardiac conditions, and pancreatitis may influence the choice for or against a particular

TABLE 101-3 General Suggestions Regarding the Use of Tyrosine Kinase Inhibitors (TKIs) and Allogeneic Stem Cell Transplantation (SCT) in Chronic Myeloid Leukemia (CML)

CML PHASE	USE OF TKI	CONSIDERATION OF ALLOGENEIC SCT
Accelerated or blastic	Interim therapy to achieve minimal CML burden	As soon as possible (exception: de novo accelerated phase)
T315I mutation	Ponatinib to achieve minimal CML burden	Depends on longer term follow-up results of ponatinib efficacy
Imatinib failure in chronic phase; no clonal evolution, no mutations, good initial response; no T315I	Second-line tyrosine kinase inhibitors long-term	Third-line after second-line TKI failures
Clonal evolution or mutations, or no cytogenetic response to second-line TKI	Interim therapy with alternative second generation TKI or ponatinib to achieve minimal CML burden	Second-line
Older patients (≥65–70 years) after imatinib failure in chronic phase	Salvage TKIs as longer-term therapy	May forgo allogeneic SCT in favor of good quality of life and survival in chronic phase
Imatinib failure; emerging nation	–	Second-line: curative, one-time cost $20,000–100,000 (versus >$40,000–100,000/year with TKI)

Note: Mutations involving Y253H, E255K/V, or F359V/C/I: prefer dasatinib or bosutinib. Mutations involving V299L, T315A, or F317L/F/I/C: prefer nilotinib.

TKI. Patients with clonal evolution, unfavorable mutations, or lack of major/complete cytogenetic response within 1 year of salvage TKI therapy have short remission durations and should consider allogeneic SCT as more urgent in the setting of salvage. Patients without clonal evolution or mutations at relapse and who achieve a complete cytogenetic response with TKI salvage, have long-lasting complete remissions and may delay the option of allogeneic SCT to third-line therapy. Finally, older patients (age 65–70 years or older) and those with high risk of mortality with allogeneic SCT may forgo this curative option for several years of disease control in chronic phase with or without cytogenetic response (Table 101-3). In emerging nations, where generic imatinib is now available at the annual price of $400–3000, frontline imatinib is a cost-effective therapy. However, second-line therapy with allogeneic SCT, a one-time curative option with a cost of $20,000–100,000, may be considered (in preference to second-generation TKIs—annual cost above $40,000–100,000) as a more cost-effective national health-care strategy in CML. Table 101-3 summarizes a general guidance to the choice of TKIs versus allogeneic SCT.

MONITORING THERAPY IN CML

Achievement of complete cytogenetic response by 12 months of imatinib therapy and its persistence later, the only consistent prognostic factor associated with survival, is now the main therapeutic endpoint in CML. Failure to achieve a complete cytogenetic response by 12 months or occurrence of later cytogenetic or hematologic relapse are considered as treatment failure and an indication to change therapy. Because salvage therapy with other TKIs re-establishes good outcome, it is important to ensure patient compliance to continued TKI therapy and change therapy when cytogenetic relapse is confirmed unless this is related to non-adherence. Patients on frontline imatinib therapy should be closely monitored until documentation of complete cytogenetic response, at which time they can be monitored every 6 months with peripheral blood FISH and PCR studies (to check for concordance of results), or more frequently if there are concerns about changes in *BCR-ABL1* transcripts (e.g., every 3 months). Monitoring by PCR only is reasonable in patients who

are in major molecular response. Cytogenetic relapse on imatinib is an indication of treatment failure and need to change TKI therapy. Mutational analysis in this instance helps in the selection of the next TKI and identifies mutations in 30–50% of patients. Mutational studies by standard Sanger sequencing (which is the technique currently available in most clinical laboratories) in patients in complete cytogenetic response (in whom there may be concerns of increasing *BCR-ABL1* transcripts) identify mutations in ≤5% and are therefore not indicated. Earlier response has been identified as a prognostic factor for long-term outcome, including achievement of partial cytogenetic response (*BCR-ABL1* transcripts ≤10%) by 3–6 months of therapy. Failure to achieve such a response has been associated with significantly worse survival.

The use of second-generation TKIs (nilotinib, dasatinib) as frontline therapy changed the monitoring approach slightly. Patients are expected to achieve major cytogenetic response (or *BCR-ABL1* transcripts ≤10%) by 3–6 months of therapy. Failure to do so is associated with worse event-free survival, transformation rates, and survival. However, the 3- to 5-year estimated survival among such patients is still high, around 80–90%, which is better than what would be anticipated if such patients were offered allogeneic SCT at that time. Changes of therapy for patients with "slow" response have not been proven to be of long-term benefit compared to changes when more obvious signs of resistance appear. Thus, this adverse response to therapy is considered a warning signal, but it is not known whether changing therapy to other TKIs at that time would improve longer-term outcome.

TREATMENT OF ACCELERATED AND BLASTIC PHASES

Patients in accelerated or blastic phase may receive therapy with TKIs, preferably second- or third-generation TKIs (dasatinib, nilotinib, bosutinib, ponatinib), alone or in combination with chemotherapy, to reduce the CML burden, before undergoing allogeneic SCT. Response rates (major hematologic) with single-agent TKIs range from 30 to 50% in accelerated phase and from 20 to 30% in blastic phase. Cytogenetic responses, particularly complete cytogenetic responses, are uncommon (10–30%) and transient in blastic phase. Studies of TKIs in combination with chemotherapy are ongoing; the general experience suggests that combined TKI-chemotherapy strategies increase the response rates and their durability and improve survival. This is particularly true in CML lymphoid blastic phase, where the combination of anti-ALL chemotherapy with TKIs results in complete response rates of 60–70% and median survival times of 2–3 years (compared with historical response rates of 40–50% and median survival times of 12–18 months). This allows many patients to undergo allogeneic SCT in a state of minimal CML burden or second chronic phase, which are associated with higher probability of long-term survival. In CML nonlymphoid blastic phase, anti-AML chemotherapy combined with TKIs results in CR rates of 30–50% and median survival times of 9–12 months (compared with historical response rates of 20–30% and median survival times of 3–5 months). In accelerated phase, response to single TKIs is significant in conditions where "softer" accelerated phase criteria are considered (e.g., clonal evolution alone, thrombocytosis alone, significant splenomegaly or resistance to hydroxyurea, but without evidence of high blast and basophil percentages). In accelerated phase, combinations frequently include TKIs with low-intensity chemotherapy such as low-dose cytarabine, low-dose idarubicin, decitabine, interferon α, hydroxyurea, or others.

OTHER TREATMENTS AND SPECIAL THERAPEUTIC CONSIDERATIONS

Interferon α Interferon α is considered in combination with TKIs (an investigational approach), sometimes after CML failure on TKIs, occasionally in patients during pregnancy, or as part of investigational strategies with TKIs to eradicate residual molecular disease.

Chemotherapeutic Agents Hydroxyurea remains a safe and effective agent (at daily doses of 0.5–10 g) to reduce initial CML burden, as a temporary measure in between definitive therapies, or in combination with TKIs to sustain complete hematologic or cytogenetic responses. Busulfan is often used in allogeneic SCT preparative regimens. Because of its side effects (delayed myelosuppression, Addison-like disease, pulmonary and cardiac fibrosis, myelofibrosis), it is now only rarely used in the chronic management of CML. Low-dose cytarabine, decitabine, anthracyclines, 6-mercaptopurine, 6-thioguanine, thiotepa, anagrelide, and other agents are sometimes useful in different CML settings to control the disease burden.

Others Splenectomy is now seldom considered to alleviate symptoms of massive splenomegaly and/or hypersplenism. Splenic irradiation is rarely used, if at all, because of the postirradiation adhesions and complications. Leukapheresis is occasionally used in patients presenting with extreme leukocytosis and leukostatic complications. Single doses of high-dose cytarabine or high doses of hydroxyurea, with tumor lysis management, may be as effective and less cumbersome.

Special Considerations Women with CML who become pregnant should discontinue TKI therapy immediately. Among 125 babies delivered to women with CML who discontinued imatinib therapy as soon as the pregnancy was known, three babies were born with neurologic, skeletal, and renal malformations, suggesting the teratogenicity of imatinib known from animal studies. A similar experience has been reported with dasatinib, the incidence of malformations was reported to be higher, 10–12%. There are no or little data with other TKIs. Control of CML during pregnancy can be managed with leukapheresis for severe symptomatic leukocytosis in the first trimester and with hydroxyurea subsequently until delivery. There are case reports of successful pregnancies and deliveries of normal babies with interferon α therapy and registry studies in essential thrombocytosis of its safety, but interferon α can be antiangiogenic and may increase the risk of spontaneous abortions.

Approximately 10–15% of patients on TKI therapy may develop chromosomal abnormalities in the Ph-negative cells. These may involve loss of chromosome Y, trisomy 8, 20q–, chromosome 5 or 7 abnormalities, and others. Most chromosomal abnormalities disappear spontaneously and may be indicative of the genetic instability of the hematopoietic stem cells that predisposes the patient to develop CML in the first place. Rarely (in <1% of instances), abnormalities involving chromosomes 5 or 7 may be truly clonal and evolve into myelodysplastic syndrome or acute myeloid leukemia. This is thought to be part of the natural course of patients in whom CML was suppressed and who live long enough to develop other hematologic malignancies.

GLOBAL ASPECTS OF CML

Routine physical examinations and blood tests in the United States and advanced countries result in early detection of CML in most patients. About 50–70% of patients with CML are diagnosed incidentally, and high-risk CML as defined by prognostic models (e.g., Sokal risk groups) is found in only 10% of patients. This is not the same situation in emerging nations where most patients are diagnosed following evaluation for symptoms and many present with high tumor burden, such as massive splenomegaly, and advanced phases of CML (high-risk CML documented in 20–30%). Therefore, the prognosis of such patients on TKI therapy may be worse than the published experience.

The high cost of TKI therapies (annual costs of $90,000–140,000 in the United States; lower but variable in the rest of the world) makes the general affordability of such treatments difficult. Although TKI treatment penetration is high in nations where cost of therapy is not an issue (e.g., Sweden, European Union), it may be less so in other nations, even in advanced ones like the United States, where out-of-pocket expenses may be prohibitive to a subset of patients. Based on the sales of imatinib worldwide and charity-free drug supplies, it is estimated that <30% of patients are treated with imatinib (or other TKIs) consistently. Although the estimated 10-year survival in CML is 85% in single-institution studies (e.g., MD Anderson Cancer Center), in national studies in countries with TKI affordability (Sweden)

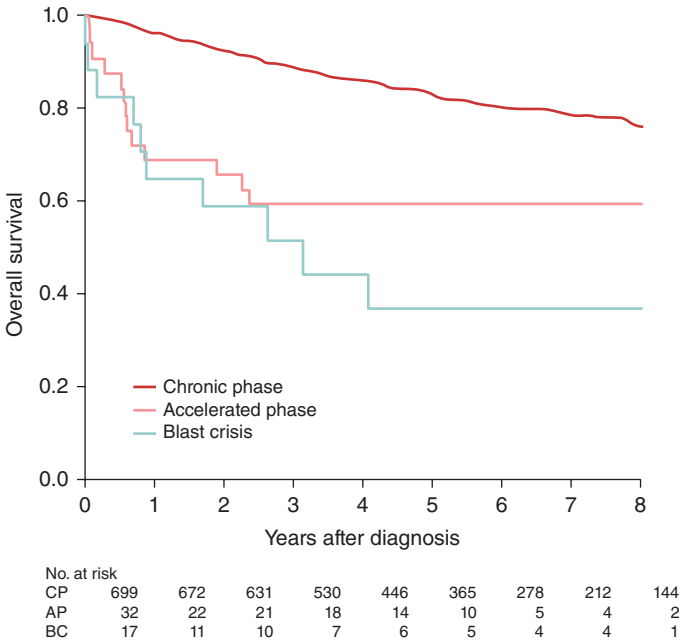

FIGURE 101-3 Survival in chronic (CP), accelerated (AP), and blastic crisis (BC) phases of chronic myeloid leukemia (CML) in the population-based Swedish national registry study. The accelerated- and blastic-phase cases are de novo presentations. The favorable outcome with de novo blastic phase may be due to use of 20% blasts or more to define blastic phase. *(With permission from Dr. Martin Hoglund, Swedish CML Registry, 2013.)*

(Figs. 101-2 and 101-3) or in company-sponsored studies (where all patients have access to TKIs throughout their care), the estimated 10-year survival worldwide, even 16 years after the introduction of TKI therapies, is likely to be <50%. The Surveillance, Epidemiology, and End Results (SEER) data from the United States report an estimated 5-year survival rate of 60% in the era of TKIs.

The current high cost of TKI therapies poses two additional considerations. The first are the treatment pathways and guidelines in nations where TKIs may not be affordable by patients or the health care system. In these conditions, there are trends of pathways advocating allogeneic SCT as frontline or second-line therapy (i.e., after imatinib failure; as a one time cost of $20,000–100,000) despite the associated mortality and morbidities. The second is the choice of frontline TKI therapy once imatinib becomes available in generic forms, hopefully at much lower annual prices, e.g., $2000–10,000 per year (currently $400 per year in India). This will depend on the maturing data in randomized studies of second-generation TKIs versus imatinib in relation to important long-term outcome endpoints, particularly survival, but also event-free survival, transformation-free survival, and treatment-free remission.

102 Acute Lymphoid Leukemia

Dieter Hoelzer

In acute lymphoblastic leukemia (ALL), the malignant clone arises from hematopoietic progenitors in the bone marrow or lymphatic system resulting in an increase of immature nonfunctioning leukemic cells. Infiltration of bone marrow leads to anemia, granulocytopenia, and thrombocytopenia with the clinical manifestations of fatigue, weakness, infection, and hemorrhages. These symptoms are more often the reason a patient first seeks medical advice rather than consequences of tumor bulk, such as lymph node enlargement, hepatosplenomegaly caused by leukemic infiltration, or symptoms of the central nervous system (meningeosis leukemica).

The diagnosis of ALL is made by morphology from smears of peripheral blood or bone marrow. The classification includes cytochemistry, immunological markers, cytogenetic, and molecular genetic analysis.

INCIDENCE AND AGE

ALL is the most frequent neoplastic disease in children with an early peak at the age of 3–4 years. The incidence in adults ranges from 0.7 to 1.8/100,000 per year, being somewhat higher in younger adults (1–1.5 for the age group 15–24 years) and decreasing thereafter, only to increase again in elderly people to 2.3 for age >65 years. The frequency of immunological, cytogenetic, and genetic subtypes changes with age.

ETIOLOGY

The etiology of acute leukemias is unknown. There are, however, internal and external factors that influence the incidence of leukemia. In ALL, inheritance of certain diseases and exposure to ionizing radiation or to chemicals, including prior chemotherapy, are associated with an increased risk of developing leukemia, but less than in acute myeloid leukemia (AML).

CONGENITAL DISORDERS

Patients with some rare congenital chromosomal abnormalities have a higher risk of development of acute leukemia; e.g., Klinefelter's syndrome, Fanconi's anemia, Bloom's syndrome, ataxia telangiectasia, and neurofibromatosis. There is a twentyfold increased incidence of leukemia in patients with Down syndrome, in whom ALL is increased in childhood or AML at an older age. Genetic predisposition may play a part in acute leukemia even, when not associated with another inherited disease, as the identical twin of a leukemic child has a fivefold risk of developing acute leukemia.

INFECTIOUS AGENTS

Human T-cell leukemia virus I (HTLV-I), endemic in Japan and the Caribbean, is the etiological agent for adult T-cell leukemia/

lymphoma, an aggressive adult T-cell leukemia (see Chap. 196). In the endemic African type of Burkitt's lymphoma, the Epstein-Barr virus, a DNA virus of the herpes family, has been implicated as a potential causative agent.

DIAGNOSIS AND CLASSIFICATION

The diagnosis of acute leukemia is made by examination of the peripheral blood and bone marrow. Classification of the patient's disease also requires cytochemical stains, assessment of expression of immunological markers, cytogenetic analysis, and molecular markers. The major aim of classification is to distinguish between AML and ALL because of the different treatment approaches and drug sensitivities. The immunological markers are the major criteria to subdivide ALL into B-cell lineage or T-cell lineage (T-ALL) leukemias. Cytogenetic and molecular evaluation provide further identification of ALL subgroups.

PERIPHERAL BLOOD

Peripheral blood counts and a differential count from a Wright-Giemsa-stained blood smear are essential at the time of presentation. The white blood cell count in about 40% of ALL patients is reduced or normal (Table 102-1). Thus, in the frequently used automatic blood cell counter, the disease may not be detected. One-third of the patients have a moderately increased initial white blood cell count, between 10×10^9 and 50×10^9/L. Leukemic blast cells (LBC) in the peripheral blood are largely responsible for the rise in white blood cell count, but it is noteworthy that in 8% of the ALL patients, no circulating leukemic blast cells are observed.

Peripheral blood observation shows characteristic anemia, thrombocytopenia, and neutropenia. The reduction in the level of hemoglobin is usually mild to moderate, but nearly one-third of the patients have hemoglobin levels <7–8 g/dL. A platelet count below the critical number of 20×10^9/L is seen in one-fifth of the ALL patients. The proportion of patients with granulocyte count $<0.5 \times 10^9$/L usually associated with high risk of infection was only one-fifth in adult ALL series.

BONE MARROW EXAMINATION

Bone marrow aspirates are important for immunological, cytogenetic, and genomic markers. Direct smears from the bone marrow are essential to confirm the diagnosis of acute leukemia and to distinguish between AML and ALL. The bone marrow is usually heavily packed with leukemic blast cells comprising >90% of the nucleated cells in ~70% of patients. The normal hemopoietic elements are greatly reduced or absent. A biopsy of the bone marrow will further demonstrate marked hypercellularity with replacement of fat spaces and normal elements by infiltration with leukemic cells.

TABLE 102-1 Laboratory Values at Diagnosis of Acute Lymphoblastic Leukemia

		ALL
N		1273*
Initial white blood cell count ($\times 10^9$/L)	<10	41%
	10–50	31%
	>50	28%
Neutrophils	<50–100	12%
	<100,000	16%
Platelets ($\times 10^9$/L)	<20	22%
	21–40	22%
	41–100	29%
	>100	27%
Hemoglobin (g/dL)	<7	20%
	7–9	33%
	>9	47%
Leukemic blasts in PB	0%	8%
	25–75%	34%
	>75%	36%
Leukemic blasts in BM	<50%	4%
	51–90%	25%
	>90%	71%

LUMBAR PUNCTURE

The examination of the cerebrospinal fluid is an essential routine diagnostic measure for ALL. There are different opinions as to when the first lumbar puncture should be done. One procedure is to delay the examination until remission is achieved in order to avoid seeding the central nervous system (CNS) by circulating leukemic blast cells from the peripheral blood. On the other hand, early recognition of CNS disease will lead to immediate CNS-specific therapy, which is required for such patients. Thus, other clinicians prefer to perform the lumbar puncture before treatment starts. This procedure is restricted to patients with an adequate platelet count ($>20 \times 10^9$/L), an absence of manifest clinical hemorrhage, and without a high white blood cell count. For safety reasons, all patients should receive intrathecal methotrexate at the first lumbar puncture.

MORPHOLOGICAL SUBTYPES IN ALL

Three morphologic subgroups of acute lymphoblastic leukemia are distinguished by the French-American-British classification. Whereas the distinction between L1 and L2 morphology has no clinical consequences, the detection of L3 ALL is of clinical and prognostic relevance. It is observed in up to 5% of adult patients and should be distinguished as it is indicative of mature B-ALL, usually termed Burkitt's leukemia, with distinct treatment options. A surface marker confirmation should be obtained.

IMMUNOLOGICAL SUBTYPES OF ALL

A series of monoclonal antibodies is employed to identify antigens expressed on the surface of normal or leukemic cells. The main aim of the immunological classification is to subdivide ALLs according to the presence or absence of B-cell or T-cell markers, or B-phenotypic/hybrid acute leukemia. A marker is positive if >20% of the cells are stained with the monoclonal antibody (Table 102-2).

B-Cell Lineage More than 70% of adult ALLs are of B-cell origin, and the most frequent immunological subtype, common ALL, is characterized by the presence of ALL antigen, a glycoprotein (gp100/CD10). Common ALL blast cells do not carry markers of mature B cells such as cytoplasmic immunoglobulins or surface membrane immunoglobulins. Pre-B-ALL (early B-ALL) is characterized by the expression of cytoplasmic immunoglobulin, being negative in common ALL but is otherwise identical with all other cell markers. Very rarely, the common ALL antigen may be absent in this subtype. Mature B-ALL comprises about 3–4% of adult ALL patients. The blast cells express surface antigens of mature B cells, including the sIgM. Common ALL antigens may also be present and also occasionally cytoplasmic immunoglobulin. Pro-B-ALL (also termed *early B-precursor ALL*) is a leukemia that was formerly termed *non-T, non-B-ALL*, or *null-ALL* as neither T-cell nor B-cell features could be demonstrated. This subtype is Tdt (terminal) deoxynucleotidyl transferase, and CD19 positive and forms about 11% of adult ALL.

T-Cell Lineage Approximately 25% of adult ALL belongs to the T-cell lineage. All cases express the T-cell antigen (gp40, CD7) and cytoplasmatic or surface CD3. They may, according to their step of T-cell differentiation, express other T-cell antigens, e.g., the E-rosette receptor (CD2) and/or the cortical thymocyte antigen T6 (CD1). A minority of T-ALL blast cells may also express common ALL antigen together with other T-cell antigens. According to these markers, it is possible to distinguish a pro-T-ALL (also termed *early T-precursor ALL*), cortical, or thymic T-ALL and a mature T-ALL expressing different stages of differentiation.

Biphenotypic or Mixed Leukemias Biphenotypic leukemias are defined as those in which markers of lymphoid and myeloid lineages are coexpressed on the same leukemic cells without the typical phenotype of either ALL or AML. Bilineage leukemias are those

TABLE 102-2 Immunological, Cytogenetic, Molecular, and Clinical Characteristics of Adult ALL

SUBTYPES	MARKER	INCIDENCE	FREQUENT CYTOGENETIC ABERRATIONS	FUSION TRANSCRIPTS AND MUTATIONS	CLINICAL CHARACTERISTICS	RELAPSE KINETICS AND LOCALIZATION
B-lineage ALL	HLA-DR+, TdT+, CD19+ and/or CD79a+ and/or CD22+	76%				
Pro B-ALL	No additional differentiation markers, Freq. myeloid coexpression (>50%)	12%	t(4;11) (q21;q23)	70% ALL1-AF4 (20% Flt3 in MLL+)	High WBC (>100.000/mL) (26%)	Mainly BM (>90%)
Common ALL	CD10	49%	t(9;22)(q34;q11) del(6q)	33% BCR–ABL (30–50% in c/preB)	Higher age >50 years (24%)	Mainly BM (>90%) Prolonged relapse kinetics (up to 5–7 years)
Pre-B-ALL	CD10±, cylg+	11%	t(9;22)(q34;q11) t(1;19)(q23;p13)	4% t(1;19)/ PBX-E2A		
Mature B-ALL	CD10 ±, slg+	4%	t(8;14)(q24;q32) t(2;8)(p12;q24) t(8;22)(q24;q11)		Higher age >55 years (27%) Frequent organ involvement (32%) and CNS-involvement (13%)	Frequent CNS (10%) Short relapse kinetics (up to 1–1.5 years)
T-lineage ALL	cyCD3 or sCD3	24%			Younger age (90% <50 years) Frequent mediastinal tumors (60%) Frequent CNS involvement (8%) High WBC (>50/mL) (46%)	Frequent CNS (10%)/ extramedullary (6%) Intermediate relapse kinetics (up to 3–4 years)
Early Pro/Pre T-ALL Cortical T-ALL Mature T-ALL	No additional differentiation markers, mostly CD2- CD1a+, sCD3± sCD3+, CD1a-	6% 12% 6%	t(10;14)(q24;q11) t(11;14)(p13;q11)	5% HOX11-TCR <5% LMO/TCR 2% SIL-TAL1 In T-ALL 4% NUP213-ABL1 33% HOX11b 5% HOX11L2b 50% Notch1b		

with two populations of blast cells with either lymphoid or myeloid antigens. They must be differentiated from AML by coexpression of lymphoid markers and from ALL by coexpression of myeloid markers.

CYTOGENETIC AND MOLECULAR ANALYSIS

Cytogenetic analysis should be performed in all cases of acute leukemia. The demonstration of a specific karyotype may be required for the confirmation of the diagnosis, but chromosome abnormalities may be also important independent prognostic variables for disease-free survival or may lead to a specific targeted therapy.

DIAGNOSTICS

The diagnostic techniques are standard cytogenetics, fluorescence in situ hybridization, and reverse transcriptase polymerase chain reaction. These methods allow the detection of Ph+ ALL, with the chromosomal translocation t(9;22)(q34;q11), and the detection of the corresponding *BCR-ABL1* gene rearrangement. Further ALL entities that have been identified are t(4;11)(q21;q23)/*MLL-AFA4*, abn11q23/*MLL*, and t(1;19)(q23;p13)/*PBX-E2A*.

Gene expression profiling, single nucleotide polymorphism array analysis, array-comparative genomic hybridization, and next generation sequencing recognize newly defined ALL entities with poor prognosis: Ph-like ALL and early T-precursor ALL.

NEW ENTITIES

Ph-Like ALL, also called *BCR-ABL1*-like ALL, is characterized by genetic lesions similar to Ph+ ALL, associated with *IKZF1* deletion, *CLRF2* overexpression, and tyrosine kinase activating rearrangements involving *ABL1*, *JAK2*, *PDGFRB*, and several others. The frequency is 10% in children and 25–30% in young adults, but does not increase further with age. Treatment could be directed at the underlying genetic pattern with BCR-ABL inhibitors (e.g., dasatinib) or JAK2 inhibitors (e.g., ruxolitinib).

Early T-Precursor ALL (ETP-ALL) is characterized by lack of CD1a and CD8, weak CD5 expression, at least one myeloid/stem cell marker, a specific transcriptional profile and the possible involvement of several critical genes. No new treatment approaches are currently available for this subtype, and thus hematopoietic stem cell transplantation in first complete remission is the preferred option.

MINIMAL RESIDUAL DISEASE (MRD)

MRD is the detection of residual leukemic cells, not recognizable by light microscopy.

Methods for determining MRD are based on the detection of leukemia-specific aberrant immunophenotypes by flow cytometry, the evaluation of leukemia-specific rearranged immunoglobulin or T-cell receptor sequences by real-time quantitative polymerase chain reaction, or the detection of fusion genes associated with chromosomal abnormalities (e.g., BCR-ABL, MLL-AF4). The detection limit with these methods is 10^{-3}–10^{-5} (0.1–0.001%). The phenotypic aberrations are unique to each patient with ALL and can be detected in up to 95% of individuals. Methods for MRD evaluation and standardization of MRD quantification have been extensively described.

MRD RESPONSE AND TERMINOLOGY

Molecular response can be evaluated only for patients in complete cytological remission, with one marker or more for MRD analysis and

TABLE 102-3 Response Parameters According to MRD

TERMINOLOGY	DEFINITION
Complete (hematologic) remission	Leukemic cells not detectable by light microscopy (<5% blast cells in bone marrow)
Complete molecular remission MRD-negativity	Patient in complete remission, MRD not detectable, ≤0.01% = ≤1 leukemia blast cell in 10,000
Molecular failure/ MRD-positivity	Patient in complete hematologic remission but not in molecular complete remission >0.01%
Molecular relapse/ MRD-positivity	Patient still in complete remission had prior molecular complete remission Leukemic blast cells detectable in bone marrow not detectable (<5%)
Hematologic relapse	>5% ALL cells in bone marrow/blood

samples available at diagnosis and followed at specific time points during the course of disease. Results are classified as presented in Table 102-3.

MOLECULAR RESPONSE AFTER INDUCTION THERAPY AND IMPACT ON OUTCOME

Achievement of molecular complete response/molecular remission is the most relevant independent prognostic factor for disease-free survival and overall survival. Patients with molecular complete remission after induction therapy had significantly superior outcome in several studies, with a disease-free survival of 54–74%, compared to 17–40% for MRD-positive patients. Patients with molecular failure after induction therapy should proceed to a targeted therapy to reduce the tumor load, to be followed by immediate allogeneic hematopoietic stem cell transplant.

PROGNOSTIC FACTORS, RISK STRATIFICATION, AND MRD

The aim of identification of prognostic parameters at diagnosis, which include age, white blood cell count, specific immunophenotypes, and cytogenetic and genetic aberrations, is to stratify patients into risk groups: standard-risk patients without any poor-risk factors, with a good chance of cure by chemotherapy, and high-risk patients with one or more of those risk factors. High-risk patients are most often candidates for a stem cell transplant in first complete remission.

WILL MINIMAL RISK DISEASE EVALUATION REPLACE PRETHERAPEUTIC RISK FACTORS?

The question arises as to whether the evaluation of MRD overcomes all of those pretherapeutic risk factors, or whether they should be combined. A practical approach is to enter the conventional prognostic factors and MRD into a decision algorithm. Thereby defined standard-risk patients who are highly likely to achieve molecular remission (about 90–95%) will remain as standard-risk patients, whereas those who are MRD-positive will be defined accordingly as high-risk patients. Clinically defined high-risk patients are potential candidates for a stem cell transplant in first complete remission. However, it is not clear how to proceed if they achieve a complete molecular remission, since some studies suggest a lack of benefit from transplant in those who are MRD negative. If MRD information is not available, the risk stratification should rely on clinical risk factors evaluated at diagnosis. Unfortunately, 20–30% of adult ALL patients who are MRD-negative after induction will relapse. Potential reasons include loss of sensitivity, evolution of leukemic subclones, and extramedullary origin of disease.

TREATMENT PRINCIPLES

The goal of induction therapy is the achievement of a complete remission, or even better, a molecular complete remission, mostly evaluated within 6–16 weeks of starting chemotherapy. With current regimens (see Fig. 102-1), the complete remission rate has increased to 80–90%, being higher for standard-risk patients (≥90%), and lower for high-risk patients (~80%). The outcome of ALL is strictly related to the age of the patient, and treatment protocols considering the age of an individual patient have emerged.

TREATMENT IN ADULT PATIENTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Pediatric-Inspired Therapies Pediatric-inspired therapies for adolescents and young adults provide increased drug intensity at several stages of treatment, including larger cumulative doses of drugs such as glucocorticoids, vincristine, L-asparaginase, and consequent central nervous system-directed therapy, which should be strictly adhered to, thereby reducing the role of stem cell transplant in such cases. In a 2012 meta-analysis of 11 trials, including 2489 adolescents and young adults, pediatric-inspired regimens were superior to conventional adult chemotherapy. However, none of the trials was a randomized comparison. Table 102-4 gives the outcome of recent studies with pediatric-inspired regimens for adolescents and young adults with a median age of 27 years. The complete remission rate was very high with 93% (85–98%), and the overall survival rate of 70% (60–78%) was very encouraging. Survival rates at ≥5 years were 70% (67–78%) compared to 34–41% with the former protocols.

Adult ALL The treatment results for adult ALL patients have moderately improved (Table 102-4). The overall survival is 36% with a wide variation from 27 to 60% due to differences in the intensity of the chemotherapy regimen and the outcome of stem cell transplantation.

In several current multicenter prospective trials, the overall survival rate for standard-risk adult ALL patients is now 50–70% with chemotherapy alone. Overall survival for high-risk patients increased from 20–30% to >50% when they received an allogeneic stem cell transplant in first complete remission.

Elderly ALL Since palliative treatments or intensive chemotherapy regimens have failed, with either low complete remission rates or high early death rates, short elderly specific ALL protocols have been initiated, with less intensive therapy (avoiding anthracyclines and alkylating agents). With these protocols, the complete remission rate was increased to 73%, early death could be reduced to 13% (0–36%), and overall survival was 42%.

MAINTENANCE

Maintenance therapy usually consists of 6-mercaptopurine and methotrexate, a strategy transferred from childhood ALL. The duration of maintenance therapy is between 2 and 2.5 years. The potential effect of further intensification cycles of maintenance therapy remains unclear. In a large multicenter Italian study after intensive consolidation treatment, patients were randomly assigned to postconsolidation therapy with conventional maintenance or to intensified maintenance with additional alternating treatment courses of different intensity. There was no difference in the survival rate at 10 years between the treatment groups, which may suggest that, after adequate induction and consolidation therapy, the intensity of the maintenance therapy has no influence on survival.

Maintenance therapies should be adapted to immunological subtypes of ALL. In mature B-ALL, maintenance is not required. In T-ALL and B-Lineage ALL with relapses up to 2.5 years, maintenance therapy is necessary. In Ph-positive ALL, maintenance should include a BCR/ABL tyrosine kinase inhibitor (TKI), most likely the one that was used during induction and consolidation therapy. It is now also standard to give a TKI after allogeneic stem cell transplant in Ph-positive ALL as a maintenance therapy. The duration of maintenance therapy with a TKI is also 2–2.5 years and may be guided by MRD evaluation.

PROPHYLAXIS OF CENTRAL NERVOUS SYSTEM LEUKEMIA

Without some form of prophylactic CNS-directed therapy, in very early studies without any intensive systemic chemotherapy, around 30% of adults with ALL developed CNS leukemia. Prophylactic CNS therapy in ALL is essential for several reasons: CNS leukemia is more easily prevented than treated; once CNS leukemia has developed, it is generally followed by systemic relapse shortly after; and effective CNS prophylaxis also prevents systemic relapse.

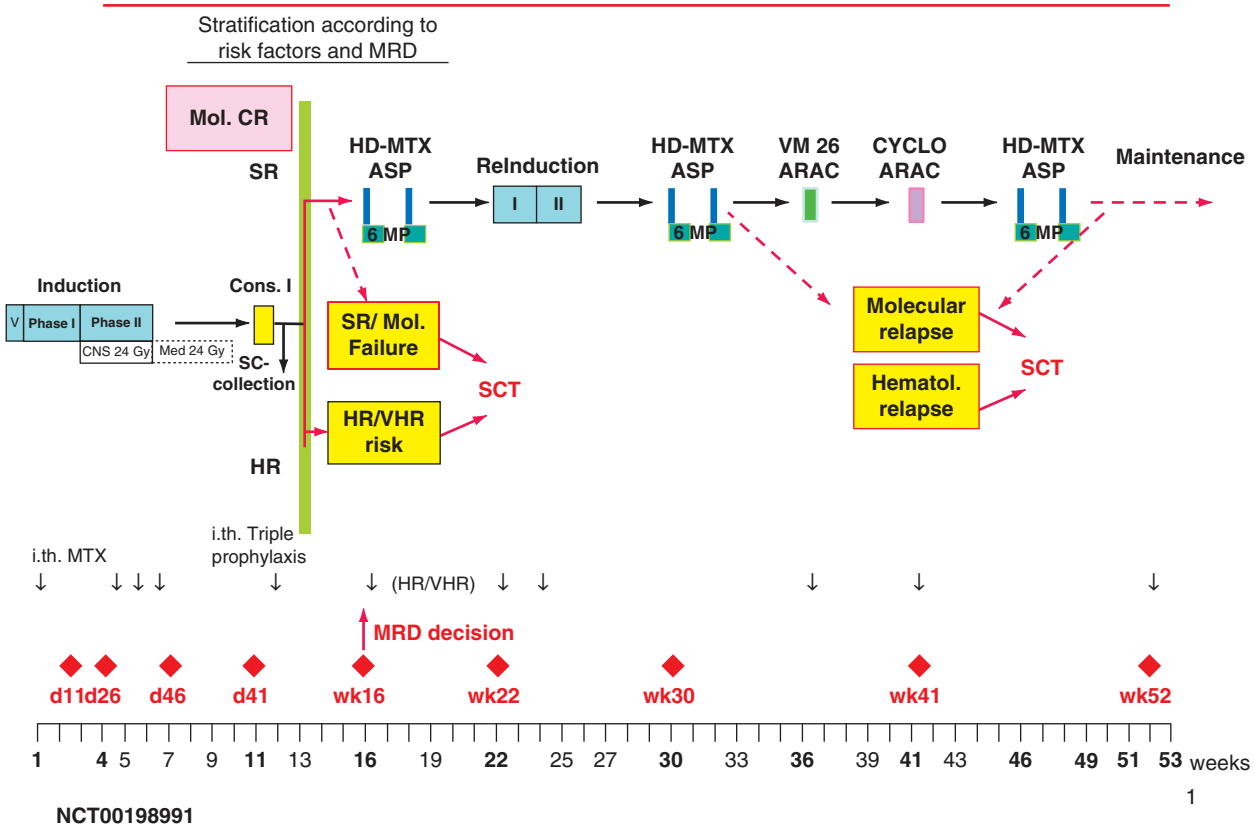

FIGURE 102-1 An example treatment schema for adult ALL. A variety of effective treatment programs are available. Each generally includes an induction phase followed by a consolidation phase and concludes with a maintenance phase. 6-MP, 6-mercaptopurine; arac, cytosine arabinoside, or cytarabine; ASP, L-asparaginase; cyclo, cyclophosphamide; HD-MTX, systemic high-dose methotrexate; HR, high risk; i.th. MTX, intrathecal methotrexate; SCT, stem cell transplantation; SR, standard risk; VM26, teniposide.

Several treatment options are available for prevention of CNS relapse: intrathecal (i.th.) therapy, cranial radiation therapy (CRT), and systemic high-dose or intrathecal therapy is usually based on methotrexate as single drug, but combinations with cytosine arabinoside and/or glucocorticoids are used in some studies. The route of application is generally lumbar puncture. CRT (18–24 Gy in 12 fractions >16 days) may be administered with or without parallel intrathecal therapy. Systemic high-dose chemotherapy may include methotrexate or cytosine arabinoside since both drugs reach cytotoxic drug levels in the cerebrospinal fluid (CSF) and showed efficacy in overt CNS leukemia. A liposomal preparation of cytosine arabinoside has been introduced for the treatment of CNS in patients with ALL or lymphoma; this formulation is more effective since it has a half-life of >2 weeks, compared to only a few hours for the other used intrathecal drugs.

In Ph-positive ALL, tyrosine kinase inhibitors are now an essential part of the treatment strategy. TKIs are equally effective at crossing the blood-brain barrier; dasatinib and ponatinib do, whereas imatinib and nilotinib do not.

In several studies with combined modalities of CNS prophylaxis, the CNS relapse rate was ≤5%. In trials with early high-dose chemotherapy and intrathecal therapy with or without CNS irradiation, the CNS relapse rate was as low as 2%.

THERAPY OF CNS DISEASE

About 5–10% of adult patients present with manifestations of CNS leukemia. The incidence is correlated with the immunological subtype and is higher in mature B-ALL up to 10–15% and in T-ALL up to 10%. For the treatment of CNS leukemia, the same treatment measures as those used for CNS prophylaxis are employed, either intrathecal MTX alone or in combination with cytosine arabinoside or hydrocortisone. The intrathecal therapy is given 2–3 times per week, continued for >2 or 3 weeks until two consecutive CSF examinations show no evidence

TABLE 102-4 Outcome of Adult ALL

TREATMENT APPROACHES	TIME PERIOD	NUMBER STUDIES	NUMBER PATIENTS	AGE* YEARS	CR* RATE	EARLY* DEATH	OVERALL* SURVIVAL

*Weighted mean and range.

of leukemic infiltration. When adult ALL patients with initial CNS leukemia are treated adequately, leukemia-free survival and CNS relapse rate are not inferior to those without CNS involvement.

Relapse in the CNS is difficult to treat. Mostly it occurs synchronously with bone marrow relapse, and if leukemic blasts are not seen morphologically, MRD is positive in nearly all cases. This requires a local as well as a systemic therapy. The outcome after CNS relapse is still dismal, and an allogeneic stem cell transplantation is the most promising option to achieve a remission.

STEM CELL TRANSPLANTATION

Hematopoietic stem cell transplantation is an essential part in the treatment strategy of adult ALL. As a stem cell source, peripheral blood cells are increasingly used compared to bone marrow. Also with regard to the donors, there is a shift from sibling donors to matched unrelated donors or haploidentical transplants from relatives. Indications for stem cell transplantation in first remission are controversial. However, in most studies, it is recommended for patients with persistent MRD and all high-risk patients either defined by conventional clinical prognostic factors or by MRD positivity. High-risk patients have a survival rate of ≥50% if transplanted in first remission. For standard risk patients with sustained molecular remission, allogeneic stem cell transplantation is not recommended in first remission. Autologous stem cell transplantation in first remission is restricted to a few disease entities, e.g., in Ph+ ALL, and should be done only in patients who are MRD negative or older patients.

For all relapsed adult ALL patients, an allogeneic stem cell transplant is the only curative option to date, and it is recommended to all patients in second or later complete remission. The potential advantages of stem cell transplant short treatment duration, favorable outcome in some trials must be balanced against the disadvantages; mortality of about 20%, morbidity, late complications, reduced quality of life, and has to be assessed in relation to the improved outcome with targeted therapies.

TARGETED THERAPIES

Substantial progress in adult acute lymphoblastic leukemia has been made in the last decade by the introduction of targeted therapies, either with tyrosine kinase inhibitors or by immunotherapeutic approaches (Table 102-5).

TYROSINE KINASE INHIBITORS IN PHILADELPHIA POSITIVE ACUTE LYMPHOBLASTIC LEUKEMIA

Patients with Ph+ ALL constitute ~25% of adult B-lineage ALL, with the incidence increasing to about 50% among elderly patients. In the "pre-Imatinib era," complete remission rates were 60–70%, the survival in those patients treated with chemotherapy alone was ~10%, and after allogeneic stem cell transplant it was ~30%. The results improved substantially when the first-generation TKI imatinib became available, with complete remission rates of 80–90%, but particularly the rate of molecular remissions (*BCR-ABL*-negativity) increased from 5 to 50% or higher, and the 5-year survival increased to ≥50–60%.

Treating adult Ph+ ALL with an allogeneic stem cell transplant in first complete remission is still the best treatment option. However, patients may receive only chemotherapy plus a TKI as primary treatment, not undergoing a stem cell transplant in first remission. Thus, a Ph+ group with lower relapse risk could probably be identified by MRD response, absence of additional chromosomal abnormalities, or *IKZF1* gene deletion. Faster and deeper molecular responses are achieved with second-generation TKIs (dasatinib, nilotinib), but it is not clear whether this translates into a survival benefit. A third-generation TKI is ponatinib, which targets the T315I and other resistant mutations either present at diagnosis, or developing after treatment with other TKIs.

IMMUNOTHERAPEUTIC APPROACHES

Immunologically based treatments with monoclonal antibodies or activated T cells are showing encouraging antitumor effects in patients with ALL.

B-lineage blast cells express a variety of specific antigens, such as CD19, CD20, and CD22. Monoclonal antibodies have been developed to target these antigens.

Anti-CD20 The anti-CD20 monoclonal antibody rituximab has substantially improved the outcome of patients with de novo Burkitt leukemia/lymphoma. With repeated short cycles of intensive chemotherapy combined with rituximab, the overall survival of such patients increased to >80% compared to earlier results of <60% without rituximab.

Anti-CD22 Monoclonal antibodies directed against CD22, linked to cytotoxic agents, such as calicheamicin (inotuzumab ozogamicin), or to plant or bacterial toxins (epratuzumab) are being explored in refractory/relapsed adult ALL. In a trial of patients with relapsed/refractory ALL treated with inotuzumab ozogamicin, the complete response rate (including responses without blood cell count recovery) was 66%, and of those, 78% achieved a molecular complete remission. When inotuzumab is combined with less intensive chemotherapy (anthracyclines and alkylating agents) encouraging results were obtained in elderly patients (>60 years) as first-line therapy.

Anti-CD19 Targeting CD19 is of great interest, as this antigen is expressed in all B-lineage cells, most likely including early lymphoid precursor cells. A promising approach is the bi-specific antibody blinatumomab, which combines single chain antibodies to CD19 and CD3, such that T cells are brought into proximity with and lyse the CD19-bearing B cells.

This antibody was effective in patients with positive MRD, and 80% converted to MRD-negativity; some patients had promising survival durations even without stem cell transplantation. In a trial of adult patients with refractory/relapsed ALL treated with blinatumomab, the rate of complete remissions was 43%, and the MRD response rate was 82%.

Chimeric Antigen Receptor (CAR) T cells The adoptive transfer of CAR-modified T cells directed against CD19 is a promising approach to the treatment of CD19+ childhood or adult ALL. Complete response rates in adults ranged from 67 to 91% with an MRD negativity in 60–81% of the complete responders. The rate of allogeneic stem cell transplantation after CAR T cells varied from about 10 to 50%. Since patients who underwent an allogeneic stem cell transplant after CAR T-cell therapy had a similar outcome as the nontransplanted patients, the value of the transplant is unclear. CAR T-cell therapy can be highly toxic. The accompanying cytokine release syndrome related to systemic immune activation produces fever, hypotension, confusion, and delirium. These effects appear in the first week of therapy and generally abate, but severe neurotoxicity may be slow to recover. The CD19 negative relapse rate after CAR T-cell therapy is 10–20%, and those patients have limited treatment options.

CONCLUSION AND FUTURE DIRECTIONS

Progress in ALL has led to the recognition of better defined ALL subentities, the importance of MRD as a prognostic factor and therapeutic target, and the value of new targeted therapies. Treatment outcome of adult ALL has improved with about half of the patients surviving >5 years and those surviving 5 years are most likely cured. Newer options, such as less intensive chemotherapy, reduction of stem cell transplantation, and incorporation of targeted therapies are promising options to reduce toxicities and improve the life quality.

103 Chronic Lymphocytic Leukemia

Jennifer A. Woyach, John C. Byrd

Chronic lymphocytic leukemia (CLL) is a monoclonal proliferation of mature B lymphocytes defined by an absolute number of malignant cells in the blood (5×10^9/mL). The presence of malignant B cells under this count in the blood without nodal, spleen, or liver involvement and absent cytopenias is a precursor of this disease called *monoclonal B-cell lymphocytosis* (MBL) with ~1–2% chance per year of progressing to overt CLL. CLL is a heterogeneous disease in terms of natural history, with some patients presenting asymptomatically and never requiring therapy, whereas others present with symptomatic disease, require multiple lines of therapy, and eventually die of their disease. Over the past 10–15 years, the understanding of CLL origin and biology has grown exponentially, leading first to more refined disease definition, prognostic markers, and, subsequently, introduction of novel therapies that have significantly changed the natural history of this disease. In this chapter, we review the epidemiology, biology, and management of CLL, with a focus on new knowledge that is currently changing standards of care.

EPIDEMIOLOGY

CLL is primarily a disease of older adults, with a median age at diagnosis of 71 and an age-adjusted incidence of 4.5/100,000 people in the United States. The prevalence of CLL has increased over the past decades due to improvements in therapy for this disease and also survival of older patients from other medical ailments. In 1980, the 5-year overall survival of patients was 69%, and this increased to 87.9% in 2007 and is likely even higher today. The male:female ratio is 2:1; however, as patients age, the ratio becomes more even, and over the age of 80, the incidence is equal between men and women. The disease is most common in Caucasians, less common in Hispanic and African Americans, and is rare in the Asian population.

Unlike many other malignancies, there have been no definitive links between CLL and exposures. Indeed, CLL is one of the only types of leukemia not linked to radiation exposure. Agent Orange exposure has been implicated, and CLL is thus a service-connected condition for those who were exposed to Agent Orange in the Vietnam conflict.

CLL is one of the most familial-associated malignancies, and the first-degree relative of a CLL patient has an 8.5-fold elevated risk of developing CLL than the general population. MBL is also more common in families with two first-degree relatives having CLL, further supporting a genetic predisposition of this disease. Despite this, specific genes conferring risk in the familial setting outside of specific families have been difficult to identify. In genome-wide association studies (GWAS), ~30 SNPs have been identified, which is estimated to account for 19% of the familial risk of CLL. Genes involved in apoptosis, telomere function, B-cell receptor (BCR) activation, and B cell differentiation have all been implicated in GWAS. Variants in shelterin complex proteins involved in telomere maintenance such as POT1 have been identified in a small number of families.

BIOLOGY AND PATHOPHYSIOLOGY

CELL OF ORIGIN

The cell of origin in CLL has not definitively been established. The morphology, immunophenotype, and gene expression pattern of CLL cells are that of a mature B cell **(Fig 103-1)**, and so it has been presumed that the initiating cell is a mature lymphocyte, perhaps memory B cells. However, many facets of CLL biology do not support this idea,

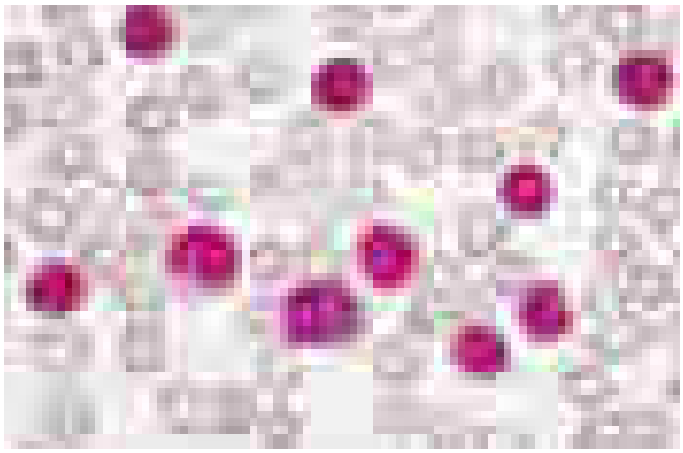

FIGURE 103-1 Chronic lymphoid leukemia in the peripheral blood. *(From Williams Hematology, 7th ed, in M Lichtman et al [eds]: New York, McGraw-Hill, 2005.)*

including antigen-binding characteristics of CLL cells and the presence of stereotyped BCRs. Other possibilities include a stepwise process including a series of transforming events at various stages of B-cell development, potentially including de-differentiation of more mature cells. The self-renewing, multipotent hematopoietic stem cell (HSC) might also be the originating cell of CLL, postulated based on transplant studies in mice showing clonal leukemic cell development with same or different characteristics from donor leukemia after transplantation of HSC. More work will be required to elucidate the origins of CLL.

B-CELL RECEPTOR SIGNALING IN CLL

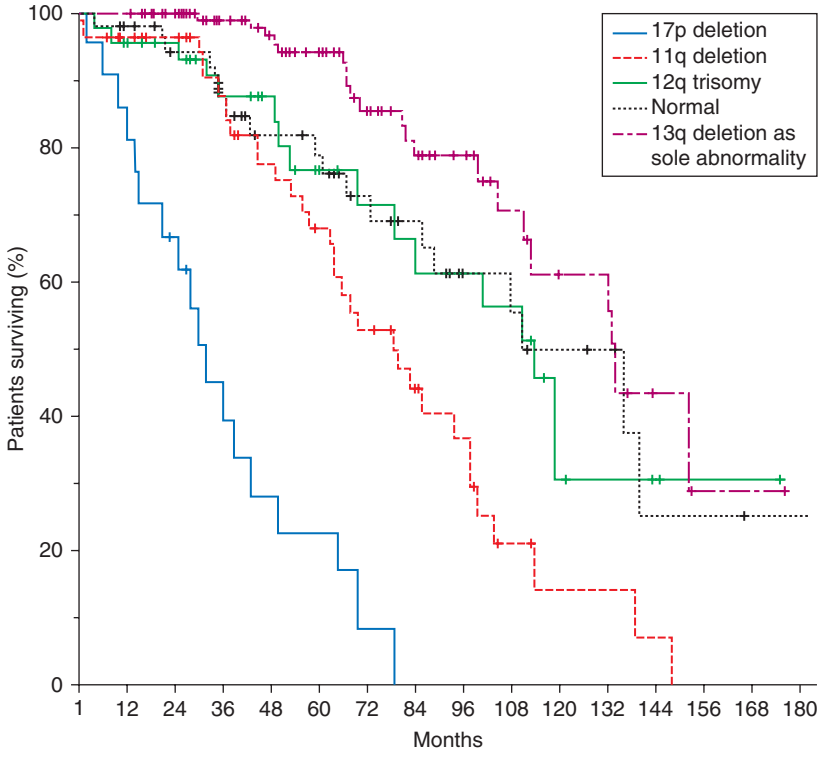
Perhaps the most important advancement in CLL biology is the understanding of the role of BCR signaling in the disease. CLL has distinct BCR signaling as compared to normal B cells, which is characterized by low-level IgM expression, variable response to antigen stimulation, and tonic activation of antiapoptotic signaling pathways that promote tumor survival. CLL cells by gene expression profiling share many features with antigen-activated mature B cells, suggesting a role for activation of BCR signaling in the disease pathogenesis. Tissue-based microarrays have revealed upregulation of BCR pathway genes in the lymph nodes and bone marrow compared to the peripheral blood, suggesting a particular importance of this pathway in microenvironmental homing.

Fitting with the role of BCR signaling in CLL, one of the most influential prognostic factors identified in this disease is the mutational status of the immunoglobulin heavy chain variable (IGHV) region. During normal B-cell maturation, the variable regions of the immunoglobulin heavy chain undergo somatic hypermutation. In CLL, ~60% of patients have IGVH that is ≥2% mutated from germline. This may indicate a more mature, postgerminal center progenitor, and is typically associated with a more indolent disease course. Conversely, ~40% of patients will have IGVH <2% mutated from germline, which is associated with more rapid progression of disease and short survival. Unfavorable biologic properties including enhanced telomerase activity, overexpression of activation-induced cytidine deaminase, increased nuclear factor-κB (NF-κB) activity, high-risk genomic features, and clonal evolution are also associated with IGHV unmutated disease.

Because IGHV sequencing was initially cumbersome to perform, a number of surrogate factors have been identified; however, none yet have been shown to be equal or superior to IGVH sequencing. The most prevalent of these surrogate markers are Zap-70 expression, *ZAP-70* methylation, and surface CD38 expression. Zap-70 protein is a normal intracellular T-cell signaling protein that is aberrantly expressed in most IGHV unmutated CLL cells. CD38 is a marker that is also more highly expressed on the surface of IGHV unmutated CLL cells. Both these prognostic factors are widely used but limited in their applicability. Zap-70 protein status is difficult to measure by flow cytometry, and it has low reproducibility. Measurement of methylation status of the *ZAP-70* promoter is much more precise but not widely available. CD38 expression is easier to measure by flow cytometry but not as highly predictive of outcomes and can change during the course of disease.

CYTOGENETIC ABNORMALITIES

Besides IGHV mutational status, recurrent cytogenetic abnormalities are the most robust prognostic factor clinically available in CLL. These abnormalities are typically identified by fluorescent in situ hybridization (FISH) analysis; however, stimulated metaphase karyotype has a role as well. The most well-characterized abnormalities include del(13)(q14.3), trisomy 12, del(11)(q22.3), and del(17)(p13.1) **(Fig. 103-2)**. The presence of sole del(13)(q14.3) is associated with more indolent disease, prolonged survival, and good response to traditional therapies. Usually



No. AT Risk

17p deletion	23	18	13	8	5	4	1	0	0	0	0	0	0	0	0	0
11q deletion	56	53	47	43	33	27	20	15	10	4	2	2	1	0	0	0

Normal	57	51	45	37	30	27	20	17	12	11	6	5	2	2	1	1
13q deletion as sole abnormality	117	117	106	91	80	63	45	36	24	16	12	11	3	1	1	0

FIGURE 103-2 Outcomes among CLL patients with various cytogenetic abnormalities. *(From Döhner H et al: N Engl J Med 343:1910, 2000.)*

this abnormality is not seen on banded karyotype analysis, and when present on karyotype, it indicates a larger deletion involving the retinoblastoma gene, which negates the favorable prognosis associated with this marker. Trisomy 12 has a more intermediate prognosis. The del(11)(q23.3) results in deletion of the *ATM* gene and is associated with bulky lymphadenopathy and aggressive disease in young patients, with inferior prognosis, more rapid progression to symptomatic disease, and shorter survival. The del(17)(p13.1) results in loss of one allele of the tumor suppressor TP53 and is associated with the poorest prognosis in CLL with rapid disease progression, poor response to traditional therapies, and shorter survival. Other abnormalities have been shown to be important in smaller studies but are not routinely performed at all centers. Finally, complex karyotype (three or more abnormalities) on stimulated metaphase karyotype analysis has significant adverse impact on time to treatment and overall survival.

Clonal evolution, or acquisition of cytogenetic or molecular abnormalities, is common in CLL, especially in patients with IGHV unmutated CLL. Because the cytogenetics of patients can change even in the absence of therapy, it is recommended that FISH +/− cytogenetics are checked before every line of therapy, mostly to evaluate acquisition of del(17)(p13.1).

GENE MUTATIONS AND MIR ALTERATIONS

Compared with many other malignancies, the genome in CLL is relatively simple, with an average CLL genome carrying ~20 nonsynonymous alterations and ~5 structural abnormalities. And, unlike many other hematologic malignancies, there is no unifying genetic lesion, and most recurrent genetic driving mutations exist at frequencies of <5%. Whole genome and whole exome sequencing have identified the most common mutations in CLL to be in *SF3B1*, *NOTCH1*, *MYD88*, *ATM*, and *TP53* **(Table 103-1).** Most of the identified mutations in these genes are common among different malignancies, and with the exception of MYD88, they are generally subclonal drivers identified with much higher frequency in IGHV unmutated disease.

NOTCH1 mutations are present in ~15% of CLL patients and are commonly associated with trisomy 12. Although multiple different mutations are seen, most are located within the PEST (proline, glutamic acid, serine, and threonine) domain and result in constitutive NOTCH signaling. *NOTCH1* mutations have been associated with lower sensitivity to CD20 antibody therapy and increased risk of transformation to aggressive diffuse large B-cell lymphoma (DLBCL; Richter's transformation).

SF3B1 is a component of the RNA spliceosome and is mutated in 10–15% of CLL cases. Mutations appear to be associated with intermediate-risk disease, and, functionally, SF3B1 may be important in the response to DNA damage.

Mutations of the tumor suppressor *TP53* are found in ~5% of CLL in previously untreated early stage disease and up to 40% in later stages. Seventy percent of the time these mutations coexist with del(17)(p13.1), effectively eliminating TP53 function. As expected, and consistent with other malignancies, TP53 mutations are associated with a poor prognosis and expected lack of response to DNA-damaging therapies.

TABLE 103-1 Recurrent Mutations in CLL

GENE	FREQUENCY OF MUTATIONS (%)
SF3B1	8–14
TP53	5–13
NOTCH1	10–13
MYD88	4–8
ATM	8–11
BIRC3	<5
XPO1	<5
FBXW7	<5
POT1	<5
BRAF	<5
EGR2	<5
IKZF3	<5

Abbreviation: CLL, chronic lymphocytic leukemia.

ATM mutations, which are heterogeneous and occur throughout the gene, occur in 10–15% of CLL patients. *ATM* mutations often coexist with del(11)(q22.3), eliminating *ATM* on the alternate allele. Similar to *TP53*, mutations in *ATM* tend to result in impaired response to DNA damage, which can reduce responsiveness to chemotherapy.

In contrast to the aforementioned mutations, those in MYD88 tend to occur in IGHV mutated CLL and be associated with a more indolent prognosis. This gene is involved in Toll-like receptor signaling, and the most common mutation, L265P, results in constitutive activation and NF-κB activity.

Along with abnormalities in coding genes, it has become apparent that noncoding genes such as microRNAs are recurrently altered in CLL. The most common cytogenetic abnormality, del(13)(q14.3) results in loss of the miR15/16 cluster, which is important in the pathogenesis of CLL. In normal cells, miR15A/miR16A inhibit antiapoptotic gene expression (including BCL2, CCND1&3, and CDK6), and this specific deletion allows for overexpression of these genes and thus increased cell survival. Loss of other miR expression such as mir-181a leads to overexpression of proteins such as the antiapoptotic gene MCL-1 and TCL1. Overexpression of miR-155, an onco-miR associated with B-cell transformation, has also been documented in the majority of CLL patients.

IMMUNOLOGY

CLL is characterized by dysregulation of the normal immune system in addition to the malignant immune cells. Besides numerical abnormalities due to bone marrow dysfunction, even in the early stages of disease there are skewed ratios of immune cells and functional abnormalities. Innate immune system defects associated with CLL include reduced complement proteins and activity, qualitative neutrophil defects, and functional defects of natural killer cells.

More focus has been placed on the impairments in the adaptive immune system in this disease. Within the CD4+ T-cell compartment, a qualitative defect is noted similar to chronic antigen stimulation inducing a phenotype of T-cell exhaustion typical of what is seen in chronic viral infections such as hepatitis. This has been demonstrated to lead to impaired T-cell cytotoxic capacity and reduced proliferative ability. Additionally, there are physical changes in the T-cell cytoskeleton that causes impaired immune synapse formation with antigen presenting cells. In addition to a lack of capacity to respond to pathogens, the T-cell defect in CLL also likely leads to tumor cell tolerance. During the course of the disease, the polarization of the CD4+ T cells shifts from a Th1 (cytotoxic) phenotype to a Th2 phenotype, which leads to expansion of immunosuppressive cytokines such as IL-10. Additionally, in the later stage of disease T regulatory cells are expanded, which contributes to an immunosuppressive phenotype.

Other components of the immune microenvironment are altered as well to form a more supportive environment for the malignant cells. M2 monocytes have been shown to differentiate into a type of tumor-associated macrophage known as a *nurse-like cell* in CLL. These cells promote survival by secreting chemokines and cytokines that increase migration and activation.

The humoral immune system in CLL is also dysregulated, as is expected for a malignancy that results in very few normal B cells. Hypogammaglobulinemia is very common and affects all subclasses of immunoglobulins, occurring in ~85% of patients at some time in their disease course, and is more common as disease progresses. A correlation between low IgG and IgA and infection risk has been established, but isolated IgM reduction does not seem to be associated with excess infection risk. Also, CLL cells can secrete monoclonal IgM in a small number of cases, and this can correlate with disease progression.

CLINICAL PRESENTATION AND DIAGNOSIS OF CLL

CLINICAL PRESENTATION AND DIAGNOSIS

The presentation of CLL most commonly occurs as an incidental diagnosis made at the time of medical evaluation for another cause. In this regard, CLL is most commonly diagnosed on routine blood work

TABLE 103-2 Typical Immunophenotype of CLL Compared with Other B-Cell Malignancies

	CD5	CD10	CD19	CD20	CD23	CYCLIN D1	SURFACE IG
Disease							
CLL	+	–	+	+ (dim)	+	–	+ (dim)
Mantle cell lymphoma	+	–	+	+ (mod/bright)	–	+	+ (mod/bright)
Marginal zone lymphoma	–/+	–	+	+ (mod/bright)	–/+	–	+ (mod/bright)
Follicular lymphoma	–	+	+	+	+	–	

Abbreviation: CLL, chronic lymphocytic leukemia.

demonstrating an elevated lymphocyte count in asymptomatic individuals, although some patients present with symptoms and require early therapy. When noting either an elevated total white blood cell (WBC) count with lymphocytic predominance or a normal WBC with a differential showing a lymphocytosis, the next step is to perform flow cytometry on the peripheral blood. In CLL, this will reveal the typical immunophenotype that includes the typical B-cell markers CD19, CD20, CD22, CD23, the T-cell marker CD5 (CD5 is also expressed on the B1 subset of B cells that typically has unmutated immunoglobulin and responds to antigens independent of cognate T-cell help), and dim surface immunoglobulin of either kappa or lambda type **(Table 103-2)**. Atypical phenotypes can be seen as well and usually can be differentiated on the basis of morphology, cytogenetics, or clinical presentation. In cases in which the clonal B cell count based on flow cytometry is $\geq 5 \times 10^9$/L, no further workup is needed to confirm the diagnosis of CLL.

Some patients will present with a small clonal proliferation of CLL cells in the peripheral blood but will also have lymphadenopathy or splenomegaly. In these cases, the likely diagnosis is small lymphocytic lymphoma (SLL), a semantic designation from CLL that denotes a primarily tissue-based disease rather than bone marrow/blood-based disease. The genetic and molecular features of SLL are identical to those of CLL. The retention of the cells in tissues may be related to the expression of particular adhesion molecule. Thus, SLL patients are managed identically to CLL, and often in the later stages of disease these patients will often have blood and bone marrow involvement as well.

MONOCLONAL B-CELL LYMPHOCYTOSIS

Patients who do not meet the diagnostic criteria for CLL based on quantification of clonal B cells in the peripheral blood and who do not have associated signs of CLL including lymphadenopathy, organomegaly, or cytopenias have a disorder known as monoclonal B-cell lymphocytosis (MBL), which is now thought to precede every case of CLL. Analogous to monoclonal gammopathy of uncertain significance (MGUS) in myeloma, not all MBL progresses to CLL. MBL is initially characterized by a CLL-like immunophenotype in ~75% of cases but can also be atypical (CD23 negative or bright CD20) or CD5 negative. More relevant for prognosis is characterization by count, with low-count MBL defining those patients with $<0.5 \times 10^9$ clonal B cells/L, and high-count MBL defining those with $>0.5 \times 10^9$ but $<5 \times 10^9$/L. Patients with low-count MBL have a negligible rate of progression to CLL, whereas those with high count progress to overt CLL at a rate of 1–2% per year, warranting continued monitoring. Population-based studies have estimated the prevalence of MBL up to ~12% in the general population, where it is most common in elderly men. It is especially common in first-degree relatives of CLL patients, where the frequency is ~18%.

Although the risk of MBL progression is relatively low, it has become apparent that patients still experience complications that suggest an immune dysfunction in MBL that is similar to that seen with CLL. Rates of serious infections requiring hospitalization appear to be significantly increased in MBL, similar to the rates seen in CLL. In a case-control study, patients with MBL had a 16% chance of hospitalization over a 4-year time period, compared with 18.4% in patients with newly diagnosed CLL. Secondary cancers also appear to be increased in MBL. These data suggest that monitoring for patients with MBL should focus on vaccinations and age-appropriate cancer screening, as the probability of complications appears to be higher than the risk of progression in most of these patients. Follow-up for patients with MBL can occur with the primary care physician as this does not represent a malignancy, whereas CLL is mostly comanaged with both a primary care physician and a hematologist.

COMPLICATIONS OF CLL

A significant amount of morbidity and mortality related to CLL is due to complications of the disease. In general, complications besides disease progression include infections, secondary cancers, autoimmune complications, and transformation to a more aggressive clonally related lymphoma.

INFECTIONS

Infections are a leading cause of both disease-related morbidity and death in patients with CLL, with ~30–50% of deaths in CLL patient attributed to infection. Owing to the immune dysfunction associated with the disease, patients are at risk for both typical and atypical infections. Besides this baseline risk of infections, most CLL therapies can increase infection risk. For many nucleoside analog-based chemotherapy regimens used in CLL, prophylaxis for *Pneumocystis* pneumonia is indicated for at least 6 months following therapy to allow recovery of functional T cells. Viral prophylaxis is also indicated for many chemotherapy regimens and for patients with a history of varicella zoster to diminish reactivation and morbidity from this virus.

Because of the abnormalities in cellular and humoral immunity, vaccine responses in CLL are limited in many patients, especially in the later stages of disease. In one study, one dose of 13-valent pneumococcal vaccine produced an adequate immune response in only 58% of patients compared with 100% in age-matched controls. Despite the known limitations, vaccination against influenza and pneumococcal pneumonia is recommended in CLL. Live vaccines, such as the varicella zoster vaccine, should be avoided because of the small risk of viral reactivation with an immunocompromised host.

As discussed earlier, hypogammaglobulinemia is common in CLL and can be associated with significant risk for infections, primarily of mucocutaneous etiology such as sinusitis and bronchitis. In addition, women can have frequent urinary tract infections. While administration of prophylactic intravenous immunoglobulin (IVIg) has not been shown to improve survival, it has been shown to reduce the number of minor or moderate bacterial infections, and thus is indicated in patients with hypogammaglobulinemia who suffer from recurrent infections or have pulmonary bronchiectasis. It is also our practice to administer at least one dose immunoglobulin to CLL patients who develop influenza with coexisting hypogammaglobulinemia to diminish risk of post-influenza pneumococcal pneumonia. IVIg is probably indicated in patients who have been hospitalized for a serious infection and in those whose IgG level is <300 mg/dL.

SECONDARY MALIGNANCIES

Multiple population-based studies have shown that patients with CLL are at an elevated risk to develop other cancers, with a rate up to three times that of the general population, even in the absence of cytotoxic chemotherapy. The most common types of cancers seen in CLL are skin cancers, prostate, and breast cancers, although other cancers are seen as well. Skin cancers are particularly common, with a rate of 8- to 15-fold higher than the general population, and may behave more aggressively. All CLL patients should be counseled on the use of sunscreen while outdoors and should undergo preventative skin examinations.

In one single-center study, older age at CLL diagnosis, male sex, high β_2 microglobulin, high lactate dehydrogenase (LDH), and chronic kidney disease were associated with excess risk of other cancers; other CLL-specific risk factors have not shown association with other cancer risk.

While cancer risk is higher, there are no specific recommendations for increased cancer screening in CLL patients. Age- and sex-appropriate screenings should be recommended.

Conflicting data exist regarding the risk of cancers following CLL-specific therapy. Chemoimmunotherapy, in particular alkylator-containing regimens, seems to be associated with an increased risk for secondary cancers.

AUTOIMMUNE COMPLICATIONS

Autoimmune complications are frequent in CLL. Most commonly, these include autoimmune cytopenias, but autoimmune complications of other organs including glomerulonephritis, vasculitis, and neuropathies have also been reported. Of the autoimmune cytopenias, the most common is autoimmune hemolytic anemia (AIHA), which is an antibody-mediated destruction of autologous red blood cells (RBCs). Second most common is immune thrombocytopenia (ITP), which shares some features with AIHA and has a similar mechanism targeting platelets. These two syndromes may occur in isolation, sequentially in the same patient, or present in combination as Evan's syndrome. Pure red cell aplasia (PRCA) and autoimmune granulocytopenia (AIG) are comparatively rare and can occur alone or in combination with other AIC. It is difficult to tease out whether autoimmune cytopenias lead to worse prognosis in CLL because of various complicating factors. However, it is clear that these can lead to significant morbidity, both due to the process itself and due to therapies required for management.

AIHA usually presents as an isolated anemia with an elevated reticulocyte count and features of hemolysis including elevated bilirubin and LDH, and low haptoglobin. Detection of a warm IgG antibody on the surface of RBCs with a Coombs test can help solidify the diagnosis, although Coombs-negative cases can occur. Immediate therapy is almost always necessary, and consists of transfusion and immunosuppression. Glucocorticoids are often used for initial therapy, although in most cases additional treatment is needed due to either poor response or recurrence with taper of steroid dosing. Rituximab can be successful, and therapy directed toward the underlying CLL is often effective in more resistant cases. Transfusion of blood in cases of robust AIHA must be initiated with caution as transfusion reactions can be seen due to poorly matched blood.

ITP can be more difficult to diagnose, as it may be difficult to differentiate from progression of disease due to the lack of laboratory tests that identify platelet destruction from this mechanism. Signs that point toward ITP include isolated thrombocytopenia and rapid decline in platelet levels in the absence of an alternative etiology. A bone marrow biopsy showing normal or increased megakaryocytes can be used to confirm the diagnosis but is often not necessary. In CLL, treatment for ITP is usually instituted when platelet levels drop to 20–30,000 or if there is evidence of bleeding complications or need for invasive procedures. Like AIHA, initial therapy consists of glucocorticoids and IVIG, with rituximab also being an effective method to induce long-term remissions. Also, the thrombopoietin receptor agonists romiplostim and eltrombopag are effective in secondary ITP. In many cases, ITP can be successfully treated without treating the underlying CLL. In cases in which anemia or thrombocytopenia appear, it is important to investigate the mechanism as the approach to therapy of autoimmune cytopenias in CLL differs from cytopenias due to marrow replacement.

RICHTER'S TRANSFORMATION

One of the most devastating complications of CLL is Richter's transformation, transformation of CLL to an aggressive lymphoma, most commonly DLBCL. The World Health Organization also recognizes Hodgkin's lymphoma (HL) as a variant of Richter's transformation; other aggressive lymphomas are rarely identified. Some older series have included prolymphocytic transformation in this category, although this has much less prognostic impact on long-term outcome. The prevalence of Richter's transformation is difficult to estimate based on previous studies, but one prospective observational study estimated a rate of 0.5% per year for DLBCL and 0.05% per year for HL. Risk factors for development include bulky lymphadenopathy, *NOTCH1* mutations, del(17)(p13.1), and a specific stereotyped IGVH usage. Lymphomas arising in the setting of CLL can either be clonally related or unrelated to the initial CLL, with prognosis significantly better for clonally unrelated lymphomas. In addition, patients with Hodgkin's transformation have improved outcome, particularly in the absence of prior fludarabine treatment.

Clinical signs of Richter's transformation include rapid progression in adenopathy, often in a specific area, and constitutional symptoms including fatigue, night sweats, fever, and weight loss. LDH is usually high. In suspected cases, the first step is ^{18}FDG-PET/CT (fluorodeoxyglucose–positron emission tomography combined with computed tomography) scan to localize an area for biopsy. Standardized uptake values (SUV) <5 is consistent with CLL and can rule out Richter's transformation in many cases. SUV >5 are suspicious for Richter's transformation, with SUV ≥10 very concerning. Excisional biopsy is diagnostic. Needle biopsy should be discouraged.

Therapy for DLBCL Richter's transformation usually involves combination chemoimmunotherapy. Outcomes are poor with median survivals of 6–16 months in most series for clonally related Richter's versus ~5 years for clonally unrelated. This highlights an area of unmet need in CLL therapy and an area of active investigation. For fit patients who achieve a response with therapy, stem cell transplantation has the possibility to induce long-term remissions and should be explored. Patients with Hodgkin's disease can be treated according to the algorithm for this disease, with many individuals being cured.

WORKUP OF CLL AND APPROACH TO THERAPY

WORKUP AND STAGING

Workup of a patient with new diagnosis of CLL based on typical immunophenotyping includes a detailed history of infectious history; family history of CLL; and careful physical examination with attention to the lymph nodes, spleen, and liver. In patients desiring to know the expected natural history of their CLL, prognostic testing using FISH and stimulated karyotype as well as IGHV sequencing can be performed. Imaging with CT scan is usually not necessary unless there are symptoms and concern for intra-abdominal nodes out of proportion to peripheral nodes. Bone marrow biopsy is not undertaken until therapy is initiated except in cases of unexplained cytopenias.

STAGING

There are two widely used staging systems in CLL: The Rai staging system is used more commonly in the United States, whereas the Binet system is more commonly used in Europe. Both characterize CLL on the basis of disease bulk and marrow failure **(Table 103-3)**. Both rely on physical examination and laboratory studies and do not require imaging or bone marrow analysis. While the initial staging systems could reliably predict survival in CLL, with the changes in therapy

TABLE 103-3 Staging of CLL

Rai Staging System	
Low risk (stage 0)	Lymphocytosis only
Intermediate risk (stage I/II)	Lymphocytosis with lymphadenopathy, with or without splenomegaly or hepatomegaly
High risk (stage III/IV)	Lymphocytosis with anemia or thrombocytopenia due to bone marrow involvement
Binet Staging System	
A	<3 areas of lymphadenopathy
B	≥3 areas of lymphadenopathy
C	Hemoglobin ≤10 g/dL and/or platelets <100,000/μL

Abbreviation: CLL, chronic lymphocytic leukemia.

TABLE 103-4 Criteria for the Initiation of Therapy

Symptoms Indicating Need for Therapy in CLL
Evidence of progressive marrow failure (worsening of anemia or thrombocytopenia not due to autoimmune destruction)
Massive (≥6 cm below costal margin), progressive, or symptomatic splenomegaly
Massive (≥10 cm), progressive, or symptomatic lymphadenopathy
Autoimmune anemia or thrombocytopenia not responsive to standard therapy
Constitutional symptoms (one or more of the following: unintentional weight loss ≥10% over 6 months, significant fatigue, fevers ≥100.5°C for 2+ weeks without infection, night sweats for >1 month without infection)

Abbreviation: CLL, chronic lymphocytic leukemia.

since the original description of the stages, the impact of initial stage on survival is not as clear. Cytogenetic and genomic testing can help refine outcome of these staging tests. An international collaboration integrated both clinical and genomic staging to better predict outcome at diagnosis and time of initial treatment.

CRITERIA FOR THE INITIATION OF THERAPY

Currently, a watchful waiting strategy is used for most patients with CLL, with therapy reserved for patients with symptomatic disease. This recommendation is based on multiple trials showing no survival advantage with earlier therapy, although this question is currently being revisited with novel targeted therapies.

With the exception of patients participating on early intervention studies in CLL, disease-related symptoms that require the initiation of therapy are outlined in Table 103-4. Except for the rare patient who presents with disease requiring urgent therapy, most times these symptoms can be monitored over short periods to determine relatedness to CLL and need for therapy.

INITIAL THERAPY FOR CLL

Chemoimmunotherapy and Monoclonal Antibody Therapy

Chemotherapy and chemoimmunotherapy are the standard therapies for CLL. For patients who are young (≤65 years), the gold standard for therapy is a combination of the nucleoside analogue fludarabine, the alkylator cyclophosphamide, and the anti-CD20 monoclonal antibody rituximab (FCR). In phase III study, this combination produced an overall response rate (ORR) of 93% with a complete response (CR) rate of 44%. Median progression-free survival (PFS) is almost 5 years. Substitution of bendamustine for fludarabine and cyclophosphamide or addition of other chemotherapy-based treatments to FCR have not improved outcome. A subset of patients treated with the FCR regimen has durable responses over 10 years. This group is primarily composed of those patients with mutated IGVH and good cytogenetic risk. However, despite the efficacy of this regimen, short- and long-term toxicities limit its adaptability to many patients with IGHV-mutated disease. Short-term toxicities are mostly related to myelosuppression and include neutropenia and infection. Long-term cytopenias are less common, but they do occur. Also, there is about a 3–5% risk of therapy-related myeloid neoplasm with this regimen that is almost always fatal. Trials in the future will need to focus on the superiority of FCR versus targeted regimens for patients who may be cured by chemoimmunotherapy.

For older patients or those with multiple comorbidities, FCR is not an appropriate option due to toxicities. For these patients, the alkylator chlorambucil in combination with the anti-CD20 antibody obinutuzumab or bendamustine with rituximab are appropriate options. While neither produces remissions as durable as FCR, both can induce CRs and remissions of 2–3 years in many patients. Toxicities with these regimens mostly relate to myelosuppression, but neither is as immunosuppressive as FCR.

Monoclonal antibodies given alone or in combination with chemotherapy were the first targeted therapies to be successful in CLL. Anti-CD20 monoclonal antibodies including rituximab, ofatumumab, and obinutuzumab are all used in this disease. Rituximab was the first agent to show a survival advantage in CLL, where the combination of FCR improved survival over the combination chemotherapy regimen FC. Alone, this antibody has shown modest activity, but activity is improved with higher doses and increased frequency of administration. Both ofatumumab and obinutuzumab are effective as single agents, but it is likely that monoclonal antibodies will be most widely used in combination. Current trials are focused on combining anti-CD20 antibodies with therapies that target BCR signaling or antiapoptotic proteins. Antibodies against other targets are also being developed, including CD19, BAFF receptor, and CD37.

B-Cell Receptor Signaling Inhibitors Three specific targets were the first identified: spleen tyrosine kinase, phosphoinositide-3-kinase (PI3K), and Bruton's tyrosine kinase (BTK). Therapeutics directed at the latter two targets have moved forward through clinical trials and are now utilized in clinical practice.

Idelalisib is a reversible, p110 delta isoform-specific PI3K inhibitor. Because the delta isoform is specific for B lymphocytes, this agent has selective effects on the CLL cells with relative sparing of other hematopoietic cells. The definitive phase III study of the idelalisib plus rituximab regimen assessed this combination versus placebo plus rituximab in 220 patients and showed an ORR of 77% (vs 15% with rituximab plus placebo) with improved progression-free and overall survival. Toxicity specific to idelalisib included elevated alanine transaminase (ALT) and aspartate transaminase (AST) in the first 3 months of therapy and diarrhea, colitis, pneumonitis, and rash later (9+ months) into treatment. These side effects appear to be more common in younger patients given idelalisib earlier in the course of their disease.

Ibrutinib is a relatively selective, irreversible inhibitor of BTK. This target is attractive because, unlike other kinases in the BCR pathway, BTK does not have natural redundancy and is selective for B cells, so inhibition leads to a B-cell–specific phenotype. As initial therapy, ibrutinib was compared with chlorambucil, and there was an 84% lower risk of progression or death with ibrutinib, with 90% of ibrutinib-treated patients alive and progression-free at 18 months. In the relapsed phase III study, ibrutinib was compared to the CD20 monoclonal antibody ofatumumab, and there was a 78% reduction in the risk of progression or death with ibrutinib. Side effects distinct to ibrutinib include rash, diarrhea, dyspepsia, increased risk of bleeding (particularly when on anticoagulation therapy or with surgery), and atrial fibrillation. Second-generation BTK inhibitors with more specificity such as acalabrutinib are in clinical trials and may diminish these side effects. Although direct comparison of agents targeting p110 delta PI3 kinase and BTK has not occurred, BTK inhibitors appear to induce more durable remissions.

The success of ibrutinib and idelalisib has generated significant interest in other molecules targeting PI3K, BTK, and other members of the BCR signaling pathway. One issue with most drugs targeting this pathway in CLL is that while durable responses are common, CRs are not, which leads to the recommendation for indefinite therapy with these molecules. Combination clinical trials are currently underway to determine whether combinations with other active agents might allow discontinuation of drug in some settings.

Antiapoptotic Therapies BCL2 is another promising target in CLL. Venetoclax is an orally bioavailable, selective BCL2 inhibitor. It is currently Food and Drug Administration (FDA) approved for marketing in patients with relapsed or refractory CLL who have the del(17)(p13.1). In a phase I study, the ORR with this agent in relapsed/refractory CLL was 79%, with 69% of patients on the recommended phase II dose being progression-free at 15 months. Unlike the BCR signaling antagonists, venetoclax is able to induce very deep responses including CRs with minimal residual disease negativity in a subset of patients. Distinct toxicities associated with venetoclax include neutropenia, diarrhea, and acute tumor lysis syndrome. Tumor lysis syndrome risk can be mitigated with stepped-up dosing at the beginning of treatment.

Immune Therapies Current immune therapies include allogenic stem cell transplantation, chimeric antigen receptor (CAR) T-cell therapy, and oral immunomodulatory agents such as lenalidomide.

TABLE 103-5 Response Criteria in CLL

	LYMPHOCYTE COUNT	LYMPH NODES[a]	SPLEEN/LIVER SIZE[b]	BONE MARROW[c]	PERIPHERAL BLOOD COUNTS
CR	<4000/μL	None >1.5 cm	Not palpable	Normocellular, <30% lymphocytes, no B lymphoid nodules	• Platelet count >100,000/μL • Hemoglobin >11 g/dL • Neutrophils >1500/μL
PR	Decrease ≥50% from baseline	Decrease ≥50% from baseline	Decrease ≥50% from baseline	Infiltrate ≤50% of baseline	One of the following: • Platelet count >100,000/μL or ≥50% from baseline • Hemoglobin >11 g/dL or ≥50% from baseline • Neutrophils >1500/μL or ≥50% from baseline
Stable disease	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria	Not meeting CR/PR/PD criteria
PD	Increase ≥50%	Increase ≥50%	Increase ≥50%		• Platelet count ≤50% of baseline due to CLL • Hemoglobin decrease >2 g/dL due to CLL

[a]Refers to sum of the products of multiple lymph nodes evaluated by CT scan. [b]Based on physical examination. [c]Bone marrow only required to confirm CR.

Abbreviations: CLL, chronic lymphocytic leukemia; CR, complete response; PD, progressive disease; PR, partial response.

Stem cell transplantation is currently considered the only standard curative approach to CLL. Because most CLL patients are older and many have significant comorbidities, myeloablative transplants incur extensive morbidity and mortality, making them prohibitive in many individuals. Reduced intensity conditioning (RIC) allogeneic transplants have been successfully incorporated into the treatment of patients up to ~75 years in age but still have a ≥50% frequency of chronic graft-versus-host disease.

ASSESSING RESPONSE TO THERAPY AND MINIMAL RESIDUAL DISEASE IN CLL

Following the completion of therapy or during therapy for indefinite targeted agents, response is initially assessed using physical examination and laboratory studies (Table 103-5). If residual disease is not detected using these methodologies, CT scans are used to assess response. Bone marrow biopsies with flow cytometry are indicated if no disease is detected to confirm CR.

It has been established in various malignancies that complete tumor eradication is associated with longer survival. In CLL, if no malignant cells can be detected in the bone marrow down to a level of 1 CLL cell in 10^4 leukocytes (0.01%), the patient is said to be negative for minimal residual disease (MRD). Following combination chemoimmunotherapy, eradication of MRD correlates with long-term survival and potentially cure in a subset of patients receiving FCR chemoimmunotherapy. It has yet to be established whether MRD negativity in the setting of targeted therapies is a meaningful endpoint.

CONCLUSION

CLL is treated only when it becomes symptomatic. At the time of therapy chemoimmunotherapy in a small subset of patients is potentially curative. In the majority of remaining individuals with symptomatic CLL, targeted therapy directed at BTK greatly improves survival and also reverses the immune deficiency associated with the disease.

104 Non-Hodgkin's Lymphoma

Caron A. Jacobson, Dan L. Longo

Non-Hodgkin's lymphomas (NHL) are cancers of mature B, T, and NK cells. They were distinguished from Hodgkin lymphoma (HL) upon recognition of the Reed-Sternberg (RS) cell, and differ from HL with respect to their biologic and clinical characteristics. Whereas ~80–85% of patients with HL will be cured of their lymphoma by chemotherapy with or without radiotherapy, the prognosis and natural history of NHL tends to be more variable. NHL can be classified as either a mature B-NHL, or a mature T/NK-NHL depending on whether the cancerous lymphocyte is a B, T, or NK-cell, respectively. Within each category are lymphomas that grow quickly and behave aggressively, as well as lymphomas that are more indolent, or slow growing in nature. For a list of the World Health Organization (WHO) classification of lymphoid neoplasms, see Table 104-1.

EPIDEMIOLOGY AND ETIOLOGY

In 2017 over 72,000 new cases of NHL were diagnosed in the United States, about 4% of all new cancers in both males and females making it the eighth and ninth most common cause of cancer-related death in women and men, respectively. The incidence is nearly 10 times the incidence of Hodgkin's lymphoma. There is a slight male-to-female predominance and a higher incidence for Caucasians than for African Americans. The incidence rises steadily with age, especially after age 40, but lymphomas are also among the most common malignancies in adolescent and young adult patients. The incidence of NHL has nearly doubled over the last 20–40 years, and continues to rise by 1.5–2% each year. Patients with both primary and secondary immunodeficiency states are predisposed to developing non-NHL. These include patients with HIV infection; patients who have undergone organ transplantation; and patients with inherited immune deficiencies and autoimmune conditions. The 5-year survival rates for NHL is 72% for Caucasians and 63% for African Americans.

TABLE 104-1 WHO Classification of Lymphoid Malignancies

B CELL	T CELL
Mature (peripheral) B-cell neoplasms	Mature (peripheral) T-cell neoplasms
Lymphoplasmacytic lymphoma (Waldenstrom's macroglobulinemia)	T-cell granular lymphocytic leukemia
Hairy cell leukemia	Adult T-cell leukemia/lymphoma (HTLV-1+)
Splenic marginal zone B-cell lymphoma	Extranodal NK/T-cell lymphoma, nasal type
Extranodal marginal zone B-cell lymphoma of MALT type	Enteropathy-associated T-cell lymphoma
Nodal marginal zone B-cell lymphoma	Hepatosplenic T-cell lymphoma
Follicular lymphoma	Subcutaneous panniculitis-like T-cell lymphoma
Mantle cell lymphoma	Mycosis fungoides
Diffuse large B-cell lymphoma (including subtypes)	Sezary syndrome
High grade B-cell lymphoma with MYC and BCL2 and/or BCL6 rearrangements	Peripheral T-cell lymphoma, NOS
High grade B-cell lymphoma NOS	Angioimmunoblastic T-cell lymphoma
Burkitt's lymphoma/Burkitt's cell leukemia	Anaplastic large cell lymphoma, ALK+
Primary mediastinal large B-cell lymphoma	Anaplastic large cell lymphoma, ALK-
Plasmablastic lymphoma	
Primary effusion lymphoma	
HHV8+ DLBCL NOS	
Intravascular large B-cell lymphoma	
ALK+ large B-cell lymphoma	

Abbreviations: HTLV, human T-cell lymphotropic virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer; WHO, World Health Organization.

Source: Adapted from SH Swerdlow et al: *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*, 5th ed. IARC, 2016.

The incidence of NHL and the patterns of expression of the various subtypes differ geographically and across age groups. T-cell lymphomas are more common in Asia than in Western countries, while certain subtypes of B-cell lymphomas such as follicular lymphoma (FL) are more common in Western countries. A specific subtype of non-Hodgkin's lymphoma known as the angiocentric nasal T/natural killer- (NK-) cell lymphoma has a striking geographic occurrence, being most frequent in Southern Asia and parts of Latin America. Another subtype of non-Hodgkin's lymphoma associated with infection by human T-cell lymphotropic virus (HTLV) 1 is seen particularly in southern Japan and the Caribbean. Likewise, there are differences in the age-dependent incidence of NHL by histologic subtype, with aggressive lymphomas like diffuse large B-cell lymphoma (DLBCL) and Burkitt's lymphoma (BL) being the most common entities in children, and DLBCL and indolent lymphomas including FL being the most common forms in adults. The relative frequencies of the various types of lymphoid malignancies, including Hodgkin's lymphoma, plasma cell disorders, and lymphoid leukemias is shown in **Fig. 104-1**.

A number of environmental factors have been implicated in the occurrence of non-Hodgkin's lymphoma, including infectious agents, chemical exposures, and medical treatments. Several studies have demonstrated an association between exposure to agricultural chemicals and an increased incidence of non-Hodgkin's lymphoma. Patients treated for Hodgkin's lymphoma can develop non-Hodgkin's lymphoma; it is unclear whether this is a consequence of the Hodgkin's lymphoma or its treatment, especially radiation.

Several NHL are associated with infectious agents **(Table 104-2)**. Epstein-Barr Virus (EBV) is associated with the development of Burkitt's lymphoma in Central Africa and the occurrence of aggressive NHL in immunosuppressed patients in Western countries. The majority of primary central nervous system (CNS) lymphomas are associated with EBV. EBV infection is strongly associated with the occurrence of extranodal nasal NK/T-cell lymphomas in Asia and South America. HTLV-1 infects T cells and leads directly to the development of adult T-cell lymphoma (ATL) in a small percentage of patients infected as babies through ingestion of breast milk of infected mothers. The median age of patients with ATL is ~56 years; thus, HTLV-1 demonstrates a long latency from infection to oncogenesis **(Chap. 196)**. Infection with HIV predisposes to the development of aggressive, B-cell non-Hodgkin's lymphoma. This may be through overexpression of interleukin 6 by infected macrophages. Infection of the stomach by the bacterium *Helicobacter pylori* induces the development of gastric MALT (mucosa-associated lymphoid tissue) lymphomas. This association is

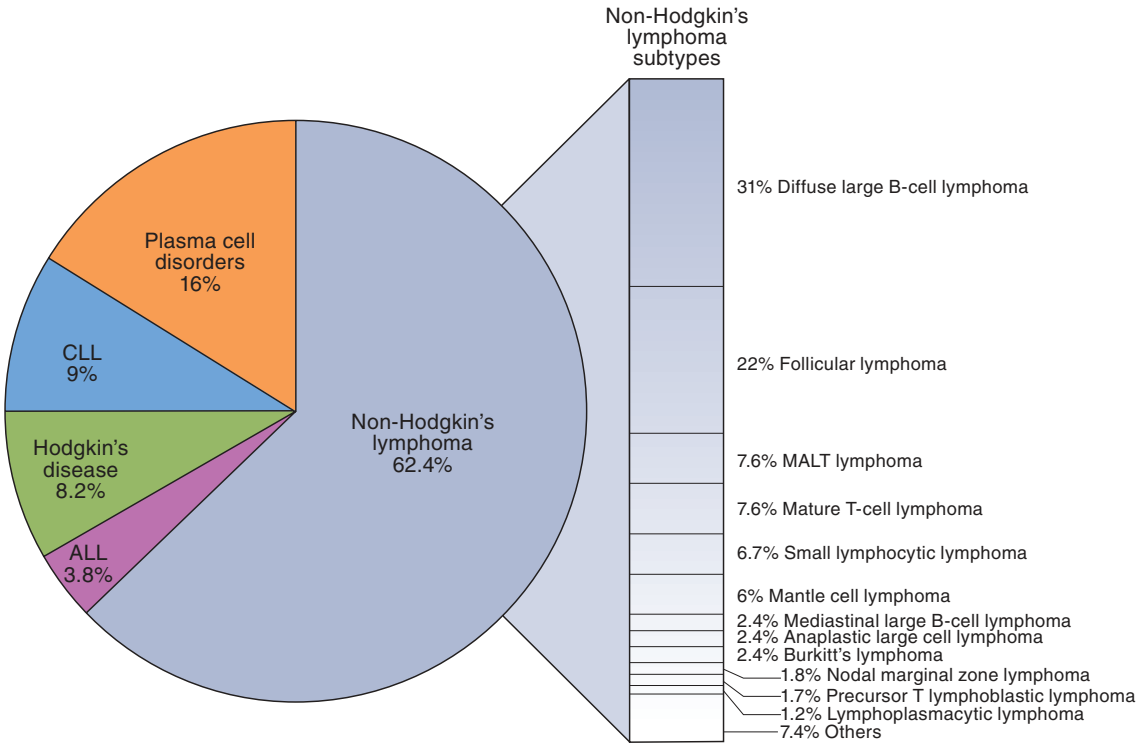

FIGURE 104-1 Relative frequency of lymphoid malignancies. ALL, acute lymphoid leukemia; CLL, chronic lymphoid leukemia; MALT, mucosa-associated lymphoid tissue.

TABLE 104-2 Infectious Agents Associated with the Development of Lymphoid Malignancies

INFECTIOUS AGENT	LYMPHOID MALIGNANCY
Epstein-Barr virus	Burkitt's lymphoma
	Post–organ transplant lymphoma
	Primary CNS diffuse large B-cell lymphoma
	Hodgkin's lymphoma
	Extranodal NK/T-cell lymphoma, nasal type
HTLV-1	Adult T-cell leukemia/lymphoma
HIV	Diffuse large B-cell lymphoma
	Burkitt's lymphoma
Hepatitis C virus	Lymphoplasmacytic lymphoma
Helicobacter pylori	Gastric MALT lymphoma
Human herpesvirus 8	Primary effusion lymphoma
	Multicentric Castleman's disease

Abbreviations: CNS, central nervous system; HIV, human immunodeficiency virus; HTLV, human T cell lymphotropic virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer.

supported by evidence that patients treated with antibiotics to eradicate *H. pylori* have regression of their MALT lymphoma. The bacterium does not transform lymphocytes to produce the lymphoma; instead, a vigorous immune response is made to the bacterium, and the chronic antigenic stimulation leads to the neoplasia. MALT lymphomas of the skin may be related to *Borrelia* sp. infections in Europe, those of the eyes to *Chlamydophila psittaci*, and those of the small intestine to *Campylobacter jejuni*. Chronic hepatitis C virus infection has been associated with the development of lymphoplasmacytic lymphoma and splenic marginal zone lymphoma (MZL). Human herpesvirus 8 is associated with primary effusion lymphoma in HIV-infected persons and multicentric Castleman's disease, a diffuse lymphadenopathy associated with systemic symptoms of fever, malaise, and weight loss.

In addition to infectious agents, a number of other diseases or exposures may predispose to developing lymphoma **(Table 104-3)**. Diseases of inherited and acquired immunodeficiency as well as autoimmune diseases are associated with an increased incidence of lymphoma. The association between immunosuppression and induction of NHLs is compelling since if the immunosuppression can be reversed, a percentage of these lymphomas regress spontaneously. The incidence of NHL is nearly hundredfold increased for patients undergoing organ transplantation necessitating chronic immunosuppression, and is greatest in the first year post-transplant. About 30% of these arise as a polyclonal B-cell proliferation that evolves into a clonal B-cell malignancy. The NHLs that occur in the context of immunosuppression or immunodeficiency, including HIV infection, are frequently associated with EBV. Histologically, DLBCLs are most frequently associated with immunosuppression and autoimmune diseases, although almost all histologies can be seen, especially MALT lymphomas in the context of autoimmune diseases like Sjogren's and Hashimoto's thyroiditis. The rare inherited immunodeficiency diseases X-linked lymphoproliferative syndrome, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, ataxia telangiectasia, and common variable immunodeficiency syndrome are complicated by highly aggressive lymphomas. The elevated incidence of lymphoma in iatrogenic immunosuppression, AIDS, and autoimmune disease argues strongly for immune dysregulation contributing in the pathogenesis of some lymphomas. An increased risk of NHL has been observed in first-degree relatives with NHL, Hodgkin's lymphoma or chronic lymphocytic leukemia (CLL). In large databases studies, about 9% of patients with lymphoma or CLL have a first-degree relative with a lymphoproliferative disorder.

TABLE 104-3 Diseases or Exposures Associated with Increased Risk of Development of Malignant Lymphoma

Inherited immunodeficiency disease	Autoimmune disease
Klinefelter's syndrome	Sjögren's syndrome
Chédiak-Higashi syndrome	Celiac sprue
Ataxia-telangiectasia syndrome	Rheumatoid arthritis and systemic lupus erythematosus
Wiskott-Aldrich syndrome	Chemical or drug exposures
Common variable immunodeficiency disease	Phenytoin
Acquired immunodeficiency diseases	Dioxin, phenoxy herbicides
Iatrogenic immunosuppression	Radiation
HIV-1 infection	Prior chemotherapy and radiation therapy
Acquired hypogammaglobulinemia	

IMMUNOLOGY

All lymphoid cells are derived from a common hematopoietic progenitor that gives rise to lymphoid, myeloid, erythroid, monocyte, and megakaryocyte lineages. Through the ordered and sequential activation of a series of transcription factors, the cell first becomes committed to the lymphoid lineage and then gives rise to B and T cells.

About 90% of all lymphomas are of B-cell origin. A cell becomes committed to B-cell development when it expresses the master B lineage transcription factor PAX5, which ultimately results in a transcriptional program that leads to the rearrangement of its immunoglobulin genes, which involves chromosomal recombination as well as somatic hypermutation to create an immunoglobulin gene that is unique to that B cell. The sequence of cellular changes, including changes in cell-surface phenotype that characterizes normal B-cell development is shown in **Fig. 104-2.** Most B-cell lymphomas arise following the process of immunoglobulin gene recombination and somatic hypermutation, which leads to class switching and affinity maturation of the mature immunoglobulin, respectively, suggesting that it is the error-prone nature of these genetic events that contributes to oncogenesis. Certainly the frequency of chromosomal translocations that result in the activation of an oncogene or the inactivation of a tumor suppressor gene in B-cell NHL may be the result of these normal cellular processes gone awry (see below). In addition, the key roles of the transcription factors MYC and BCL6 and the anti-apoptotic protein BCL2 in the process of B-cell development explain why the genes encoding these proteins are commonly mutated in B-cell lymphomas.

A cell becomes committed to T-cell differentiation upon migration to the thymus and rearrangement of T-cell receptor (TCR) genes. This requires the expression of the T-cell master regulatory transcription factor, NOTCH-1. As in B cells, the development of the mature TCR involves the rearrangement and recombination of the TCR loci, which is error-prone and potentially oncogenic. The sequence of the events that characterize T-cell development is depicted in **Fig. 104-3.**

Although lymphoid malignancies often retain the cell-surface phenotype of lymphoid cells at particular stages of differentiation, this information is of little clinical or prognostic consequence. The so-called stage of differentiation of a malignant lymphoma does not predict its natural history. The antigen footprint, or immunophenotype, of the cell, however, is valuable diagnostically as it allows for the distinguishing of specific NHL subtypes. It can be detected by flow cytometry of single cell suspension from blood, bone marrow, body fluid or disaggregated tissue using fluorescently labeled antibodies against these antigens, or by immunohistochemical staining of paraffin-embedded tissue sections with enzyme-linked antibodies against these antigens followed by a colorimetric reaction.

As already mentioned, malignancies of lymphoid cells are associated with recurring genetic abnormalities including chromosomal translocations and genetic mutations that may in part be the result of aberrant immunoglobulin or TCR development. While specific genetic abnormalities have not been identified for all subtypes of lymphoid malignancies, it is presumed that they exist. As previously discussed, B cells are even more susceptible to acquiring mutations during their maturation in germinal centers; the generation of antibody of higher affinity requires the introduction of mutations into the variable region genes in the germinal centers. Given this, other nonimmunoglobulin genes, e.g., *bcl-6*, may acquire mutations as well. Likewise, many lymphomas contain balanced chromosomal translocations involving the antigen receptor genes; immunoglobulin genes on chromosomes 2, 14,

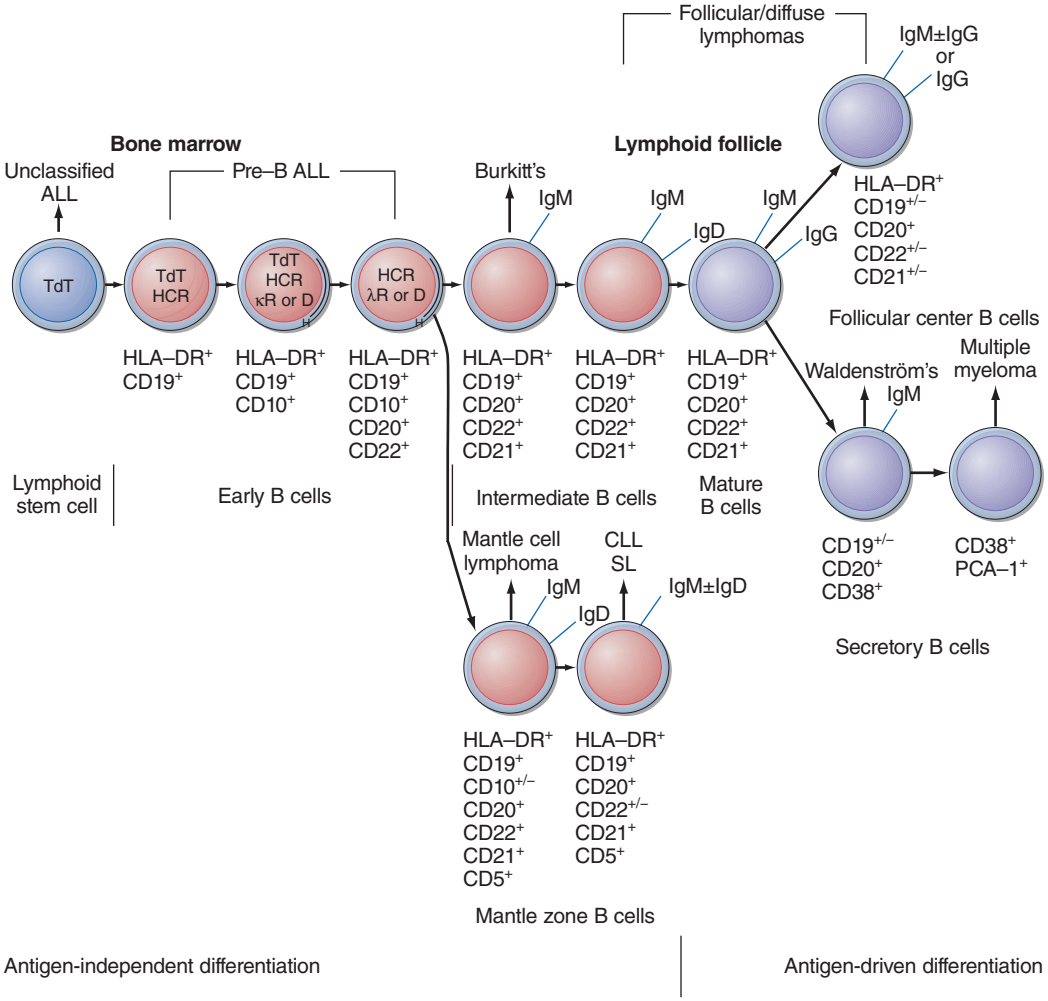

FIGURE 104-2 Pathway of normal B-cell differentiation and relationship to B-cell lymphomas. HLA-DR, CD10, CD19, CD20, CD21, CD22, CD5, and CD38 are cell markers used to distinguish stages of development. Terminal transferase (TdT) is a cellular enzyme. Immunoglobulin heavy chain gene rearrangement (HCR) and light chain gene rearrangement or deletion (κR or D, λR or D) occur early in B-cell development. The approximate normal stage of differentiation associated with particular lymphomas is shown. ALL, acute lymphoid leukemia; CLL, chronic lymphoid leukemia; SL, small lymphocytic lymphoma.

and 22 in B cells; and T-cell antigen receptor genes on chromosomes 7 and 14 in T cells. The rearrangement of chromosome segments to generate mature antigen receptors must create a site of vulnerability to aberrant recombination. Examples of this type of event include the (8;14)(q24;q32) translocation in BL, involving the *MYC* proto-oncogene and the IgH gene; the (14;18)(q32;q32) translocation in FL, involving the *BCL2* proto-oncogene and the IgH gene; and the (11;14) (q13;q32) translocation in mantle cell lymphoma (MCL), involving the gene encoding cyclin D1 (*CCDN1*) and the IgH gene. Less commonly, chromosomal translocations produce fusion genes that encode chimeric oncogenic proteins. Examples of this include the (2;5)(p23;q35) translocation involving the *ALK* and *NPM1* genes in anaplastic large cell lymphoma (ALCL) and the t(11;18)(q21;q21) translocation involving the *API2* and *MLT* genes in MALT lymphoma. Table 104-4 presents the most common translocations and associated oncogenes for various subtypes of lymphoid malignancies.

Gene profiling using array technology allows the simultaneous assessment of the expression of thousands of genes. This technology provides the possibility to identify new genes with pathologic importance in lymphomas, the identification of patterns of gene expression with diagnostic and/or prognostic significance, and the identification of new therapeutic targets. Recognition of patterns of gene expression is complicated and requires sophisticated mathematical techniques. Early successes using this technology in lymphoma include the identification of previously unrecognized subtypes of DLBCL whose gene expression patterns resemble either those of follicular, or germinal center B (GCB) cells or activated peripheral blood B cells (ABC). Patients whose lymphomas have a GCB-like pattern of gene expression have a considerably better prognosis than those whose lymphomas have a pattern resembling ABCs. This improved prognosis is independent of other known prognostic factors. Similar information is being generated in FL and MCL. The challenge remains to provide information from such techniques in a clinically useful time frame.

APPROACH TO THE PATIENT

Regardless of the type of lymphoid malignancy, the initial evaluation of the patient should include performance of a careful history and physical examination. These will help confirm the diagnosis, identify those manifestations of the disease that might require prompt attention, and aid in the selection of further studies to optimally characterize the patient's status to allow the best choice of therapy. It is difficult to overemphasize the importance of a carefully done history and physical examination. They might provide observations that lead to reconsidering the diagnosis, provide hints at etiology, clarify the stage, and allow the physician to establish rapport with the patient that will make it possible to develop and carry out a therapeutic plan.

The duration of symptoms and pace of symptomatic progression are important in distinguishing aggressive from more indolent lymphomas, as are the presence or absence of "B" symptoms, such as

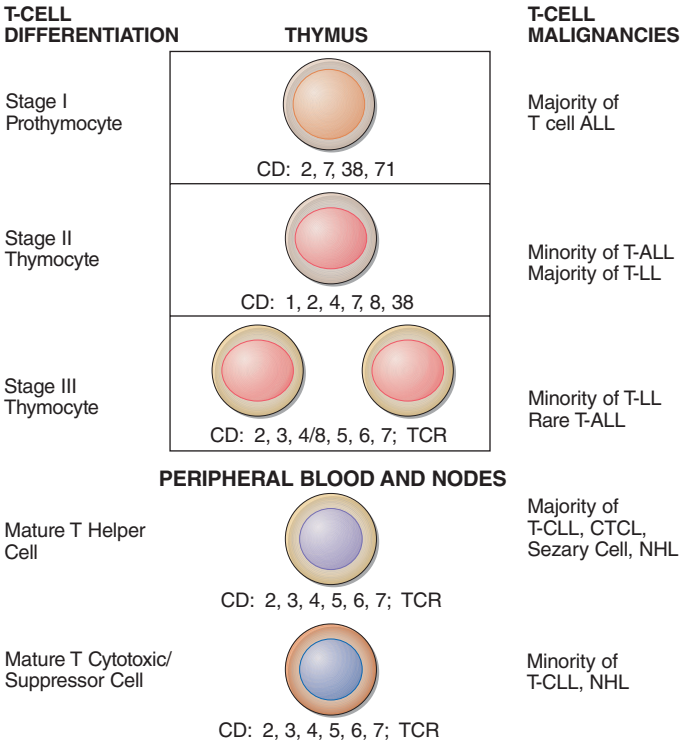

FIGURE 104-3 Pathway of normal T-cell differentiation and relationship to T-cell lymphomas. CD1, CD2, CD3, CD4, CD5, CD6, CD7, CD8, CD38, and CD71 are cell markers used to distinguish stages of development. T-cell antigen receptors (TCR) rearrange in the thymus, and mature T cells emigrate to nodes and peripheral blood. ALL, acute lymphoid leukemia; T-ALL, T-cell ALL; T-LL, T-cell lymphoblastic lymphoma; T-CLL, T-cell chronic lymphoid leukemia; CTCL, cutaneous T-cell lymphoma; NHL, non-Hodgkin's lymphoma.

fevers, night sweats, or unexplained weight loss. Patients should be asked about localizing symptoms that may point towards lymphomatous involvement of specific sites, such as the chest, abdomen, or CNS. Comorbid diagnoses that may impact therapy or monitoring on therapy should be reviewed and acknowledged, including a history of diabetes or congestive heart failure. A physical examination should pay close attention to all the peripherally accessible sites of lymph nodes, the liver and spleen size, Waldeyer's ring, whether there is a pleural or pericardial effusion or abdominal ascites, whether there is an abdominal, testicular or breast mass, and whether there is cutaneous involvement as all of these findings may influence further evaluation and disease management.

Laboratory studies should include a complete blood count, routine chemistries, liver function tests, and serum protein electrophoresis to document the presence of circulating monoclonal paraproteins. The serum β-2 microglobulin level and serum lactate dehydrogenase (LDH) are important independent prognostic factors in NHL. Staging of certain diseases may involve a bone marrow biopsy; results of other laboratory and staging studies may also warrant a marrow evaluation. A lumbar puncture for evaluation of lymphomatous involvement may be indicated in the setting of concerning neurologic signs or symptoms, or diseases that are high risk for CNS involvement. The latter may include disease involving the paranasal sinuses, testes, breast, kidneys, adrenal glands, and epidural space, as well as highly aggressive histologies like BL. Since HIV and hepatitis B and C infection can be risk factors for developing NHL, and since treatment for some NHL can result in the potentially life threatening reactivation of hepatitis B, patients with a new diagnosis of NHL should be screened for these viruses as well.

Lymphoma histology and clinical presentation dictates which imaging studies should be ordered. Chest, abdominal, and pelvic computed tomography (CT) scans are essential for accurate staging to assess lymphadenopathy for indolent lymphomas, whereas positron emission tomography (PET) using ^{18}F-fluorodeoxyglucose (FDG PET) is useful for aggressive lymphomas, including BL, DLBCL, plasmablastic lymphoma, and the aggressive T-cell NHLs. It is highly sensitive for detecting both nodal and extranodal sites involved by NHL. The intensity of FDG avidity, or SUV, correlates with histologic aggressiveness, and may be useful in cases when disease transformation of an indolent lymphoma to a diffuse aggressive lymphoma is suspected. PET scanning can also differentiate between treated disease and active disease at the end of therapy in patients with residual masses on CT scans. Consensus recommendations regarding PET scanning were published as a result of an International Harmonization Project, and state that PET should only be used for DLBCL and Hodgkin's lymphoma, that scanning during therapy should only be done as part of clinical trials, and that the end-of-treatment scan should not be done before 3 weeks but preferably 6–8 weeks after chemotherapy and 8–12 weeks after radiation or chemoradiotherapy. There is no evidence that long-term follow-up should include PET scanning. More recently, though, PET scan results at the end of therapy for FL have been associated with prognosis, with patients with residual PET avid disease at the end of treatment having a poorer prognosis than those who are PET negative, and so it may be used for this prognostic purpose. Finally, magnetic resonance imaging (MRI) is useful in detecting bone, bone marrow and CNS disease in the brain and spinal cord. The staging evaluation is outlined in **Table 104-5**.

The Ann Arbor staging system developed in 1971 for HL was adapted for staging NHLs **(Table 104-6)**. This staging system focuses on the number of tumor sites (nodal and extranodal), location, and the presence or absence of systemic, or B, symptoms. Table 104-6 summarizes the essential features of the Ann Arbor system.

This anatomic based system is less useful in NHL, which disseminates widely, not in an ordered stepwise fashion. A majority of patients with NHL have advanced stage disease at diagnosis. Apart from early-stage disease limited to a radiation field where local

TABLE 104-7 International Prognostic Index for NHL

Five Clinical Risk Factors	
Age ≥60 years	
Serum lactate dehydrogenase levels elevated	
Performance status ≥2 (ECOG) or ≤70 (Karnofsky)	
Ann Arbor stage III or IV	
>1 site of extranodal involvement	
For Diffuse Large B-cell Lymphoma	
0, 1 factor = low risk	35% of cases; 5-year survival, 73%
2 factors = low-intermediate risk	27% of cases; 5-year survival, 51%
3 factors = high-intermediate risk	22% of cases; 5-year survival, 43%
4, 5 factors = high risk	16% of cases; 5-year survival, 26%
For Diffuse Large B-cell Lymphoma Treated With R-CHOP	
0 factor = good	10% of cases; 4-year survival, 94%
1, 2 factors = intermediate	45% of cases; 4-year survival, 80%
3, 4, 5 factors = poor	45% of cases; 4-year survival, 53%

Abbreviations: ECOG, Eastern Cooperative Oncology Group; R-CHOP, rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone.

therapy with radiation is an option, all other disease is treated the same regardless of stage. Histology and clinical parameters at presentation are more important than stage with respect to prognosis. The International Prognostic Index (IPI) is perhaps the best predictor of outcome (Table 104-7). The IPI was developed based on the analysis of over 2000 patients with aggressive NHLs treated with an anthracycline containing regimen. Age (≤60 vs >60); serum LDH (≤normal vs >normal); performance status (0 or 1 vs 2–4); stage (I or II vs III or IV); and extranodal involvement (<1 site vs >1 site) were identified as independently prognostic for overall survival (OS). A point is awarded for each risk factor and then summed, defining four risk groups: low-risk (0 or 1); low-intermediate (2); high-intermediate (3); and high (4–5). The 5-year OS rates for patients with scores of 0 to 1, 2, 3, and 4–5 were 73, 51, 43, and 26%, respectively. The age-adjusted IPI separates patients ≤60 from patients >60. For the age adjusted IPI, only stage, LDH, and performance status were important. Younger patients with 0, 1, 2, or 3 risk factors had 5-year survival rates of 83%, 69%, 46%, and 32%, compared to 56%, 44%, 37%, and 21% for older patients. When factoring in the introduction and clinical benefit of rituximab, the 4-year progression-free survival is 94%, 80%, and 53% for 0 and 1, 2, or 3 or more risk factors, respectively.

The follicular lymphoma prognostic index (FLIPI) is a similar predictive model for FL, derived from the analysis of over 4000 patients. Age >60, stage III/IV disease, the presence of >4 nodal sites, an elevated serum LDH concentration and a hemoglobin <12 were identified as independent prognostic variables, and summation of each variable identified three risk groups. The median 10-year survival rates for patients with zero to one (low-risk), two (intermediate-risk), or three or more (high-risk) of these adverse factors were 71, 51, and 36%, respectively. Similar disease-specific IPIs have been developed for MCL and peripheral T-cell lymphoma (PTCL) as well. These prognostic indices take into account the proliferative index and cell surface markers, respectively.

Finally, as mentioned previously, gene expression profiling has identified DLBCLs with differential prognoses: GCB and ABC, where GCB-like DLBCL is associated with a significantly better OS. A more readily accessible immunohistochemical algorithm has been developed, based on the presence of absence of CD10, BCL6, and MUM1 that correlates closely with gene expression profiles and can differentiate the majority of GCB from non-GCB-like DLBCL. These profiles have prognostic importance but to date do not alter treatment recommendations for the primary treatment of DLBCL. Current clinical trials do stratify by DLBCL subtype, and it appears that agents like the Bruton's tyrosine kinase (BTK) inhibitor ibrutinib and lenalidomide are most active in non-GCB DLBCL in the relapsed setting. Treatment may then be differentiated by these subtypes in the future.

TABLE 104-6 Ann Arbor Staging for Lymphoma*

STAGE	DESCRIPTION
I	Involvement of a single lymph node region (I) or single extranodal site (IE)
II	Involvement of two or more lymph node regions or lymphatic structures on the same side of the diaphragm alone (II) or with involvement of limited, contiguous, extralymphatic organ or tissue (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may include the spleen (IIIS), or limited, contiguous, extralymphatic organ or tissue (IIIE), or both (IIIES)
IV	Diffuse or disseminated foci of involvement of one or more extralymphatic organs or tissues, with or without associated lymphatic involvement

*All stages are further subdivided according to the absence (A) or presence (B) of systemic B symptoms including fevers, night sweats, and/or weight loss (>10% of body weight over 6 months prior to diagnosis).

CLINICAL FEATURES, TREATMENT, AND PROGNOSIS OF SPECIFIC NHL

MATURE B-CELL NEOPLASMS

B-cell NHLs can be characterized into two broad groups—those that behave aggressively, require immediate or urgent treatment with combination chemotherapy regimens, and are potentially curable, and those that are more indolent in nature, can be observed and treated only when they cause symptoms or signs of organ function impairment, are very responsive to therapy, but are not ultimately curable in the vast majority of cases. Among the aggressive diseases, the most common are NHL and DLBCL; and the most rapidly prolific are NHL and BL. FL is the second most common NHL and the most common indolent NHL. Other indolent NHLs include MZL, lymphoplasmacytic lymphoma (LPL), and hairy cell leukemia (HCL). MCL is an intermediate grade lymphoma that shares some characteristics with the aggressive lymphomas (fairly urgent need for treatment and aggressive upfront combination chemotherapy regimens), but like the indolent lymphomas, it is not readily curable with conventional dose therapies.

Burkitt's Lymphoma Burkitt's lymphoma/leukemia is a rare disease in adults in the United States, making up <1% of NHL, but it makes up ~30% of childhood non-Hodgkin's lymphoma. It is one of the fastest growing neoplasms, with a doubling time of <24 h. In general it is a pediatric tumor that has three major clinical presentations. The endemic (African) form presents as a jaw or facial bone tumor that spreads to extranodal sites including ovary, testis, kidney, breast, and especially to the bone marrow and meninges. The non-endemic form has an

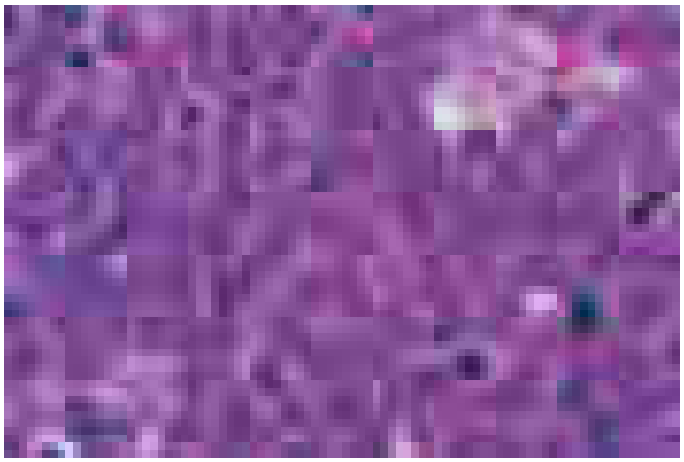

FIGURE 104-4 Burkitt's lymphoma. The neoplastic cells are homogeneous, medium-sized B cells with frequent mitotic figures, a morphologic correlate of high growth fraction. Reactive macrophages are scattered through the tumor, and their pale cytoplasm in a background of blue-staining tumor cells gives the tumor a so-called starry sky appearance.

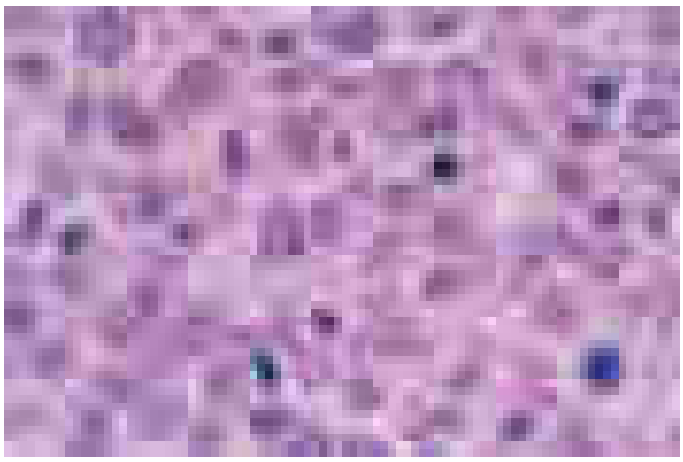

FIGURE 104-5 Diffuse large B-cell lymphoma. The neoplastic cells are heterogeneous but predominantly large cells with vesicular chromatin and prominent nucleoli.

abdominal presentation with massive disease, ascites, and renal, testis, and/or ovarian involvement, and, like the endemic form, also spreads to the bone marrow and CNS. Immunodeficiency-related cases more often involve lymph nodes and may present as acute leukemia. BL has a male predominance and is typically seen in patients <35 years of age.

On biopsy, there is a monotonous infiltration of medium-sized cells with round nuclei, multiple nucleoli, and basophilic cytoplasm with vacuoles. The proliferation rate is ~100%, and tingible body macrophages give rise to the classic "starry sky" appearance of this tumor **(Fig. 104-4)**. Tumor cells are positive for B-cell antigens CD19, CD20, and surface immunoglobulin. They are also uniformly positive for CD10 and BCL6 but negative for BCL2. Endemic BLs are EBV positive, whereas the majority of non-endemic BLs are EBV negative. BL is associated with a translocation involving MYC on chromosome 8q24 in >95% of the cases. The most common partners are chromosomes 14, 2, or 22, rearrangements that produce fusions of MYC with either the IgH (80%), kappa (15%), or lambda (5%) light chain genes, respectively.

While exquisitely chemosensitive, it is imperative that treatment for BL be initiated quickly given the rapid doubling time and high morbidity of this disease. There are several effective intensive combination chemotherapy regimens, all of which incorporate high doses of cyclophosphamide. Prophylactic therapy to the CNS is mandatory. Cure can be expected in 70–80% of patients when treated promptly and correctly. Salvage therapy has been generally ineffective in patients whose disease progresses after upfront therapy, emphasizing the importance of the initial treatment approach and referral to a tertiary cancer center with experience treating this disease.

Diffuse Large B-Cell Lymphoma Diffuse large B-cell lymphoma (DLBCL) is the most common histologic subtype of NHL diagnosed, representing about one-third of all cases. Previously felt to be "one disease" it is now recognized as a heterogeneous collection of multiple entities. It is slightly more common in Caucasians and men, and the median age at diagnosis is 64. The relative risk of DLBCL is higher amongst people with affected first-degree relatives (RR 3.5-fold), and patients with congenital or acquired immunodeficiency, patients on immunosuppression, and patients with autoimmune disorders also have a higher risk of developing DLBCL, often EBV-related. The majority of patients present with advanced stage disease, with only 30–40% of patients having stage I or II disease; about 40% of patients will have "B" symptoms, and 50% of patients will have an elevated LDH. Up to 40% of patients will have involvement of non-lymph node sites including bone marrow, CNS, GI track, thyroid, liver, and skin. Patients with extensive bone marrow involvement, or involvement of the testes, breast, kidney, adrenal gland, paranasal sinus, or epidural space are at increased risk of CNS dissemination.

The tumor consists of a diffuse proliferation of large, atypical lymphocytes with a high proliferative index **(Fig. 104-5)**. These cells typically express the B-cell antigens CD19, CD20, and CD79a. Expression of CD10 and BCL6 is consistent with the tumor cell being of germinal center origin (GCB), while the expression of MUM1 corresponds with the non-GC or activated B cell (ABC) subtype. BCL2 is overexpressed in anywhere from 25 to 80% of DLBCL, whereas BCL6 is positive in more than two-thirds of cases, either as the result of translocations, gain of copy number, or promoter mutations. MYC is rearranged in 10% of DLBCLs, and ~20% of MYC-rearranged cases have concurrent BCL2 or BCL6 rearrangements, a combination referred to as "double-hit lymphoma." These double-hit lymphomas are associated with an extremely poor prognosis with a median OS of only 12–18 months. Amplification and/or overexpression of MYC independent of rearrangements or amplification has also been described and is also associated with a poor, albeit better, prognosis.

Combination chemotherapy offers potentially curative therapy for DLBCL, regardless of the stage. The addition of the anti-CD20 antibody rituximab to cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) improved survival beyond CHOP alone and is the standard first-line chemotherapy for this disease. For patients with early stage disease localized to a radiation field, treatment options include full course chemotherapy with R-CHOP every 3 weeks for 6 cycles, or abbreviated chemotherapy for 3–4 cycles followed by involved field radiotherapy. For advanced stage DLBCL, therapy is with a full course of chemotherapy. On average, about 60–65% of patients with DLBCL can be expected to be cured with this approach, and the likelihood of cure is predicted by the IPI, gene expression profile cell of origin, and/or MYC cytogenetics and expression. Several studies have investigated alternative anthracycline-containing chemotherapy regimens and/or consolidation autologous stem cell transplantation in first remission for higher-risk disease without improvement over R-CHOP alone. Dose adjusted R-EPOCH (rituximab, infusional etoposide/vincristine/adriamycin, cyclophosphamide, prednisone) is one such regimen. Although this regimen is no better than R-CHOP for DLBCL in general, it is often used to treat primary mediastinal large B-cell lymphoma and double-hit DLBCL based on results from phase 2 and retrospective studies, respectively. CNS prophylaxis with either intrathecal chemotherapy or high-dose systemic methotrexate and leucovorin rescue should be considered for patients with high risk of CNS dissemination. This includes patients with primary testicular involvement and breast involvement, as well as patients with several IPI risk factors and diffuse bone marrow involvement, renal involvement, or adrenal involvement. The use of CNS prophylaxis for disease involving the paranasal sinuses or the epidural space is less clear but may be considered.

Over one-third of patients will either have primary refractory disease or disease that relapses after first-line chemotherapy. These patients may still be cured with salvage chemotherapy regimens

followed by autologous stem cell transplantation. Patients with a poor performance status or advanced age that are not candidates for such an approach, however, are often managed with palliative intentions. Radiation to symptomatic areas of disease can be transiently helpful. Less intensive chemotherapy with drugs like gemcitabine, cytarabine, or bendamusine can help control disease and symptoms for a limited period of time. These patients should be referred for clinical trials when applicable. For patients in whom more aggressive therapy is an option, treatment is with combination chemotherapy using various combinations of drugs primarily in order to identify patients with chemosensitive disease. Patients with chemosensitive disease have the greatest likelihood of benefiting from high-dose chemotherapy and autologous stem cell transplant, which improves response duration and survival over salvage chemotherapy alone and leads to long-term disease free survival in about 40–50% of patients. For patients with chemorefractory disease, clinical trials or palliative therapy or clinical trials should be considered, with a goal of achieving a disease response sufficient for allogeneic stem cell transplant. Several new agents have shown some promise in patients with relapsed DLBCL, including ibrutinib, particularly in the ABC cell of origin subtype, lenalidomide, and everolimus.

Chimeric antigen receptor T cells (CAR-T cells) are an investigational immunotherapy approach for treating malignancies that have had early success in CLL and B-cell acute lymphoblastic leukemia, as well as B-cell NHL. This strategy uses T cells collected from a patient that are genetically modified to express a receptor that will bind to a surface antigen expressed on the patient's own tumor cells. In the case of B-cell malignancies, CD19 has been targeted most commonly. After infusion, autologous CAR-T cells home to sites of disease and also persist over time. The CARs consist of an extracellular antigen recognition domain (typically a single chain Fv variable fragment from a monoclonal antibody) linked via a transmembrane domain to an intracellular signaling domain (usually the CD3ζ endodomain), resulting in the redirection of T-cell specificity toward target antigen-positive cells, and one or more costimulatory domains including CD28, 4-1BB, or OX40 to enhance cytokine secretion and effector cell expansion, and prevent activation-induced apoptosis and immune suppression by tumor-related metabolites. Anti-CD19 CAR-T cells have been approved for the treatment of relapsed/refractory DLBCL following two prior systemic therapies. This would include patients with chemoinsensitive disease following second-line salvage chemotherapy for whom autologous stem cell transplant is not an option, or for patients who relapse after autologous stem cell transplant. In this setting, the response rate of CAR-T cells is over 80%, with over 50% of patients achieving a complete response. These responses appear to be durable, with 70% of complete responders still in remission past 1 year of therapy.

Other large B-cell lymphomas include intravascular large B-cell lymphoma, T-cell/histiocyte–rich large B-cell lymphoma, EBV-positive DLBCL of the elderly, and ALK-positive large B-cell lymphoma. Patients with the latter two diseases tend to have a poor prognosis, whereas the addition of rituximab to CHOP chemotherapy has dramatically improved outcomes with intravascular large B-cell lymphoma, and the outcomes in T-cell/histiocyte-rich large B-cell lymphoma are similar to DLBCL. R-CHOP remains the treatment of choice for each of these lymphomas.

Follicular Lymphoma FLs are the second leading NHL diagnosis in the United States and Europe and makes up 22% of NHL worldwide and at least 30% of NHL diagnosed in the United States. This type of lymphoma can be diagnosed accurately on morphologic findings alone and has been the diagnosis in the majority of patients in therapeutic trials for "low-grade" lymphoma in the past.

Evaluation of an adequate biopsy by an expert hematopathologist is sufficient to make a diagnosis of FL. The tumor is composed of small cleaved and large cells in varying proportions organized in a follicular pattern of growth **(Fig. 104-6)**. Confirmation of B-cell immunophenotype (monoclonal immunoglobulin light chain, CD19, CD20, CD10 and BCL6 positive, and CD5 and CD23 negative) and the existence of the t(14;18) and abnormal expression of BCL-2 protein are confirmatory. While >85% of FL will harbor a t(14;18) and overexpress the antiapoptotic protein BCL2, this genetic event is necessary but not sufficient for malignant transformation of the B lymphocytes and multiple genetic events are required for the development of FL. Studies have identified the most common recurrent genetic events in FL, and they included mutations in several epigenetic modifying genes, including *MLL2, EZH2, CREBBP*, and *EP300*. The major differential diagnosis is between lymphoma and reactive follicular hyperplasia. The coexistence of DLBCL must be considered. Patients with FL are often subclassified, or graded, into those with predominantly small cells, those with a mixture of small and large cells, and those with predominantly large cells. The WHO Classification adopted grading from 1 to 3 based on the number of centroblasts, or large cells, counted per high power field (hpf): grade I, from 0 to 5 centroblasts/hpf; grade II, from 6 to 15 centroblasts/hpf; and grade III, >15 centroblasts/hpf. Grade III has been subdivided into grade IIIa, in which centrocytes predominate, and grade IIIb, in which there are sheets of centroblasts. While this distinction cannot be made simply or very reproducibly, these subdivisions do have prognostic significance. Patients with FL with predominantly large cells have a higher proliferative fraction, progress more rapidly, and have a shorter OS with simple chemotherapy regimens. Grade IIIb FL is an aggressive disease and considered most similar to DLBCL and treated as such with curative intent.

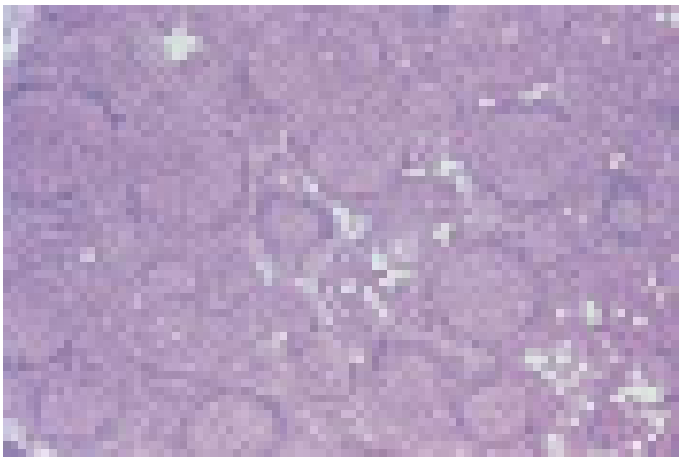

FIGURE 104-6 Follicular lymphoma. The normal nodal architecture is effaced by nodular expansions of tumor cells. Nodules vary in size and contain predominantly small lymphocytes with cleaved nuclei along with variable numbers of larger cells with vesicular chromatin and prominent nucleoli.

The most common presentation for FL is with new, painless lymphadenopathy. Multiple sites of lymphoid involvement are typical, and unusual sites such as epitrochlear nodes are sometimes seen. However, essentially any organ can be involved, and extranodal presentations do occur. Most patients do not have an elevated LDH or fevers, night sweats, or weight loss, although histologic transformation to DLBCL does occur at a rate of ~3% per year and can be associated with these signs/symptoms. As discussed previously, prognosis is best predicted by the FLIPI. Staging is typically done with CT scans of the chest, abdomen and pelvis, as well as the neck if neck disease is suspected, although PET/CT scans can be helpful in cases where disease transformation is suspected, as transformed disease will be more FDG avid than indolent disease, or for confirmation of early-stage disease, where definitive local therapy with radiation may be considered.

Although FL is highly sensitive to chemotherapy and radiotherapy, these therapies are usually not ultimately curative, except in the setting of early-stage disease. If the disease can be encompassed in a radiation field, involved field radiotherapy at a dose of 24–30 Gy may be curative, with 5-, 10-, and 15-year freedom from treatment failure of 72%, 46%, and 39%, and an overall 5-, 10-, and 15-year survival rates of 93%, 75%, and 62%, respectively. If radiation therapy would not be tolerated, or if a patient prefers not to receive radiation, observation is a reasonable alternative with a median time to treatment not reached at 7 years of follow-up in one study. Many of these patients are diagnosed incidentally or at a time when their lymphoma is not causing symptoms

or signs of organ function impairment. Numerous studies have shown that treating patients with asymptomatic disease does not improve survival compared with a program of close observation with treatment reserved for symptomatic disease progression or organ dysfunction. Thus, asymptomtic patients should be observed. When treatment is indicated, there are a variety of treatment options, ranging from the use of the monoclonal antibody against CD20, rituximab, alone or its use in combination with chemotherapy. Treatment decisions are often determined by the indication for treatment and/or by the volume of disease being treated. For patients requiring therapy for inflammatory or autoimmune phenomenon thought to be driven by FL, or for patients with low volume disease, single-agent rituximab is associated with a response rate of ~70% and a median response duration of >2 years. This response duration is improved with the addition of maintenance rituximab following a favorable response to rituximab induction therapy. For patients with a larger volume of disease at the time of treatment initiation, the addition of rituximab to chemotherapy like cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) or cyclophosphamide, vincristine, and prednisone (CVP) has improved survival in this disease. The combination of bendamustine and rituximab (BR) has been compared to R-CHOP and results in longer response duration and less toxicity. BR then has become the standard of care for the first-line therapy of medium to high-volume FL. Similarly, the addition of maintenance rituximab following a good response to R-CHOP or R-CVP improves response duration when used in newly treated FL patients.

In patients with FL, the disease nearly always recurs following therapy, after which retreatment is again reserved for symptomatic disease or disease interfering with organ function. Single agent rituximab or alternative chemotherapy regimens can again be employed. Both autologous and allogeneic hematopoietic stem cell transplantation yield high complete response rates in patients with relapsed FL, and long-term remissions can occur in 40 and 60% of patients, respectively. The latter is associated with considerable treatment-related morbidity and mortality and so is usually reserved for patients with multiply relapsed FL that is no longer responsive to chemotherapy. More targeted oral therapies like lenalidomide and the PI3 kinase inhibitor idelalisib are active in both untreated and relapsed FL. On average, most patients will live with FL for 15–20 years, a number that is increasing given our improved understanding of the genetics and microenvironment of FL, and the increasing number of drugs and therapies being tested in this disease. However, in addition to a high risk FLIPI, patients who do not have a complete metabolic response by PET/CT scanning to their primary therapy, and patients who relapse within 2 years of the completion of their primary chemotherapy tend to do poorly with chemotherapy.

Patients with FL have a high rate of histologic transformation to DLBCL (~3% per year). This is recognized ~40% of the time during the course of the illness by repeat biopsy and is present in almost all patients at autopsy. This transformation is usually heralded by rapid growth of lymph nodes—often localized—and the development of systemic symptoms such as fevers, sweats, and weight loss. When this happens in patients who have had previously untreated FL, treatment with R-CHOP chemotherapy, as for DLBCL, can be curative for the aggressive component while the FL may eventually recur. In patients with previously treated FL that transforms to DLBCL, prognosis is poor, and successful therapy with an aggressive combination chemotherapy regimen should be consolidated with an autologous stem cell transplant. Finally, as discussed previously, grade 3B FL is more similar to DLBCL than it is to FL and should be treated as such.

Marginal Zone Lymphoma The second most common indolent B-cell NHL is MZL. There are three main types: splenic MZL, extranodal MZL of MALT, and nodal MZL.

Nodal MZL most closely resembles FL clinically, and much of the way we manage and treat it is based on studies done in FL. Tumor biopsies in this disease show parafollicular and perivascular infiltration by monocytoid-appearing atypical lymphocytes with folded nuclear contours that are positive for CD19, CD20, and CD79a but negative for CD10 and largely negative for CD5. Some cases can have plasmacytoid differentiation and can be associated with a monoclonal expression of kappa or lambda light chains and with small monoclonal immunoglobulin spikes.

Splenic MZL is largely a disease of older Caucasian patients; infection with hepatitis C is a risk factor for this disease and treatment of hepatitis C can result in regression of the lymphoma. Patients present with a lymphocytosis with or without cytopenias and splenomegaly. Bone marrow involvement is common. Diagnosis can be made by flow cytometry of the peripheral blood; malignant lymphocytes will be positive for surface immunoglobulin, CD19, and CD20 and will generally lack CD5 and CD10. On peripheral smear they have small nuclei and abundant cytoplasm with "shaggy" or villous projections. It can be differentiated from hairy cell leukemia by the absence of CD25, CD103, and annexin A1. Recurrent cytogenetic abnormalities include trisomy 3 and abnormalities of chromosome 7q. Therapy is indicated for symptomatic disease or significant cytopenias. Splenectomy is reasonable for selected patients with excellent relief of symptoms and cytopenias. Splenectomy is associated with an overall response rate of 85% and an estimated progression-free and OS at 5 years of 58 and 77%, respectively. Single-agent rituximab can improve splenomegaly and cytopenias in >90% of patients. In a study of induction with weekly rituximab followed by maintenance, the response rate was 95%, with overall and progression-free survival at 5 years of 92 and 73%, respectively. Other options for therapy at relapse are similar to those used for FL and include retreatment with rituximab, alkylating agents, and purine analogues in combination with rituximab. The survival rate of patients is in excess of 70% at 10 years.

MALT lymphoma is an MZL lymphoma of extranodal tissue, most commonly the stomach but other common sites include the skin, salivary glands, lung, small bowel, ocular adnexa, breasts, bladder, thyroid, dura, and synovium. It is associated with states of chronic inflammation either due to autoimmune diseases like Sjogren's syndrome or Hashimoto's thyroiditis, or chronic infections with organisms like *Helicobacter pylori* (gastric), *Borrelia burgdorferi* (skin), *Chlamydia psittaci* (conjunctiva), *Campylobacter jejuni* (intestines), and hepatitis C virus. The essential pathologic feature of MALT lymphoma is the presence of lymphepithelial lesions, which result from invasion of mucosal glands and crypts by the neoplastic lymphocytes. These cells are positive for CD19, CD20, and CD79a and negative for CD5 and CD10. Recurrent cytogentic abnormalities include t(11;18), t(14;18), t(1;14), t(3;14), and trisomy 8. The t(11;18) is most common, occurring in up to 50% of MALT lymphomas. It results in the fusion of the apoptosis inhibitor 2 (API2) gene and the MALT1 gene, resulting in activation of nuclear factor κB (NFκB). Unlike other indolent B-cell lymphomas, MALT lymphomas present most commonly with stage I or II disease. In these cases, radiation therapy may be curative. Alternatively, patients may respond to antibiotics for the associated underlying infection. Treatment of symptomatic or organ impairing relapsed, refractory, or advanced stage disease is similar to approaches used in FL with chemotherapy, immunotherapy, or chemoimmunotherapy.

Lymphoplasmacytic Lymphoma About 1% of all NHLs will be lymphoplasmacytic lymphomas, which are indolent B-cell NHLs with lymphoplasmacytic differentiation, most commonly associated with a monoclonal IgM paraprotein. Nearly all patients will have stage IV disease at diagnosis with bone marrow involvement. Patients with high levels of circulating IgM paraproteins constitute a specific entity known as Waldenstrom macroglobulinemia and can have symptoms due to hyperviscosity as a result of the circulating IgM. Activating mutations in MYD88, an adaptor protein that is involved in signaling downstream of the Ig receptor leading to NFκB activation, is present in >90% of cases. Tumor biopsies are notable for proliferation of small lymphocytes, lymphoplasmacytic cells, and plasma cells, and malignant lymphocytes are positive for CD19, CD20, and surface IgM but generally negative for CD5 and CD10. Like the other indolent NHLs, treatment is indicated for disease that causes symptoms or interferes with organ function; hyperviscosity related to elevated serum IgM and paraneoplastic neuropathy are additional indications for therapy. Single-agent rituximab may be useful for low-volume disease, but can be associated with a transient rise in serum IgM concentrations that

can cause or exacerbate hyperviscosity. Chemoimmunotherapy with regimens like BR and rituximab, cyclophosphamide, and dexamethasone are active, as are myeloma therapies such as bortezomib. Given that 85% of IgM remains intravascular, acute relief of hyperviscosity symptoms can be obtained by plasmapheresis. For recurrent disease, one can often utilize agents that were previously used. For patients with more refractory LPL, the mTOR inhibitor everolimus and the oral BTK ibrutinib are active. Selected patients with relapsed disease are considered for high-dose therapy with ASCT or alloSCT. The results seen are similar to that of other indolent lymphomas.

Mantle Cell Lymphoma MCL comprises about 6% of NHLs. It is an intermediate grade lymphoma that like the indolent B-cell NHLs is not curable with conventional therapies, but like the aggressive lymphomas often requires more aggressive chemoimmunotherapy regimens with or without an autologous stem cell transplant to achieve a reasonable response duration. This therapy is not curative, however, and median survival with this disease is on the order of 5–10 years. An exception to this is a more indolent, SOX11 variant that often presents with circulating disease with splenomegaly but without significant lymphadenopathy and with a low Ki67 (<10%). This subset behaves more like the indolent B-cell NHLs and can be observed until treatment is indicated by symptoms or organ function impairment. Similarly, there is a blastic variant with a high Ki67 index that is associated with a poor prognosis and a median OS of only 18 months. For other patients, prognosis is best predicted by the biologic mantle cell prognostic index (MIPI), which factors in age, performance status, LDH, white blood cell count, and Ki67 expression to determine a risk group. This disease is more common in men, and the average age of diagnosis is 63. Over two-thirds of patients will have stage IV disease, mostly with bone marrow and peripheral blood involvement, at the time of diagnosis. Other common extranodal sites of involvement include the GI tract where diffuse lymphomatous polyposis may be seen.

The pathognomonic cytogentic finding in MCL is t(11;14), which brings the gene for the cell cycle control protein cyclin D1 under the control of the immunoglobulin heavy chain gene promoter on chromosome 14. This translocation is present in >90% of cases. The remaining cases usually overexpress cyclin D2, cyclin D3, or cyclin E. Tumor cells also are positive for B-cell markers CD19 and CD20, as well as CD5. They usually lack CD10 and CD23.

Therapies for MCL are evolving. Patients with localized disease might be treated with combination chemotherapy followed by radiotherapy; however, these patients are exceedingly rare. Similarly, patients with the indolent variant can be observed until disease progresses to cause symptoms or signs of organ function impairment. For the usual presentation with disseminated disease, standard lymphoma treatments like R-CHOP have been unsatisfactory, with the minority of patients achieving complete remission. The addition of high dose cytarabine to an R-CHOP-like backbone with or without consolidation autologous stem cell transplantation in first remission has improved progression-free survival, but it has not elicited cures in this disease. These include the Nordic regimens and R-HyperCVAD (rituximab, cyclophosphamide, vincristine, doxorubicin, dexamethasone, cytarabine, and methotrexate). BR has activity in this disease and is more effective and better tolerated than R-CHOP. Newer studies with short follow-up suggest that strategies that combine BR with cytarabine with or without autologous stem cell transplant may be effective and well tolerated. Maintenance rituximab, following a good response to induction chemotherapy or after autologous stem cell transplant, also improves outcomes over observation alone. For relapsed disease, the BTK inhibitor ibrutinib has single-agent activity with a response rate of almost 70% but a response duration of only 18 months. Drugs like lenalidomide, bortezomib, and temsirolimus can similarly induce transient partial responses. Appropriate patients who respond to salvage therapy should be considered for allogeneic stem cell transplant, which can lead to long-term disease-free survival in 30–50% of patients.

MATURE (PERIPHERAL) T-CELL DISORDERS

Mature T-cell disorders include cutaneous lymphomas, like mycosis fungoides, and the PTCLs, some of which are distinguished based on specific clinical presentations or contexts or by molecular or biologic features, but many of which fall into the category of PTCL not otherwise specified (NOS). T-cell NHLs are significantly more rare than the B-cell NHLs, and as such, our understanding of their biology is less advanced, and our therapies are less well developed. While some T-cell lymphomas, like mycosis fungoides, can behave indolently and some, like ALK-positive ALCL, can be cured with chemotherapy, the majority are associated with a poor prognosis. The advent of genomic technologies is enhancing our ability to understand the genetic and biologic basis of these neoplasms.

Mycosis Fungoides Mycosis fungoides is also known as cutaneous T-cell lymphoma. This lymphoma is more often seen by dermatologists than internists. The median age of onset is in the mid-fifties, and the disease is more common in males and in blacks.

Mycosis fungoides is an indolent lymphoma with patients often having several years of eczematous or dermatitic skin lesions before the diagnosis is finally established. The skin lesions progress from patch stage to plaque stage to cutaneous tumors. Early in the disease, biopsies are often difficult to interpret, and the diagnosis may only become apparent by observing the patient over time. Adenopathy may reflect involvement with mycosis fungoides or be read as dermatopathic change. In advanced stages, the lymphoma can spread to lymph nodes and visceral organs. Patients with this lymphoma may develop generalized erythroderma and circulating tumor cells, called *Sézary's syndrome*.

Rare patients with localized early-stage mycosis fungoides can be cured with radiotherapy, often total-skin electron beam irradiation. More advanced disease has been treated with topical glucocorticoids, topical nitrogen mustard, phototherapy, psoralen with ultraviolet A (PUVA), extracorporeal photopheresis, retinoids (bexarotene), electron beam radiation, interferon, antibodies, fusion toxins, histone deacetylase inhibitors, and systemic cytotoxic therapy. Unfortunately, these treatments are palliative.

Peripheral T-Cell Lymphoma, Not Otherwise Specified PTCLs include a number of entities, which constitute 15% of all NHLs in adults. PTCL, NOS, comprising 6% of all NHLs, is the term used for cases that are not other entities defined in the WHO classification. Named varieties include ALCL, angioimmunoblastic T-cell lymphoma (AITL), hepatosplenic T-cell lymphoma, enteropathy-associated T-cell lymphoma, and subcutaneous panniculitis T-cell lymphoma. PTCL NOS is a disease of older individuals, with a median age at presentation of 65, and the majority of patients will have advanced-stage disease at diagnosis, with involvement of the bone marrow, liver, spleen, and skin being common. Associated "B" symptoms and pruritis are also common. These lymphomas can be associated with a reactive eosinophilia as well as hemophagocytic syndrome. The IPI has been applied to PTCL NOS and provides some assessment of outcomes, but even the low-risk group has a median OS of just >2 years.

This diagnostic category is a collection of heterogeneous lymphomas that vary widely and lack typical findings of other specific PTCL subgroups. Because of this heterogeneity, histology, immunophenotype, and genetics are variable. Often lymph nodes are effaced by atypical lymphoid cells of various sizes, sometimes associated with vascular proliferation or an infiltrate of eosinophils and/or macrophages. As most of these lymphomas behave aggressively, note is often made of mitotic and apoptotic figures as well as geographic necrosis. The cells often are positive for CD3, and the majority of PTCL NOS is positive for CD4 rather than CD8, but some are negative for both markers. There can be loss of more mature T-cell markers like CD5 and CD7, and this is associated with a more aggressive course. There are some recurrent translocations, including t(7;14), t(11;14), inv(14), and t(14;14), all of which involve the TCR genes.

The most common primary therapy for PTCL NOS involves a CHOP-like chemotherapy backbone—either CHOP alone or CHOP in combination with etoposide, or CHOEP. The latter may provide the most benefit to younger patients and patients with more favorable disease risk factors. Autologous stem cell transplant has been investigated for patients in their first remission and does seem to improve PFS in certain contexts. Drugs like gemcitabine, bendamustine, and

pralatrexate have activity in relapsed disease, as do the histone deacetylase inhibitors romidepsin and belinostat. All of these agents are associated with transient responses in a minority of patients. Patients should be considered for clinical trials. For patients who do achieve remission, reduced intensity allogeneic stem cell transplantation can yield long-term non-relapse survival on the order of 40–50%.

Angioimmunoblastic T-Cell Lymphoma AITL constitutes about 20% of T-cell NHL and about 4% of all NHL diagnosed. Patients present with a variety of signs and symptoms, most often including lymphadenopathy, hepatosplenomegaly, B symptoms, rash, polyarthritis, and hemolytic anemia. Over 80% of patients have advanced stage disease at diagnosis, and bone marrow involvement is common. Polyclonal hypergammaglobulinemia is common, as are elevated LDH, eosinophilia, a positive Coombs test, and opportunistic infections.

On biopsy, lymph nodes are effaced by a polymorphous infiltrate of lymphoctyes, ranging in size and shape, and of immunoblasts. The neoplastic lymphocytes are positive for CD3 as well as CXCL13, PD-1, CD10, and BCL6, most closely resembling CD4-positive follicular helper T cells. There is an expanded follicular dendritic cell network surrounding tumor cells. Scattered immunoblasts are often EBV positive and may give rise to secondary EBV-positive B-cell lymphomas at a later time. Genetic analysis of this disease has revealed recurrent mutations in *TET2* (76%), *DNMT3* (33%), and *IDH2* (20%).

There is a subset of AITL that can remit with immunosuppression with agents like glucocorticoids or methotrexate. Most patients, however, will need combination chemotherapy with regimens like those used in PTCL NOS. Median response duration is short, median OS is only 15–36 months. Treatment of relapsed disease is similar to that of relapsed PTCL NOS.

Anaplastic Large Cell Lymphoma ALCL is the next most common T-cell lymphoma after AITL but is more common in children, accounting for up to 10% of pediatric lymphomas. Approximately 40–60% of cases with harbor t(2;5) which fuses a portion of the nucleolar protein nucleophosmin-1 (NPMI) gene to a part of the anaplastic lymphoma kinase (ALK) gene, the product of which has constitutive tyrosine kinase activity. These patients have a much more favorable prognosis compared to ALK-negative ALCL, akin to that of DLBCL. There is an additional, more indolent and favorable subtype that occurs in the breast tissue of patients with breast implants, and there is a cutaneous variant. In general, this is a disease that is more common in men. ALK-positive disease is a disease of younger patients with a median age at diagnosis of 34 years, whereas the median age at diagnosis of ALK negative patients is 58. With the exception of the cutaneous variant and the variant associated with breast implants, most patients present with rapidly growing lymphadenopathy with or without extranodal involvement; B symptoms are common.

Most cases of ALCL involve large atypical lymphocytes with a horseshoe-shaped nuclei with prominent nucleoli ("hallmark" cells). Tumor cells tend to be localized within the lymph node sinuses, and almost all are positive for CD30 but negative for CD15. A majority will also express CD3, CD25, CD43, and CD4. ALK rearranged ALCL can be diagnosed by FISH cytogenetics for t(2;5) or by immunohistochemical staining for ALK.

ALCL is generally treated with CHOP, although like PTCL NOS, CHOEP may benefit younger patients, particularly with ALK+ disease. Overall, ALCL has a better prognosis than PTCL, and this is particularly true for ALK-positive disease, which has an 8-year OS of 82 versus 49% for ALK-negative disease. Relapsed ALK-positive ALCL is treated similarly to relapsed DLBCL, with salvage combination chemotherapy to identify chemotherapy sensitivity followed by autologous stem cell transplant. For patients with chemoinsensitive diseaese or for ALK-negative disease, the conjugated anti-CD30 antibody to monomethyl aurostatin E (MMAE) brentuximab is highly active with a response rate of 86% and a complete response rate of 57%. It is currently being investigated in combination with cyclophosphamide, adriamycin, and prednisone for the primary treatment of disease. The ALK inhibitors, including crizotinib, are active in refractory ALK-positive ALCL with excellent outcomes.

Other PTCL Subtypes Enteropathy-associated T-cell lymphoma, hepatosplenic T-cell lymphoma, and subcutaneous panniculitis-like T-cell lymphoma are other less common PTCL subtypes. Enteropathy-type intestinal T-cell lymphoma is a rare disorder. Type I occurs in patients with a history of gluten-sensitive enteropathy and is associated with HLADQA1*0501, DQB1*0201; a gluten-free diet can prevent the development of this lymphoma. Type II is not associated with celiac disease and may be a separate disease entity. Patients are frequently cachectic and sometimes present with intestinal perforation. The prognosis is poor with a median survival of 10 months. Therapy is often with combination chemotherapy, including high-dose methotrexate, and autologous stem cell transplant in first remission. *Hepatosplenic γδ T-cell lymphoma* is a systemic illness that presents with sinusoidal infiltration of the liver, spleen, and bone marrow by malignant T cells. Tumor masses generally do not occur. The disease is associated with systemic symptoms and is often difficult to diagnose. Recurrent genetic events include isochromosome 7q and trisomy 8. Treatment outcome is poor, but regimens that include ifosphamide, like ifosphamide, carboplatin, etoposide (ICE) or ifosphamide, etoposide, cytarabine (IVAC), are associated with better outcomes in small series of patients. Responding patients should be considered for allogeneic stem cell transplantation. *Subcutaneous panniculitis-like T-cell lymphoma* is a rare disorder that is often confused with panniculitis. Patients present with multiple subcutaneous nodules, which progress and can ulcerate. There is a more indolent form that tends to express α/β TCRs and can be managed with immune suppression, whereas lymphomas that express γ/δ TCRs are more aggressive and are associated with a worse prognosis and coincident hemophagocytic syndrome. This is a disease of young men in their fifth and sixth decades of life. Patients with aggressive disease are managed with multiagent chemotherapy, and responding patients should be considered for allogeneic stem cell transplantation.

Adult T-Cell Leukemia/Lymphoma Adult T-cell leukemia/lymphoma (ATLL) is a disease that is most prevalent in Japan and the Caribbean basin. It is a neoplasm that is driven by HTLV-1, often contracted through the breast milk of infected mothers. The average age at diagnosis is 60, so there is a long latency between viral infection and viral transformation, and only 4% of infected patients will develop the disease. This suggests that HTLV-1 may not be sufficient to cause the malignant phenotype. There are four disease variants: acute (60% of patients), lymphomatous (20% of patients), chronic (15% of patients), and smoldering (5% of patients). Prognosis varies across these groups with with median survivals of 6 months, 10 months, 24 months, and not yet reached, respectively. Presentation depends on the subtype, but most commonly patients present with circulating disease and bone marrow involvement, hypercalcemia, lytic bone lesions, lymphadenopathy, heptosplenomegaly, skin lesions, and opportunistic infections.

The pathognomonic finding is the malignant "flower cell" that is positive for CD4 and CD25, as well as CD2, CD3, and CD5 but lacking CD7 **(Fig. 104-7).** Combination chemotherapy is generally used,

FIGURE 104-7 Adult T-cell leukemia/lymphoma. Peripheral blood smear showing leukemia cells with typical "flower-shaped" nucleus.

but for patients fortunate enough to respond, response durations are very short. Other active agents in this disease include the antiretroviral agent zidovudine, interferon α, and arsenic. In any patients who do respond to therapy, allogeneic stem cell transplant should be considered.

Extranodal NK/T-Cell Lymphoma, Nasal Type Extranodal NK/T-cell lymphoma, nasal type, is a lymphoma that is associated with EBV infection in nearly all cases and more common in Asia and native populations in Peru. It usually presents with a mass and obstructive symptoms in the upper aerodigestive tract with occasional extranodal sites, but over two-thirds of patients will have localized disease. It is more common in men, and the median age at diagnosis is 60. This disease has its own prognostic score, which takes into account the presence or absence of B symptoms, disease stage, whether LDH is elevated, and whether there is lymph node involvement. EBV viral load at diagnosis and end of therapy is also predictive.

Treatment for early stage disease is usually with combined modality therapy of chemotherapy (commonly using etoposide, ifosfamide, cisplating, and dexamethasone) and intensity-modulated radiation therapy (50–55 Gy), and patients with localized disease involving the nasal passages do quite well, with 3-year OS of ~85%. Patients with more advanced stage disease do poorly with disseminated extranodal relapse occurring frequently, and median OS is only 4.3 months. The most commonly used regimen for the regimens is the SMILE regimen (dexamethasone, methotrexate, ifosfamide, L-asparaginase, and etoposide).

105 Hodgkin's Lymphoma

Caron A. Jacobson, Dan L. Longo

Hodgkin's lymphoma (HL) is a malignancy of mature B lymphocytes. It represents ~10% of all lymphomas diagnosed each year. The majority of HL diagnoses are classical HL (cHL), but there is a second subtype of HL, nodular lymphocyte predominant HL (NLPHL). While this diagnosis does resemble cHL morphologically in certain respects, there is some evidence that it is more related to the indolent B-cell NHLs biologically than it is to cHL. The majority of this chapter will be specific to cHL, with a discussion of NLPHL at the end.

Classical HL is one of the success stories of modern oncology. Until the advent of extended-field radiotherapy in the mid-twentieth century, it was a highly fatal disease of young people. Radiation therapy cured some patients with early stage disease, and the introduction of multi-agent chemotherapy in the 1970s resulted in further improved cure rates, both for patients with early and advanced stage disease. Cure rates now are >85%. The new challenge in the treatment of HL is late therapy-related toxicity, including a high rate of secondary malignancies and cardiovascular disease. Current clinical trials are aimed at minimizing this risk while preserving efficacy.

EPIDEMIOLOGY AND ETIOLOGY

HL is of B-cell origin. The incidence of HL appears fairly stable, with 8260 new cases diagnosed in 2017 in the United States. HL is more common in whites than in blacks and more common in males than in females. A bimodal distribution of age at diagnosis has been observed, with one peak incidence occurring in patients in their twenties and the other in those in their eighties. Some of the late age peak may be attributed to confusion among entities with similar appearance such as anaplastic large cell lymphoma and T-cell/histiocyte–rich B-cell lymphoma. There are four distinct subtypes of classical Hodgkin's lymphoma (cHL) that are differentiated based on their histopathologic features **(Table 105-1)**: nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted. Patients in the younger age groups diagnosed in the United States largely have the nodular sclerosing subtype of HL. Elderly patients, patients infected with HIV, and patients in Third World countries more commonly have mixed-cellularity HL or lymphocyte-depleted HL. Together, nodular sclerosis and mixed cellularity types account for nearly 95% of cases. Infection by HIV is a risk factor for developing HL. In addition, an association between infection by Epstein-Barr virus (EBV) and HL has been suggested. A monoclonal or oligoclonal proliferation of EBV-infected cells in 20–40% of the patients with HL has led to proposals for this virus having an etiologic role in HL. However, the matter is not settled definitively. Viral oncogenesis appears to play a greater role in HIV-related cHL: EBV can be detected in nearly all cases of HIV-associated cHL, compared to only one-third of cases of non-HIV-associated cHL. Reed-Sternberg (HRS) cells are the malignant cells in HL. HRS cells in HIV-associated cHL express the EBV-transforming protein latent membrane protein 1 (LMP-1), and the EBV genomes from multiple disease sites in the same HIV-associated cHL patient are episomal and clonal, suggesting that EBV is directly involved in early lymphomagenesis.

Histologically, the HRS cell is diagnostic of cHL **(Fig. 105-1)**. These cells are large cells with abundant cytoplasm with bilobed and/or multiple nuclei. By immunohistochemistry they are often PAX-5 positive but have low to no expression of other B-cell antigens like CD19 and CD20. They express CD15 and CD30 in 85 and 100% of cases, respectively. These cells, though, comprise <1% of the tumor cellularity, with the majority of the tumor made up of a surrounding inflammatory infiltrate of polyclonal lymphocytes, eosinophils, neutrophils, macrophages, plasma cells, fibroblasts, and collagen. The HRS cell interacts with its microenvironment via cell-cell contact and elaboration of growth factors and cytokines, which results in a surrounding cellular milieu that protects it from host immune attack. The surrounding environmental cells likewise support the HRS cells via cell-cell signaling and cytokine production which provides signals that promote proliferation and survival of the HRS cell itself. Interestingly, 97% of HRS cells in cHL harbor genetic aberrations in the PD-L1 locus on chromosome 9p24.1, resulting in overexpression of PD-L1, the ligand for

the inhibitory PD-1 receptor on immune cells. This is one mechanism whereby the HRS cell may be able to avoid immune destruction in its inflammatory microenvironment and may contribute to the generalized immune suppression in HL patients.

APPROACH TO THE PATIENT

Classic Hodgkin's Lymphoma

Most patients with cHL present with palpable lymphadenopathy that is nontender; in most patients, these lymph nodes are in the neck, supraclavicular area, and axilla. More than half of the patients will have mediastinal adenopathy at diagnosis, and this is sometimes the initial manifestation. Subdiaphragmatic presentation of cHL is unusual and more common in older males. One-third of patients present with fevers, night sweats, and/or weight loss, or "B" symptoms. Occasionally, HL can present as a fever of unknown origin. This is more common in older patients who are found to have mixed-cellularity HL in an abdominal site. Rarely, the fevers persist for days to weeks, followed by afebrile intervals and then recurrence of the fever. This pattern is known as *Pel-Ebstein* fever. HL can occasionally present with unusual manifestations. These include severe and unexplained itching, cutaneous disorders such as erythema nodosum and ichthyosiform atrophy, paraneoplastic cerebellar degeneration and other distant effects on the CNS, nephrotic syndrome, immune hemolytic anemia and thrombocytopenia, hypercalcemia, and pain in lymph nodes on alcohol ingestion.

Evaluation of patients with HL will typically begin with a careful history and physical examination. Patients should be asked about the presence or absence of "B" symptoms. Comorbid diagnoses that may impact therapy should be reviewed, including a history of pulmonary disease and congestive heart failure given the use of chemotherapy drugs that can cause both lung and heart toxicity. A physical examination should pay attention to the peripherally accessible sites of lymph nodes and to the liver and spleen size. Laboratory evaluation should include a complete blood count with differential; erythrocyte sedimentation rate; chemistry studies reflecting major organ function including serum albumin; and HIV and hepatitis virus testing. A PET/CT scan is used for staging, and is more accurate than a bone marrow biopsy for evaluation of bone marrow involvement as the bone marrow involvement in cHL tends to be patchy and therefore potentially missed on a unilateral bone marrow biopsy. The initial evaluation of a patient with HL or NHL is similar. In both situations, the determination of an accurate anatomic stage is an important part of the evaluation. Staging is done using the Ann Arbor staging system **(Table 105-2)**.

TABLE 105-2 The Ann Arbor Staging System for Hodgkin's Lymphoma

STAGE	DEFINITION
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar lymph nodes should be considered "lateralized" and, when involved on both sides, constitute stage II disease)
III	Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm
III_1	Subdiaphragmatic involvement limited to spleen, splenic hilar nodes, celiac nodes, or portal nodes
III_2	Subdiaphragmatic involvement includes paraaortic, iliac, or mesenteric nodes plus structures in III_1
IV	Involvement of extranodal site(s) beyond that designated as "E"
	More than one extranodal deposit at any location
	Any involvement of liver or bone marrow
A	No symptoms
B	Unexplained weight loss of >10% of the body weight during the 6 months before staging investigation
	Unexplained, persistent, or recurrent fever with temperatures >38°C during the previous month
	Recurrent drenching night sweats during the previous month
E	Localized, solitary involvement of extralymphatic tissue, excluding liver and bone marrow

The diagnosis of HL is established by review of an adequate biopsy specimen by an expert hematopathologist. HL is a tumor characterized by rare neoplastic cells of B-cell origin (immunoglobulin genes are rearranged but not expressed) in a tumor mass that is largely polyclonal inflammatory infiltrate, probably a reaction to cytokines produced by the tumor cells. The differential diagnosis of a lymph node biopsy suspicious for HL includes inflammatory processes, mononucleosis, NHL, phenytoin-induced adenopathy, and nonlymphomatous malignancies.

Staging for cHL is anatomically based given the propensity of the disease to march from one lymph node group to the next group, often contiguous to the first. Staging is important for selecting therapy of appropriate intensity, but the outcome of optimal therapy for all the stages is excellent. Patients are stratified based on whether they have early stage, stage I or II, or advanced stage, stage III or IV, disease. Patients with early stage disease have a better prognosis overall but are further classified as favorable or unfavorable based on a variety of factors. These factors vary from study to study but include bulky disease, number of lymph node areas involved, an elevated ESR (>30 if B symptoms are present; >50 if B symptoms are absent), and age. Prognosis in advanced stage disease is best predicted by the International Prognostic Score (IPS), which ascribes a point for male sex, older age (>45 years), stage IV disease, serum albumin <4 g/dL, hemoglobin <10.5 g/dL, white blood cell count ≥15,000/μL, and a lymphocyte count <600/μL and/or <8% of white blood cell count. Five-year progression-free survival ranges from 88% for patients with no risk factors, to 62% for patients with four or more factors, but very few patients have multiple risk factors.

TREATMENT

Classic Hodgkin's Lymphoma

The overwhelming majority of patients with HL will be cured with either chemotherapy alone, or a combination of chemotherapy and radiation therapy. It has long been appreciated that patients with advanced stage disease do not benefit from the addition of radiation

therapy to chemotherapy and are thus treated with chemotherapy alone. For early stage disease, however, treatment with combined modality therapy has been associated with a small decrease in risk of relapse but with an increased risk of late toxicity including secondary malignancies, thyroid disease, and premature cardiovascular disease and stroke resulting in minimal or no improvement in long-term survival. Much of this risk can be attributed to radiation therapy. Thus, investigation into the treatment of early stage HL at present is aimed at trying to maximize treatment outcome without using radiotherapy. This is an area of controversy in the treatment of HL.

EARLY STAGE DISEASE

The most common chemotherapy regimen used to treat HL in the United States is ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine). This regimen is given every other week, with each cycle including two treatments. In patients with low-risk, or favorable disease, the use of 4–6 cycles of ABVD alone, without radiation therapy, results in progression-free and overall survivals of 88–92% and 97–100% at 5–7 years. This may be associated with a slightly increased risk of relapse when compared with abbreviated chemotherapy (ABVD x4 cycles) followed by involved field radiation therapy (30 Gy), but with no difference in overall survival owing to the excellent salvage strategies used for relapsed HL and to the late toxicities seen following radiation therapy to the chest. German studies have examined a very abbreviated chemotherapy regimen (ABVD x2 cycles) and low-dose radiation (20 Gy) for particularly good risk disease with two or fewer lymph node areas involved and found that this was equally effective to standard combined modality therapy of ABVD x4 cycles and 30 Gy of radiation, though long-term follow-up is not yet available to assess the impact of the lower radiotherapy dose on late toxicities. Finally, the use of an early interim PET/CT scan can aid decisions on the duration and extent of therapy. In one study, a negative PET/CT scan after 3 cycles of ABVD predicted for excellent outcomes with no additional therapy; in another, a negative PET/CT scan after 2 cycles of ABVD predicted for good outcomes with 2 additional cycles of ABVD alone, without radiation therapy.

For unfavorable risk disease, the omission of radiation therapy following chemotherapy is associated with a more significant increased risk of relapse compared to favorable risk disease, but again with no change in overall survival. For these patients, treatment options would include ABVD x4 cycles followed by involved field radiation therapy or ABVD alone for 6 cycles. Treatment decisions are often based on the extent of the radiation field and the unfavorable risk factor, with patients with non-bulky disease being candidates for chemotherapy alone if radiation would be contraindicated for another reason. Combined modality therapy has typically been used for patients with bulky disease, although patients with bulky disease who have a negative PET/CT scan after chemotherapy may not benefit from additional radiation therapy.

Alternative chemotherapy regimens to ABVD have been developed and include the Stanford V regimen and escalated BEACOPP. Neither of these regimens has resulted in improved outcomes in patients with early stage disease.

ADVANCED STAGE DISEASE

Patients with advanced stage disease do not benefit from the addition of radiation therapy after a complete response to chemotherapy alone and should be treated with chemotherapy alone. The most common regimen used in the United States is ABVD x6 cycles. Again, Stanford V and escalated BEACOPP have been evaluated in advanced stage disease and are not associated with an improvement in overall survival but are associated with increased toxicity. The small fraction of patients who do not achieve complete remission with chemotherapy alone (partial responders with persistent PET scan positivity account for <10% of patients) may benefit from the addition of involved field radiotherapy.

Newer drugs have been developed for the treatment of relapsed HL (see "Relapsed Disease," below). These include the antibody drug conjugate brentuximab, which is an antibody against CD30 conjugated to the microtubule inhibitor MMAE. This drug has been combined with adriamycin, bleomycin, and dacarbazine in early phase studies for advanced stage HL with favorable efficacy compared to historical controls. We await the data from the randomized trial of AVD+brentuximab compared to ABVD. Drugs that target the PD-1/PD-L1 axis have been developed in an attempt to boost the host immune recognition of tumors. This was particularly attractive in HL given the overexpression of PD-L1 on the HRS cell surface. In the setting of relapsed disease, these drugs, which include pembrolizumab and nivolumab, have very high response rates and are associated with durable responses. These are now being tested in conjunction with chemotherapy both as salvage therapy for relapsed disease and in previously untreated patients.

RELAPSED DISEASE

Patients who relapse after primary therapy of Hodgkin's lymphoma can frequently still be cured. Patients who relapse after an effective chemotherapy regimen are usually not curable with subsequent chemotherapy administered at standard doses. Alternative salvage chemotherapy administered at standard doses, then, is given in order to document sensitivity to chemotherapy and to achieve maximum reduction of tumor mass. For patients who respond completely or nearly so, autologous bone marrow transplantation can cure over half of patients. Standard salvage chemotherapy regimens include ICE (ifosfamide, carboplatin, etoposide) or GND (gemcitabine, navelbine, doxil). For patients with early stage disease who do not respond sufficiently to salvage chemotherapy, radiation therapy can be very effective to achieve a remission; whether to consolidate such a remission with an autologous stem cell transplant is debated. For patients with advanced stage disease in whom salvage chemotherapy fails, the antibody drug conjugate brentuximab vedotin, a CD30-directed antibody linked to the microtubule toxin MMAE, is active and can be tried as a bridge to allogeneic transplant. This immunotoxin is also being combined with chemotherapy for use in both the first-line salvage setting and for the upfront treatment of both early- and advanced-stage disease. The anti-PD-1 immune checkpoint inhibitors, nivolumab and pembrolizumab, have efficacy in relapsed HL, and many responses are durable.

SURVIVORSHIP

Because of the very high cure rate in patients with HL, long-term complications have become a major focus for clinical research. In fact, in some series of patients with early-stage disease, more patients died from late complications of therapy than from HL itself. This is particularly true in patients with localized disease. The most serious late side effects include second malignancies and cardiac injury. Patients are at risk for the development of acute leukemia in the first 10 years after treatment with combination chemotherapy regimens that contain alkylating agents plus radiation therapy. The risk for development of acute leukemia is greater after MOPP-like and BEACOPP-like regimens than with ABVD. The risk of development of acute leukemia after treatment for HL is also related to the number of exposures to potentially leukemogenic agents (i.e., multiple treatments after relapse) and the age of the patient being treated, with those aged >60 years at particularly high risk. The development of carcinomas as a complication of treatment for HL is a major problem. These tumors usually occur ≥10 years after treatment and are associated with use of radiotherapy. For this reason, young women treated with thoracic radiotherapy for HL should institute screening mammograms 5–10 years after treatment, and all patients who receive thoracic radiotherapy for HL should be discouraged from smoking. Mediastinal radiation also accelerates coronary artery disease, and patients should be encouraged to minimize risk factors for coronary artery disease such as smoking and elevated cholesterol levels. Cervical radiation therapy increases the risk of carotid atherosclerosis and stroke and thyroid disease, including cancer.

A number of other late side effects from the treatment of HL are well known. Patients who receive thoracic radiotherapy are at very high risk for the eventual development of hypothyroidism and should be observed for this complication; intermittent measurement of thyrotropin should be made to identify the condition before it becomes symptomatic. Lhermitte's syndrome occurs in ~15% of patients who receive thoracic radiotherapy. This syndrome is manifested by an "electric shock" sensation into the lower extremities on flexion of the neck. Because of the young age at which HL is often diagnosed, infertility is a concern for patients undergoing treatment for HL. Chemotherapy regimens containing alkylating agents induce permanent infertility in nearly all men. The risk of permanent infertility in women treated with alkylating agent-containing chemotherapy is age-related, with younger women more likely to recover fertility. Infertility is very rare after treatment with ABVD.

NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

NLPHL is now recognized as an entity distinct from cHL. Previous classification systems recognized that biopsies from a small subset of patients diagnosed as having HL contained a predominance of small lymphocytes and rare Reed-Sternberg-like cells; tumors have a nodular growth pattern and a clinical course that varied from that of patients with cHL. This is an unusual clinical entity and represents <5% of cases of HL and defines NLPHL.

NLPHL has a number of characteristics that suggest its relationship to NHL, rather than cHL, however. The HRS-like cell, or L&H (lymphocyte and histiocyte) or "popcorn" cell, is a clonal proliferation of B cells that are positive for B cell markers CD45, CD79a, CD20, CD19, and BCL2. They do not express two markers normally found on HRS cells, CD30 and CD15. This lymphoma tends to have a chronic, relapsing course and sometimes transforms to diffuse large B-cell lymphoma, including a specific subtype of diffuse large B-cell lymphoma known as T cell/histiocyte-rich B-cell lymphoma, which shares an immunophenotype with the L&H cell. This natural history most closely resembles that of the indolent B cell NHLs outlined in **Chaps. 104 and 106.**.

Patients with NLPHL are more commonly male (75%). Like cHL, the age distribution of patients with this disease has two peaks, but unlike cHL these peaks include children and adults ages 30–40 years, respectively. The majority of patients diagnosed have stage I or II disease (75%), with a minority having advanced stage disease at diagnosis. B symptoms are uncommon.

Patients with early stage disease at diagnosis should be treated with definitive radiotherapy. This is associated with a 15-year non-relapse survival of 82%. The treatment of patients with advanced stage NLPHL is controversial. Some clinicians favor no treatment of asymptomatic disease and merely close follow-up, akin to the indolent B cell NHLs. For patients who need therapy due to symptoms or signs of organ function impairment, both cHL regimens and B-cell NHL regimens have been used, including ABVD and R-CHOP. A single institution experience with R-CHOP resulted in a 100% response rate in a small group of patients without a single relapse with 42 months follow-up. Although this is short follow-up for an indolent disease, some believe R-CHOP may be curative in this disease and advocate treating with advanced stage disease at diagnosis, regardless of symptoms or organ function.

106 Less Common Hematologic Malignancies

Ayalew Tefferi, Dan L. Longo

The most common lymphoid malignancies are discussed in **Chaps. 102, 103, 104, 105 and 107**, myeloid leukemias in **Chaps. 100 and 101**, myelodysplastic syndromes (MDS) in **Chap. 98**, and myeloproliferative syndromes in **Chap. 99**. This chapter will focus on the more unusual forms of hematologic malignancy. The diseases discussed here are listed in **Table 106-1**. Each of these entities accounts for <1% of hematologic neoplasms.

TABLE 106-1 Unusual Lymphoid and Myeloid Malignancies

Lymphoid
Mature B-cell neoplasms
B-cell prolymphocytic leukemia
Splenic marginal zone lymphoma
Hairy cell leukemia
Nodal marginal zone B-cell lymphoma
Mediastinal large B-cell lymphoma
Intravascular large B-cell lymphoma
Primary effusion lymphoma
Lymphomatoid granulomatosis
Mature T-cell and natural killer (NK) cell neoplasms
T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Aggressive NK cell leukemia
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-type T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Blastic NK cell lymphoma
Primary cutaneous CD30+ T-cell lymphoma
Angioimmunoblastic T-cell lymphoma
Myeloid
Chronic neutrophilic leukemia
Chronic eosinophilic leukemia/hypereosinophilic syndrome
Histiocytic and Dendritic Cell Neoplasms
Histiocytic sarcoma
Langerhans cell histiocytosis
Langerhans cell sarcoma
Interdigitating dendritic cell sarcoma
Follicular dendritic cell sarcoma
Mast Cells
Mastocytosis
Cutaneous mastocytosis
Systemic mastocytosis
Mast cell sarcoma
Extracutaneous mastocytoma

RARE LYMPHOID MALIGNANCIES

All the lymphoid tumors discussed here are mature B-cell or T-cell natural killer (NK) cell neoplasms.

MATURE B-CELL NEOPLASMS

B-Cell Prolymphocytic Leukemia (B-PLL) This is a malignancy of medium-sized (about twice the size of a normal small lymphocyte), round lymphocytes with a prominent nucleolus and light blue cytoplasm on Wright's stain. It dominantly affects the blood, bone marrow (BM), and spleen and usually does not cause adenopathy. The median age of affected patients is 70 years, and men are more often affected than women (male-to-female ratio is 1.6). This entity is distinct from chronic lymphoid leukemia (CLL) and does not develop as a consequence of that disease.

Clinical presentation is generally from symptoms of splenomegaly or incidental detection of an elevated white blood cell (WBC) count. The clinical course can be rapid. The cells express surface IgM (with or without IgD) and typical B-cell markers (CD19, CD20, CD22). CD23 is absent, and about one-third of cases express CD5. The CD5 expression along with the presence of the t(11;14) translocation in 20% of cases leads to confusion in distinguishing B-PLL from the leukemic form of mantle cell lymphoma. No reliable criteria for the distinction have emerged and gene expression studies suggest a close relationship between mantle cell lymphoma and B-PLL and significant differences with CLL. About half of patients have mutation or loss of p53, and deletions have been noted in 11q23 and 13q14. Nucleoside analogues like fludarabine and cladribine and combination chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]) have produced responses. CHOP plus rituximab may be more effective than CHOP alone, but the disease is sufficiently rare that large series have not been reported. Splenectomy can produce palliation of symptoms but appears to have little or no impact on the course of the disease. BM transplantation may be curative. Imatinib may also have activity.

Splenic Marginal Zone Lymphoma (SMZL) This tumor of mainly small lymphocytes originates in the marginal zone of the spleen white pulp, grows to efface the germinal centers and mantle, and invades the red pulp. Splenic hilar nodes, BM, and peripheral blood (PB) may be involved. The circulating tumor cells have short surface villi and are called villous lymphocytes. Table 106-2 shows differences in tumor cells of a number of neoplasms of small lymphocytes that aid in the differential diagnosis. SMZL cells express surface immunoglobulin and CD20, but are negative for CD5, CD10, CD43, and CD103. Lack of CD5 distinguishes SMZL from CLL, and lack of CD103 separates SMZL from hairy cell leukemia.

The median age of patients with SMZL is mid-fifties, and men and women are equally represented. Patients present with incidental or symptomatic splenomegaly or incidental detection of lymphocytosis in the PB with villous lymphocytes. Autoimmune anemia or thrombocytopenia may be present. The immunoglobulin produced by these cells contains somatic mutations that reflect transit through a germinal center, and ongoing mutations suggest that the mutation machinery has remained active. About 40% of patients have either deletions or translocations involving 7q21, the site of the *FLNC* gene (filamin Cγ, involved in cross-linking actin filaments in the cytoplasm). *NOTCH2* mutations are seen in 25% of patients. Chromosome 8p deletions may also be noted. The genetic lesions typically found in extranodal marginal zone lymphomas (e.g., trisomy 3 and t[11;18]) are uncommon in SMZL.

The clinical course of disease is generally indolent with median survivals exceeding 10 years. Patients with elevated lactate dehydrogenase (LDH) levels, anemia, and hypoalbuminemia generally have a poorer prognosis. Long remissions can be seen after splenectomy. Rituximab is also active. A small fraction of patients undergo histologic progression to diffuse large B-cell lymphoma with a concomitant change to a more aggressive natural history. Experience with combination chemotherapy in SMZL is limited.

Hairy Cell Leukemia Hairy cell leukemia is a tumor of small lymphocytes with oval nuclei, abundant cytoplasm, and distinctive membrane projections (hairy cells). Patients have splenomegaly and diffuse BM involvement. While some circulating cells are noted, the clinical picture is dominated by symptoms from the enlarged spleen and pancytopenia. The mechanism of the pancytopenia is not completely clear and may be mediated by both inhibitory cytokines and marrow replacement. The marrow has an increased level of reticulin fibers; indeed, hairy cell leukemia is a common cause of inability to aspirate BM or so-called "dry tap" (Table 106-3). Monocytopenia is profound and may explain a predisposition to atypical mycobacterial infection that is observed clinically. The tumor cells have strong expression of CD22, CD25, and CD103; soluble CD25 level in serum is an excellent tumor marker for disease activity. The cells also express tartrate-resistant acid phosphatase. The immunoglobulin genes are rearranged and mutated, indicating the influence of a germinal center. No specific cytogenetic abnormality has been found, but most cases contain the activating *BRAF* mutation V600E.

The median age of affected patients is mid-fifties, and the male-to-female ratio is 5:1. Treatment options are numerous. Splenectomy is often associated with prolonged remission. Nucleosides including cladribine and deoxycoformycin are highly active but are also associated with further immunosuppression and can increase the risk of certain opportunistic infections. However, after brief courses of these agents, patients usually obtain very durable remissions during which immune function spontaneously recovers. Interferon α is also an effective therapy but is not as effective as nucleosides. Chemotherapy-refractory patients have responded to vemurafenib, a BRAF inhibitor. It is not yet clear if vemurafenib can induce long-term remissions without continuous treatment.

Nodal Marginal Zone B-Cell Lymphoma This rare node-based disease bears an uncertain relationship with extranodal marginal zone lymphomas, which are often mucosa-associated and are called mucosa-associated lymphoid tissue (MALT) lymphomas, and SMZLs. Patients may have localized or generalized adenopathy. The neoplastic cell is a marginal zone B cell with monocytoid features and has been called monocytoid B-cell lymphoma in the past. Up to one-third of the patients may have extranodal involvement, and involvement of the lymph nodes can be secondary to the spread of a mucosal primary lesion. In authentic nodal primaries, the cytogenetic abnormalities

TABLE 106-3 Differential Diagnosis of "Dry Tap"—Inability to Aspirate Bone Marrow

Dry taps occur in about 4% of attempts and are associated with:	
Metastatic carcinoma infiltration	17%
Chronic myeloid leukemia	15%
Myelofibrosis	14%
Hairy cell leukemia	10%
Acute leukemia	10%
Lymphomas, Hodgkin's disease	9%
Normal marrow	Rare

associated with MALT lymphomas (trisomy 3 and t[11;18]) are very rare. The clinical course is indolent. Patients often respond to combination chemotherapy, although remissions have not been durable. Few patients have received CHOP plus rituximab, which is likely to be an effective approach to management.

Mediastinal (Thymic) Large B-Cell Lymphoma This entity was originally considered a subset of diffuse large B-cell lymphoma; however, additional study has identified it as a distinct entity with its own characteristic clinical, genetic, and immunophenotypic features. This is a disease that can be bulky in size but usually remains confined to the mediastinum. It can be locally aggressive, including progressing to produce a superior vena cava obstruction syndrome or pericardial effusion. About one-third of patients develop pleural effusions, and 5–10% can disseminate widely to kidney, adrenal, liver, skin, and even brain. The disease affects women more often than men (male-to-female ratio is 1:2–3), and the median age is 35–40 years.

The tumor is composed of sheets of large cells with abundant cytoplasm accompanied by variable, but often abundant, fibrosis. It is distinguished from nodular sclerosing Hodgkin's disease by the paucity of normal lymphoid cells and the absence of lacunar variants of Reed-Sternberg cells. However, more than one-third of the genes that are expressed to a greater extent in primary mediastinal large B-cell lymphoma than in usual diffuse large B-cell lymphoma are also overexpressed in Hodgkin's disease, suggesting a possible pathogenetic relationship between the two entities that affect the same anatomic site. Tumor cells may overexpress *MAL*. The genome of tumor cells is characterized by frequent chromosomal gains and losses. The tumor cells in mediastinal large B-cell lymphoma express CD20, but surface immunoglobulin and HLA class I and class II molecules may be absent or incompletely expressed. Expression of lower levels of class II HLA identifies a subset with poorer prognosis. The cells are CD5 and CD10 negative but may show light staining with anti-CD30. The cells are CD45 positive, unlike cells of classical Hodgkin's disease.

Methotrexate, leucovorin, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin (MACOP-B) and rituximab plus CHOP are effective treatments, achieving 5-year survival of 75–87%. Dose-adjusted therapy with prednisone, etoposide, vincristine, cyclophosphamide, and doxorubicin (EPOCH) plus rituximab has produced 5-year survival of 97%. A role for mediastinal radiation therapy has not been definitively demonstrated, but it is frequently used, especially in patients whose mediastinal area remains positron emission tomography–avid after 4–6 cycles of chemotherapy.

Intravascular Large B-Cell Lymphoma This is an extremely rare form of diffuse large B-cell lymphoma characterized by the presence of lymphoma in the lumen of small vessels, particularly capillaries. It is also known as malignant angioendotheliomatosis or angiotropic large cell lymphoma. It is sufficiently rare that no consistent picture has emerged to define a clinical syndrome or its epidemiologic and genetic features. It is thought to remain inside vessels because of a defect in adhesion molecules and homing mechanisms, an idea supported by scant data suggesting absence of expression of β-1 integrin and ICAM-1. Patients commonly present with symptoms of small-vessel occlusion, skin lesions, or neurologic symptoms. The tumor cell clusters can promote thrombus formation. In general, the clinical course is aggressive and the disease is poorly responsive to therapy. Often a diagnosis is not made until very late in the course of the disease.

Primary Effusion Lymphoma This entity is another variant of diffuse large B-cell lymphoma that presents with pleural effusions, usually without apparent tumor mass lesions. It is most common in the setting of immune deficiency disease, especially AIDS, and is caused by human herpes virus 8 (HHV-8)/Kaposi's sarcoma herpes virus (KSHV). It is also known as *body cavity–based lymphoma*. Some patients have been previously diagnosed with Kaposi's sarcoma. It can also occur in the absence of immunodeficiency in elderly men of Mediterranean heritage, similar to Kaposi's sarcoma but even less common.

The malignant effusions contain cells positive for HHV-8/KSHV, and many are also co-infected with Epstein-Barr virus. The cells are large with large nuclei and prominent nucleoli that can be confused with Reed-Sternberg cells. The cells express CD20 and CD79a (immunoglobulin-signaling molecule), although they often do not express immunoglobulin. Some cases aberrantly express T-cell markers such as CD3 or rearranged T-cell receptor genes. No characteristic genetic lesions have been reported, but gains in chromosome 12 and X material has been seen, similar to other HIV-associated lymphomas. The clinical course is generally characterized by rapid progression and death within 6 months. CHOP plus lenalidomide or bortezomib may produce responses. HAART therapy for HIV should be maintained during treatment.

Lymphomatoid Granulomatosis This is an angiocentric, angiodestructive lymphoproliferative disease comprised by neoplastic Epstein-Barr virus–infected monoclonal B cells accompanied and outnumbered by a polyclonal reactive T-cell infiltrate. The disease is graded based on histologic features such as cell number and atypia in the B cells. It is most often confused with extranodal NK/T-cell lymphoma, nasal type, which can also be angiodestructive and is Epstein-Barr virus–related. The disease usually presents in adults (males > females) as a pulmonary infiltrate. Involvement is often entirely extranodal and can include kidney (32%), liver (29%), skin (25%), and brain (25%). The disease often but not always occurs in the setting of immune deficiency.

The disease can be remitting and relapsing in nature or can be rapidly progressive. The course is usually predicted by the histologic grade. The disease is highly responsive to combination chemotherapy and is curable in most cases. Some investigators have claimed that low-grade disease (grade I and II) can be treated with interferon α.

MATURE T-CELL AND NK CELL NEOPLASMS

T-Cell Prolymphocytic Leukemia This is an aggressive leukemia of medium-sized prolymphocytes involving the blood, marrow, nodes, liver, spleen, and skin. It accounts for 1–2% of all small lymphocytic leukemias. Most patients present with elevated WBC count (often >100,000/μL), hepatosplenomegaly, and adenopathy. Skin involvement occurs in 20%. The diagnosis is made from PB smear, which shows cells about 25% larger than those in small lymphocytes, with cytoplasmic blebs and nuclei that may be indented. The cells express T-cell markers like CD2, CD3, and CD7; two-thirds of patients have cells that are CD4+ and CD8–, and 25% have cells that are CD4+ and CD8+. T-cell receptor β chains are clonally rearranged. In 80% of patients, inversion of chromosome 14 occurs between q11 and q32. Ten percent have t(14;14) translocations that bring the T-cell receptor alpha/beta gene locus into juxtaposition with oncogenes *TCL1* and *TCL1b* at 14q32.1. Chromosome 8 abnormalities are also common. Deletions in the *ATM* gene are also noted. Activating *JAK3* mutations have also been reported.

The course of the disease is generally rapid, with median survival of about 12 months. Responses have been seen with the anti-CD52 antibody, alemtuzumab, nucleoside analogs, and CHOP chemotherapy. Histone deacetylase inhibitors like vorinostat and romidepsin may also have activity. Small numbers of patients with T-cell prolymphocytic leukemia have also been treated with high-dose therapy and allogeneic BM transplantation after remission has been achieved with conventional-dose therapy.

T-Cell Large Granular Lymphocytic Leukemia T-cell large granular lymphocytic leukemia (LGL leukemia) is characterized by increases in the number of LGLs in the PB (2000–20,000/μL) often accompanied by severe neutropenia, with or without concomitant anemia. Patients may have splenomegaly and frequently have evidence of systemic autoimmune disease, including rheumatoid arthritis, hypergammaglobulinemia, autoantibodies, and circulating immune complexes. BM involvement is mainly interstitial in pattern, with fewer than 50% lymphocytes on differential count. Usually the cells express CD3, T-cell receptors, and CD8; NK-like variants may be CD3–. The leukemic cells often express Fas and Fas ligand.

The course of the disease is generally indolent and dominated by the neutropenia. Paradoxically, immunosuppressive therapy with cyclosporine, methotrexate, or cyclophosphamide plus glucocorticoids can produce an increase in granulocyte counts. Nucleosides have been used anecdotally. Occasionally the disease can accelerate to a more aggressive clinical course.

Aggressive NK Cell Leukemia NK neoplasms are very rare, and they may follow a range of clinical courses from very indolent to highly aggressive. They are more common in Asians than whites, and the cells frequently harbor a clonal Epstein-Barr virus episome. The PB white count is usually not greatly elevated, but abnormal large lymphoid cells with granular cytoplasm are noted. The aggressive form is characterized by symptoms of fever and laboratory abnormalities of pancytopenia. Hepatosplenomegaly is common; node involvement is less common. Patients may have hemophagocytosis, coagulopathy, or multiorgan failure. Serum levels of Fas ligand are elevated.

The cells express CD2 and CD56 and do not have rearranged T-cell receptor genes. Deletions involving chromosome 6 are common. The disease can be rapidly progressive. Some forms of NK neoplasms are more indolent. They tend to be discovered incidentally with LGL lymphocytosis and do not manifest the fever and hepatosplenomegaly characteristic of the aggressive leukemia. The cells are also CD2 and CD56 positive, but they do not contain clonal forms of Epstein-Barr virus and are not accompanied by pancytopenia or autoimmune disease.

Extranodal NK/T-Cell Lymphoma, Nasal Type Like lymphomatoid granulomatosis, extranodal NK/T-cell lymphoma tends to be an angiocentric and angiodestructive lesion, but the malignant cells are not B cells. In most cases, they are CD56+ Epstein-Barr virus–infected cells; occasionally they are CD56–Epstein-Barr virus–infected cytotoxic T cells. They are most commonly found in the nasal cavity. Historically, this illness was called lethal midline granuloma, polymorphic reticulosis, and angiocentric immunoproliferative lesion. This form of lymphoma is prevalent in Asia, Mexico, and Central and South America; it affects males more commonly than females. When it spreads beyond the nasal cavity, it may affect soft tissue, the gastrointestinal tract, or the testis. In some cases, hemophagocytic syndrome (HPS) may influence the clinical picture. Patients may have B symptoms. Many of the systemic manifestations of disease are related to the production of cytokines by the tumor cells and the cells responding to their signals. Deletions and inversions of chromosome 6 are common.

Many patients with extranodal NK/T-cell lymphoma, nasal type have excellent antitumor responses with combination chemotherapy regimens, particularly those with localized disease. Radiation therapy is often used after completion of chemotherapy. Four risk factors have been defined, including B symptoms, advanced stage, elevated LDH, and regional lymph node involvement. Patient survival is linked to the number of risk factors: 5-year survival is 81% for zero risk factors, 64% for one risk factor, 32% for two risk factors, and 7% for three or four risk factors. Combination regimens without anthracyclines have been touted as superior to CHOP, but data are sparse. High-dose therapy with stem cell transplantation has been used, but its role is unclear.

Enteropathy-Type T-Cell Lymphoma Enteropathy-type T-cell lymphoma is a rare complication of longstanding celiac disease. It most commonly occurs in the jejunum or the ileum. In adults, the lymphoma may be diagnosed at the same time as celiac disease, but the suspicion is that the celiac disease was a longstanding precursor to the development of lymphoma. The tumor usually presents as multiple ulcerating mucosal masses, but may also produce a dominant exophytic mass or multiple ulcerations. The tumor expresses CD3 and CD7 nearly always and may or may not express CD8. The normal-appearing lymphocytes in the adjacent mucosa often have a similar phenotype to the tumor. Most patients have the HLA genotype associated with celiac disease, HLA DQA1*0501 or DQB1*0201.

The prognosis of this form of lymphoma is typically (median survival is 7 months) poor, but some patients have a good response to CHOP chemotherapy. Patients who respond can develop bowel perforation from responding tumor. If the tumor responds to treatment, recurrence may develop elsewhere in the celiac disease–affected small bowel.

Hepatosplenic T-Cell Lymphoma Hepatosplenic T-cell lymphoma is a malignancy derived from T cells expressing the gamma/delta T-cell antigen receptor that affects mainly the liver and fills the sinusoids with medium-size lymphoid cells. When the spleen is involved, dominantly the red pulp is infiltrated. It is a disease of young people, especially young people with an underlying immunodeficiency or with an autoimmune disease that demands immunosuppressive therapy. The use of thiopurine and infliximab is particularly common in the history of patients with this disease. The cells are CD3+ and usually CD4– and CD8–. The cells may contain isochromosome 7q, often together with trisomy 8. The lymphoma has an aggressive natural history. Combination chemotherapy may induce remissions, but most patients relapse. Median survival is about 2 years. The tumor does not appear to respond to reversal of immunosuppressive therapy.

Subcutaneous Panniculitis-Like T-Cell Lymphoma Subcutaneous panniculitis-like T-cell lymphoma involves multiple subcutaneous collections of neoplastic T cells that are usually cytotoxic cells in phenotype (i.e., contain perforin and granzyme B and express CD3 and CD8). The rearranged T-cell receptor is usually alpha/beta-derived, but occasionally the gamma/delta receptors are involved, particularly in the setting of immunosuppression. The cells are negative for Epstein-Barr virus. Patients may have a HPS in addition to the skin infiltration; fever and hepatosplenomegaly may also be present. Nodes are generally not involved. Patients frequently respond to combination chemotherapy, including CHOP. When the disease is progressive, the HPS can be a component of a fulminant downhill course. Effective therapy can reverse the HPS.

Blastic NK Cell Lymphoma The neoplastic cells express NK cell markers, especially CD56, and are CD3 negative. They are large blastic-appearing cells and may produce a leukemia picture, but the dominant site of involvement is the skin. Morphologically, the cells are similar to the neoplastic cells in acute lymphoid and myeloid leukemia. No characteristic chromosomal abnormalities have been described. The clinical course is rapid, and the disease is largely unresponsive to typical lymphoma treatments.

Primary Cutaneous CD30+ T-Cell Lymphoma This tumor involves the skin and is composed of cells that appear similar to the cells of anaplastic T-cell lymphoma. Among cutaneous T-cell tumors, about 25% are CD30+ anaplastic lymphomas. If dissemination to lymph nodes occurs, it is difficult to distinguish between the cutaneous and systemic forms of the disease. The tumor cells are often CD4+, and the cells contain granules that are positive for granzyme B and perforin in 70% of cases. The typical t(2;5) of anaplastic T-cell lymphoma is absent; indeed, its presence should prompt a closer look for systemic involvement and a switch to a diagnosis of anaplastic T-cell lymphoma. This form of lymphoma has sporadically been noted as a rare complication of silicone on saline breast implants. The natural history of breast implant associated lymphoma is generally indolent. Cutaneous CD30+ T-cell lymphoma often responds to therapy. The anti-CD30 immunotoxin conjugate, brentuximab vedotin, is active. Radiation therapy can be effective, and surgery can also produce long-term disease control. Five-year survival exceeds 90%.

Angioimmunoblastic T-Cell Lymphoma Angioimmunoblastic T-cell lymphoma is a systemic disease that accounts for about 15% of all T-cell lymphomas. Patients frequently have fever, advanced stage, diffuse adenopathy, hepatosplenomegaly, skin rash, polyclonal hypergammaglobulinemia, and a wide range of autoantibodies including cold agglutinins, rheumatoid factor, and circulating immune complexes. Patients may have edema, arthritis, pleural effusions, and ascites. The nodes contain a polymorphous infiltrate of neoplastic T cells and nonneoplastic inflammatory cells together with proliferation of high endothelial venules and follicular dendritic cells (FDCs). The most common chromosomal abnormalities are trisomy 3, trisomy 5, and

an extra X chromosome. Aggressive combination chemotherapy can induce regressions. The underlying immune defects make conventional lymphoma treatments more likely to produce infectious complications.

RARE MYELOID MALIGNANCIES

The World Health Organization (WHO) system uses PB counts and smear analysis, BM morphology, cytogenetic and molecular genetic tests in order to classify myeloid malignancies into several major categories **(Table 106-4)**. Amongst them, acute myeloid leukemia (AML) is discussed in **Chap. 100**, MDS in **Chap. 98**, chronic myeloid leukemia (CML) in **Chap. 101**, and *JAK2* mutation-enriched myeloproliferative neoplasms (MPN) in **Chap. 99**. In this chapter, we focus on the rest (listed in Table 106-4) including chronic neutrophilic leukemia (CNL), "atypical CML, *BCR-ABL1* negative (aCML)," chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia (JMML), "chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)," mastocytosis, "MPN, unclassifiable (MPN-U)," MDS/MPN, unclassifiable (MDS/MPN-U), "MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T)," and "myeloid/lymphoid neoplasms with eosinophilia and rearrangements of *PDGFRA, PDGFRB, FGFR1* or with *PCM1-JAK2*." This chapter also includes histiocytic and DC neoplasms, transient myeloproliferative disorders (TMD) as well as a broader discussion on primary eosinophilic disorders including hypereosinophilic syndrome (HES).

CHRONIC NEUTROPHILIC LEUKEMIA

CNL is a clonal proliferation of mature neutrophils with few or no circulating immature granulocytes. In 2013, CNL was associated with activating mutations of the gene (*CSF3R*) encoding for the receptor for granulocyte colony-stimulating factor (G-CSF), also known as colony stimulating factor 3 (CSF3). Patients with CNL might be asymptomatic at presentation but also display constitutional symptoms, splenomegaly, anemia, and thrombocytopenia. Median survival is ~2 years and causes of death include leukemic transformation, progressive disease associated with severe cytopenias, and marked treatment-refractory leukocytosis. CNL is rare with <200 reported cases. Median age at diagnosis is ~67 years, and the disease is equally prevalent in both genders.

TABLE 106-4 World Health Organization Classification of Myeloid Malignancies

1. **Acute myeloid leukemia (AML) and related precursor neoplasms**
2. **Myeloproliferative neoplasms (MPN)**
   - **2.1.** Chronic myeloid leukemia (CML), *BCR-ABL1* positive
   - **2.2.** *JAK2* mutation-enriched MPN
     - **2.2.1.** Polycythemia vera
     - **2.2.2.** Primary myelofibrosis
     - **2.2.3.** Essential thrombocythemia
   - **2.3.** Chronic neutrophilic leukemia (CNL)
   - **2.4.** Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)
   - **2.5.** Myeloproliferative neoplasm, unclassifiable (MPN-U)
3. **Myelodysplastic syndromes (MDS)**
   - **3.1.** MDS with single lineage dysplasia
   - **3.2.** MDS with ring sideroblasts (MDS-RS)
   - **3.3.** MDS with multilineage dysplasia
   - **3.4.** MDS with excess blasts
   - **3.5.** MDS with isolated del(5q)
   - **3.6.** MDS, unclassifiable (MDS-U)
   - **3.7.** *Provisional entity: Refractory cytopenia of childhood*
4. **MDS/MPN overlap**
   - **4.1.** Chronic myelomonocytic leukemia (CMML)
   - **4.2.** Atypical chronic myeloid leukemia (aCML), *BCR-ABL1* negative
   - **4.3.** Juvenile myelomonocytic leukemia (JMML)
   - **4.4.** MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T)
   - **4.5.** MDS/MPN, unclassifiable (MDS/MPN-U)
5. **Mastocytosis**
6. **Myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRA*, *PDGFRB*, *FGFR1* or with *PCM1-JAK2***
   - **6.1.** Myeloid/lymphoid neoplasms with *PDGFRA* rearrangement
   - **6.2.** Myeloid/lymphoid neoplasms with *PDGFRB* rearrangement
   - **6.3.** Myeloid/lymphoid neoplasms with *FGFR1* rearrangement
   - **6.4.** *Provisional entity: Myeloid/lymphoid neoplasms with PCM1-JAK2 translocation*

Myeloid neoplasms with germline predisposition

Pathogenesis CSF3 is the main growth factor for granulocyte proliferation and differentiation. Accordingly, recombinant CSF3 is used for the treatment of severe neutropenia, including severe congenital neutropenia (SCN). Some patients with SCN acquire *CSF3R* mutations and the frequency of such mutations is significantly higher (~ 80%) in those patients who experience leukemic transformation. SCN-associated *CSF3R* mutations occur in the region of the gene coding for the cytoplasmic domain of CSF3R, and result in truncation of the C-terminal-negative regulatory domain. In 2013, Maxson et al. described a different class of *CSF3R* mutations in ~ 90% of patients with CNL; these were mostly membrane proximal, the most frequent being a C-to-T substitution at nucleotide 1853 (T618I). In a subsequent confirmatory study, *CSF3R* mutations were found to be specific to WHO-defined CNL. About 40% of the T618I-mutated cases also harbored *SETBP1* mutations. *CSF3R*T618I has been shown to induce lethal myeloproliferative disorder in a mouse model and in vitro sensitivity to JAK inhibition.

Diagnosis Diagnosis of CNL requires exclusion of the more common causes of neutrophilia including infections and inflammatory processes. In addition, one should be mindful of the association between some forms of metastatic cancer or plasma cell neoplasms with secondary neutrophilia. Neoplastic neutrophilia also occurs in other myeloid malignancies including aCML and CMML. Accordingly, the WHO diagnostic criteria for CNL are designed to exclude the possibilities of both secondary/reactive neutrophilia and leukocytosis associated with myeloid malignancies other than CNL (Table 106-2): leukocytosis ($\geq 25 \times 10^9$/L), ≥80% segmented/band neutrophils, <10% immature myeloid cells, <1% circulating blasts and absence of dysgranulopoiesis or monocytosis (monocyte count $< 1 \times 10^9$/L). BM in CNL is hypercellular and displays increased number and percentage of neutrophils with very high myeloid to erythroid ratio and minimal left shift, myeloid dysplasia or reticulin fibrosis.

The recent discovery of *CSF3R* mutations (see above) and their almost invariable association with WHO-defined CNL has allowed its incorporation in the WHO diagnostic criteria **(Table 106-5)**. In practical terms, the presence of a membrane proximal *CSF3R* mutation in a patient with predominantly neutrophilic granulocytosis should be sufficient for the diagnosis of CNL, regardless of the degree of leukocytosis. Unfortunately, several exclusionary criteria still need to be met for diagnosing CNL in the absence of *CSF3R* mutations (Table 106-5).

Treatment Current treatment in CNL is largely palliative and suboptimal in its efficacy. Several drugs alone or in combination have been tried and none have shown remarkable efficacy. As such, allogeneic stem cell transplant (ASCT) is reasonable to consider in the presence of symptomatic disease, especially in younger patients. Otherwise, cytoreductive therapy with hydroxyurea is probably as good as anything, and a more intensive combination chemotherapy may not have additional value. However, response to hydroxyurea therapy is often transient, and some have successfully used interferon α as an alternative drug. Response to treatment with ruxolitinib (a JAK1 and JAK2 inhibitor) has been reported in several case reports but, as is the case with hydroxyurea treatment, the response is often incomplete and temporary.

ATYPICAL CHRONIC MYELOID LEUKEMIA

"Atypical chronic myeloid leukemia, *BCR-ABL1* negative (aCML)" is formally classified under the MDS/MPN category of myeloid malignancies and is characterized by left shifted granulocytosis and

TABLE 106-5 2016 World Health Organization (WHO) Diagnostic Criteria for Chronic Neutrophilic Leukemia (CNL), Atypical Chronic Myeloid Leukemia, *BCR-ABL1*-negative (aCML), and Chronic Myelomonocytic Leukemia (CMML)

VARIABLES	CHRONIC NEUTROPHILIC LEUKEMIA	ATYPICAL CHRONIC MYELOID LEUKEMIA	CHRONIC MYELOMONOCYTIC LEUKEMIA
PB leukocyte count	≥25 × 10^9/L	Granulocytosis	
PB segmented neutrophils/bands	≥80%		
PB immature granulocytes[a]	<10%	≥10%	
PB blast count	<1%	<20%	<20%
PB monocyte count	<1 x 10(9)/L	No or minimal monocytosis	≥1 × 10^9/L Persistent and lasting for at least 3 months
Dysgranulopoiesis	No	Yes	
PB basophil percentage		<2%	
PB monocyte percentage		<10%	≥10%
Bone marrow	Hypercellular ↑Neutrophils, number and % <5% blasts Normal neutrophilic maturation	Hypercellular ↑Granulocyte proliferation Granulocytic dysplasia ±erythroid/megakaryocyte Dysplasia <20% blasts	Dysplasia in ≥1 myeloid lineages or clonal cytogenetic/molecular abnormality <20% blasts or promonocytes
BCR-ABL1	No	No	No
PDGFRA, *PDGFRB*, *FGFR1*, or *PCM1-JAK2* rearrangement	No	No	No
CSF3R T618I or other activating CSF3R mutation or persistent neutrophilia, splenomegaly, and no identifiable cause of reactive neutrophilia	Yes		
PB and BM blasts/promonocytes		<20%	<20%
Evidence for other MPN: CML, PV, ET, or PMF	No	No	No
Evidence for reactive Leukocytosis[b] or monocytosis	No		No

[a]Immature granulocytes include myeloblasts, promyelocytes, myelocytes, and metamyelocytes. [b]Causes of reactive neutrophilia include plasma cell neoplasms, solid tumor, infections, and inflammatory processes.

Abbreviations: BM, bone marrow; CML, chronic myeloid leukemia; ET, essential thrombocythemia; MPN, myeloproliferative neoplasms; PB, peripheral blood; PMF, primary myelofibrosis; PV, polycythemia vera.

dysgranulopoiesis. The differential diagnosis of aCML includes CML, which is distinguished by the presence of *BCR-ABL1*; CNL, which is distinguished by the absence of dysgranulopoiesis and presence of *CSF3R* mutations; and CMML, which is distinguished by the presence of monocytosis (absolute monocyte count ≥1 × 10^9/L). The WHO diagnostic criteria for aCML are listed in Table 106-5 and include granulocytosis, dysgranulopoiesis, ≥10% immature granulocytes, <20% PB or BM myeloblasts, <10% PB monocytes, <2% basophils, absence of otherwise specific mutations such as *BCR-ABL1, PDGFRA, PDGFRB, FGFR1,* or *PCM1-JAK2* and not meeting WHO criteria for CML, PMF, PV, or ET. The BM in aCML is hypercellular with granulocyte proliferation and dysplasia with or without erythroid or megakaryocytic dysplasia.

The molecular pathogenesis of aCML is incompletely understood; about a fourth of the patients express *SETBP1* mutations, which are, however, also found in several other myeloid malignancies, including CNL and CMML. *SETBP1* mutations in aCML were prognostically detrimental and mostly located between codons 858 and 871; similar mutations are seen with Schinzel-Giedion syndrome (a congenital disease with severe developmental delay and various physical stigmata including midface retraction, large forehead, and macroglossia). A somatic missense mutation in ethanolamine kinase 1 (*ETNK1*N244S) was described in 9% of patients with aCML but was also seen in 14% of patients with CMML, 6% of patients with mastocytosis (especially in association with eosinophilia), and rarely in other MPN.

In a series of 55 patients with WHO-defined aCML, median age at diagnosis was 62 years with female preponderance (57%), splenomegaly was reported in 54% of the patients, red cell transfusion requirement in 65%, abnormal karyotype in 20% (20q- and trisomy 8 being the most frequent) and leukemic transformation in 40%. Median survival was 25 months. Outcome was worse in patients with marked leukocytosis, transfusion requirement, and increased immature cells in the PB. Conventional chemotherapy is largely ineffective in the treatment of aCML. However, a favorable experience with ASCT was reported in nine patients; after a median follow-up of 55 months, the majority of the patients remained in complete remission.

CHRONIC MYELOMONOCYTIC LEUKEMIA

CMML is classified under the WHO category of MDS/MPN and is defined by an absolute monocyte count (AMC) of ≥1 × 10^9/L in the PB and accounting for ≥10% of the leukocyte count. Median age at diagnosis ranges between 65 and 75 years and there is a 2:1 male predominance. Clinical presentation is variable and depends on whether the disease presents with MDS-like or MPN-like phenotype; the former is associated with cytopenias and the latter with splenomegaly and features of myeloproliferation such as fatigue, night sweats, weight loss, and cachexia. About 20% of patients with CMML experience serositis involving the joints (arthritis), pericardium (pericarditis and pericardial effusion), pleura (pleural effusion), or peritoneum (ascites).

Pathogenesis Clonal cytogenetic abnormalities are seen in about a third of patients with CMML and include trisomy 8 and abnormalities of chromosome 7. Almost all patients with CMML harbor somatic mutations involving epigenetic regulator genes (e.g., *ASXL1, TET2*), spliceosome pathway genes (e.g., *SRSF2*), DNA damage response genes (e.g., *TP53*), and tyrosine kinases/transcription factors (e.g., *KRAS, NRAS, CBL*, and *RUNX1*). However, none of these mutations are specific to CMML, and their precise pathogenetic contribution is unclear.

Diagnosis Reactive monocytosis is uncommon but has been reported in association with certain infections and inflammatory conditions. Clonal (i.e., neoplastic) monocytosis defines CMML but is also seen with JMML and AML with monocytic differentiation. The WHO diagnostic criteria for CMML are listed in Table 106-5 and include (1) persistent PB monocyte count of ≥1 × 10^9/L with monocyte percentage

of ≥10%, (2) absence of *BCR-ABL1, PDGFRA, PDGFRB, FGFR1, or PCM1-JAK2 rearrangements*, (3) not meeting WHO criteria for CML, PV, ET, or PMF, (4) <20% blasts and promonocytes in the PB and BM, and (5) dysplasia involving one or more myeloid lineages or, in the absence of dysplasia, presence of an acquired clonal cytogenetic or molecular genetic abnormality or non-reactive monocytosis lasting for at least 3 months.

The BM in CMML is hypercellular with granulocytic and monocytic proliferation. Dysplasia is often present and may involve one, two, or all myeloid lineages. On immunophenotyping the abnormal cells often express myelomonocytic antigens such as CD13 and CD33, with variable expression of CD14, CD68, CD64, and CD163. Monocytic-derived cells are almost always positive for the cytochemical non-specific esterases (e.g., butyrate esterase), while normal granulocytic precursors are positive for lysozyme and chloroacetate esterase. In CMML, it is common to have a hybrid cytochemical staining pattern with cells expressing both chloroacetate and butyrate esterases simultaneously (dual esterase staining).

Prognosis A recent meta-analysis showed median survival of 1.5 years in CMML. Numerous prognostic systems have attempted to better define and stratify the natural history of CMML. One of these, the Mayo prognostic model, assigns one point each to the following four independent prognostic variables: AMC >10 × 10^9/L, presence of circulating immature cells, hemoglobin <10 gm/dL and platelet count <100,000/mL. This model stratified patients into three risk groups: low (0 points), intermediate (1 point), and high (≥2 points), translating to median survival of 32, 18, and 10 months, respectively.

A French study incorporated *ASXL1* mutational status in 312 CMML patients. In a multivariable model, independent predictors of poor survival were WBC >15 × 10^9/L (3 points), *ASXL1* mutations (2 points), age >65 years (2 points), platelet count <100,000/mL (2 points), and hemoglobin <10 gm/dL in females and <11 gm/dL in males (2 points). This model stratified patients into three groups: low (0–4 points), intermediate (5–7 points), and high risk (8–12 points), with median survival of "not reached," 38.5 and 14.4 months, respectively.[27] *ASXL1* and *DNMT3A* mutations also have an adverse effect on CMML.

Treatment Current treatment in CMML consists of hydroxyurea and supportive care, including red cell transfusions and use of erythropoiesis-stimulating agents (ESA). The value of hydroxyurea was reinforced by a randomized trial against oral etoposide. No other single or combination chemotherapy has been shown to be superior to hydroxyurea. ASCT is a viable treatment option for transplant-eligible patients with poor prognostic features. Given the MDS/MPN overlap phenotype and the presence of MDS-like genetic/methylation abnormalities in CMML, hypomethylating agents such as 5-azacitidine and decitabine have been used with limited efficacy; in a study using decitabine in CMML, overall response rate was 48% with 17% complete remissions and median survival of 17 months. The experience with 5-azacytidine was somewhat similar.

JUVENILE MYELOMONOCYTIC LEUKEMIA

JMML is primarily a disease of early childhood and is included, along with CMML, in the "MDS/MPN" WHO category. Both CMML and JMML feature leukocytosis, monocytosis, and hepatosplenomegaly. Additional characteristic features in JMML include thrombocytopenia and elevated fetal hemoglobin. Myeloid progenitors in JMML display GM-CSF hypersensitivity that has been attributed to dysregulated RAS/MAPK signaling. The latter is believed to result from mutually exclusive mutations involving *RAS*, *PTPN11*, and *NF1*. A third of patients with JMML that is not associated with Noonan syndrome carry *PTPN11* mutations while the incidence of *NF1* in patients without neurofibromatosis, type 1 and *RAS* mutations are ~15% each. In general, in about 85% of JMML cases, one of the classical RAS pathway mutations (*PTPN11*, *NRAS*, *KRAS*, *NF1*, and *CBL*) is present; in addition, a myrof other mutations, such as *ASXL1*, *RUNX1*, *SETBP1*, *JAK3*, *CUX1*, and others have been reported. Drug therapy is relatively ineffective in JMML, and the treatment of choice is ASCT, which results in a 5-year survival of ~50%.

The 2016 revised WHO diagnostic criteria for JMML requires the presence of PB monocyte count ≥1 × 10^9/L, <20% blasts in blood or BM, splenomegaly, and absence of *BCR-ABL1*. Diagnosis also requires the presence of one of the following: somatic mutation of *PTPN11, KRAS*, or *NRAS*; clinical diagnosis of NF1 or *NF1* mutation; germline mutation of *CBL* and loss of heterozygosity. Diagnosis of JMML can still be considered without the aforementioned genetic features, in the presence of monosomy 7 or any other cytogenetic abnormality or in the presence of two of the following: increased hemoglobin F, presence of myeloid or erythroid precursors in the PB, GM-CSF hypersensitivity in colony assay, and hyperphosphorylation of STAT5.

MDS/MPN, UNCLASSIFIABLE (MDS/MPN-U)

The WHO classifies patients with morphologic and laboratory features that resemble both MDS and MPN as "MDS/MPN overlap." This category includes CMML, aCML, and JMML, which have been described above. In addition, MDS/MPN includes a fourth category referred to as MDS/MPN, unclassifiable (MDS/MPN-U). Diagnosis of MDS/MPN-U requires the presence of both MDS and MPN features that are not adequate to classify patients as CMML, aCML, or JMML. MDS/MPN also includes the provisional category of refractory anemia with ring sideroblasts and thrombocytosis (RARS-T); the 2016 revision of the WHO classification document has changed the term RARS-T into "MDS/MPN-RS-T."

In a study of 85 patients with MDS/MPN-U, median age was 70 years and 72% were males. Splenomegaly at presentation was present in 33%, thrombocytosis in 13%, leukocytosis in 18%, *JAK2* mutations in 30%, and abnormal karyotype 51%; the most frequent cytogenetic abnormality was trisomy 8. Median survival was 12.4 months and favorably affected by thrombocytosis. Treatment with hypomethylating agents, immunomodulators, or ASCT did not appear to favorably affect survival.

MDS/MPN WITH RING SIDEROBLASTS AND THROMBOCYTOSIS (MDS/MPN-RS-T)

MDS/MPN-RS-T is classified in the MDS/MPN category because it shares dysplastic features with MDS-RS and myeloproliferative features with ET. The 2016 revised WHO diagnostic criteria for MDS/MPN-RS-T includes anemia associated with erythroid lineage dysplasia, presence of ≥15% ring sideroblasts, blast count of <5% in BM and <1% in the PB, platelet count of ≥450 × 10^9/L, and absence of *BCR-ABL1*, *PDGFRA, PDGFRB, FGFR1, PCM1-JAK2* mutations or t(3;3)(q21;q26), inv(3)(q21q26), or del(5q). These diagnostic criteria also require the absence of history of MPN, MDS, or other type of MDS/MPN and also either the presence of *SF3B1* mutation or absence of exposure to cytotoxic or other treatment that could be blamed for the morphologic abnormalities.

One hundred eleven patients with MDS/MPN-RS-T were compared with 33 patients with RARS. The frequency of *SF3B1* mutations in MDS/MPN-RS-T-T (87%) was similar to that in MDS-RS (85%). *JAK2 V617F* mutation was detected in 49% of MDS/MPN-RS-T patients (including 48% of those mutated for *SF3B1*), but none of those with MDS-RS. In MDS/MPN-RS-T, *SF3B1* mutations were more frequent in females (95%) than in males (77%), and mean ring sideroblast counts were higher in *SF3B1-mutated* patients. Median overall survival was 6.9 years in *SF3B1-mutated* vs 3.3 years in unmutated cases. Six-year survival was 67% in *JAK2*-mutated vs 32% in unmutated cases. Multivariable analysis identified younger age, *JAK2* and *SF3B1* mutations as favorable factors. Predictors of poor survival in MDS/MPN-RS-T include anemia, abnormal karyotype, and presence of *ASXL1* or *SETBP1* mutations. Interestingly, the presence of *SF3B1* mutations in MDS/MPN-RS-T is associated with increased risk of thrombosis. Several case reports have suggested that treatment with lenalidomide might induce red cell transfusion independence and complete remissions in MDS/MPN-RS-T.

MYELOPROLIFERATIVE NEOPLASM, UNCLASSIFIABLE (MPN-U)

The category of MPN-U includes MPN-like neoplasms that cannot be clearly classified as one of the other seven subcategories of MPN

(Table 106-4). Examples include patients presenting with unusual thrombosis or unexplained organomegaly with normal blood counts but found to carry MPN-characteristic mutations such as *JAK2* and *CALR* or display BM morphology that is consistent with MPN. It is possible that some cases of MPN-U represent earlier disease stages in PV or ET, which however fail to meet the threshold hemoglobin levels or platelet counts that are required per WHO diagnostic criteria. Specific treatment interventions might not be necessary in asymptomatic patients with MPN-U, whereas patients with arterial thrombotic complications might require cytoreductive and aspirin therapy, and those with venous thrombosis might require systemic anticoagulation.

MYELOID NEOPLASMS WITH GERM LINE PREDISPOSITION

The 2016 WHO revision on the classification of myeloid neoplasms adds a section referred to as "myeloid neoplasms with germ line predisposition" and includes cases of AML, MDS, and MDS/MPN that arise in the setting of a germ line predisposition mutation, such as *CEBPA, DDX41, RUNX1, ANKRD26, ETV6*, or *GATA2*. This particular category of diseases also includes myeloid neoplasms that arise in the background of BM failure syndromes, Down syndrome, Noonan syndrome, neurofibromatosis, and telomeropathies.

TRANSIENT MYELOPROLIFERATIVE DISORDER

TMD, also referred to as transient abnormal myelopoiesis (TAM), constitutes an often but not always transient phenomenon of abnormal megakaryoblast proliferation, which occurs in ~10% of infants with Down syndrome. TMD is usually recognized at birth and either undergoes spontaneous regression (75% of the cases) or progress into acute megakaryoblastic leukemia (AMKL) (25% of the cases). Almost all patients with TMD and TMD-derived AMKL display somatic *GATA1* mutations. TMD-associated *GATA1* mutations constitute exon 2 insertions, deletions, or missense mutations, affecting the N-terminal transactivation domain of GATA-1 and result in loss of full-length (50-kD) GATA-1 and its replacement with a shorter isoform (40-kD) that retains friend of GATA-1 (FOG-1) binding. In contrast, inherited forms of exon 2 *GATA1* mutations produce a phenotype with anemia whereas exon 4 mutations that affect the N-terminal, FOG-1-interactive domain, produce familial dyserythropoietic anemia with thrombocytopenia[51] or X-linked macrothrombocytopenia.

PRIMARY EOSINOPHILIA

Eosinophilia refers to a PB absolute eosinophil count (AEC) that is above the upper normal limit of the reference range. The term "hypereosinophilia" is used when the AEC is above 1500×10^9/L. Eosinophilia is operationally classified into secondary (non-neoplastic proliferation of eosinophils) and primary (proliferation of eosinophils that is either neoplastic or otherwise unexplained). Secondary eosinophilia is by far the most frequent cause of eosinophilia and is often associated with infections, especially those related to tissue-invasive helminths, allergic/vasculitic diseases, drugs, and metastatic cancer. Primary eosinophilia is the focus of this chapter and is considered when a cause for secondary eosinophilia is not readily apparent.

Primary eosinophilia is classified as clonal or idiopathic. Diagnosis of clonal eosinophilia requires morphologic, cytogenetic, or molecular evidence of a myeloid neoplasm. Idiopathic eosinophilia is considered when both secondary and clonal eosinophilias have been ruled out as a possibility. HES is a subcategory of idiopathic eosinophilia with persistent AEC of $\geq 1.5 \times 10^9$/L and associated with eosinophil-mediated organ damage **(Table 106-6)**. An HES-like disorder that is associated with clonal or phenotypically abnormal T cells is referred to as "lymphocytic variant hypereosinophilia" (Table 106-6).

Clonal Eosinophilia Examples of clonal eosinophilia include eosinophilia associated with AML, MDS, CML, mastocytosis, and MDS/MPN overlap. Myeloid neoplasm-associated eosinophilia also includes the WHO MPN subcategory of chronic eosinophilic leukemia, not otherwise specified (CEL-NOS) and the WHO myeloid malignancy subcategory referred to as "myeloid/lymphoid neoplasms with eosinophilia and rearrangement of platelet-derived growth factor receptor (*PDGFR*) α/β or fibroblast growth factor receptor 1 (*FGFR1*)" or with *PCM1-JAK2* (Table 106-4).

The diagnostic workup for clonal eosinophilia that is not associated with morphologically overt myeloid malignancy should start with PB mutation screening for *FIP1L1-PDGFRA* and *PDGFRB* mutations using fluorescence in situ hybridization (FISH) or reverse transcription-polymerase chain reaction. This is crucial since such eosinophilia is easily treated with imatinib. If mutation screening is negative, a BM examination with cytogenetic studies is indicated. In this regard, one must first pay attention to the presence or absence of 5q33, 4q12, 8p11.2, or t(8;9)(p22;p24.1) translocations, which, if present, would suggest *PDGFRB*, *PDGFRA*, or *FGFR1*-rearranged or *PCM1-JAK2*-associated clonal eosinophilia, respectively. The presence of 5q33 or 4q12 translocations predicts favorable response to treatment with imatinib mesylate and that of t(8;9)(p22;p24.1), a transient response to ruxolutinib while 8p11.2 translocations are associated with aggressive myeloid malignancies that are refractory to current drug therapy.

Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL-NOS) CEL-NOS is a subset of clonal eosinophilia that is neither molecularly defined nor classified as an alternative clinicopathologically assigned myeloid malignancy. We prefer to use the term strictly in patients with an "HES" phenotype who also display either a clonal cytogenetic/molecular abnormality or excess blasts in the BM or PB. The WHO defines CEL-NOS in the presence of $\geq 1.5 \times 10^9$/L AEC that is accompanied by either the presence of myeloblast excess (either >2% in the PB or 5–19% in the BM) or evidence of myeloid clonality. Cytogenetic abnormalities in CEL, other than those that are associated

TABLE 106-6 Primary Eosinophilia Classification

VARIABLES	EOSINOPHILIA ASSOCIATED WITH *PDGFRA, PDGFRB, FGFR1* OR *PCM1-JAK2* ABNORMALITY	CHRONIC EOSINOPHILIA NOT OTHERWISE SPECIFIED (CEL-NOS)	LYMPHOCYTIC VARIANT HYPEREOSINOPHILIA	HYPEREOSINOPHILIC SYNDROME
Absolute eosinophil count	>600 × 10^9/L	>1500 × 10^9/L	>1500 × 10^9/L	>1500 × 10^9/L
Peripheral blood blast >2%	Yes or no	Yes or no	No	No
Bone marrow blast >5%	Yes or no	Yes or No	No	No
Abnormal karyotype	Yes or no	Yes or no	No	No
PDGFRA, *PDGFRB*, *FGFR1* or *PCM1-JAK2* abnormality	Yes	No	No	No
BCR-ABL1	No	No	No	No
Abnormal T lymphocyte phenotype or clonal T cell clones	No	No	Yes	No
Eosinophil-mediated tissue damage	Yes or no	Yes or no	Yes or no	Yes

with molecularly defined eosinophilic disorders, include trisomy 8 (the most frequent), t(10;11)(p14;q21), and t(7;12)(q11;p11). CEL-NOS does not respond to imatinib, and treatment strategies are often not different from those utilized in other similar MPNs; ASCT for transplant-eligible patients with poor risk factors and participation in experimental treatment protocols otherwise.

***PDGFR* Mutated Eosinophilia** Both platelet-derived growth factor receptors α (*PDGFRA* located on chromosome 4q12) and β (*PDGFRB* located on chromosome 5q31-q32) are involved in MPN-relevant activating mutations. Clinical phenotype in both instances includes prominent blood eosinophilia and excellent response to imatinib therapy. In regards to *PDGFRA* mutations, the most popular is *FIP1L1-PDGFRA*, a karyotypically occult del(4)(q12), that was described in 2003 as an imatinib-sensitive activating mutation. Functional studies have demonstrated transforming properties in cell lines and the induction of MPN in mice. Cloning of the *FIP1L1-PDGFRA* fusion gene identified a novel molecular mechanism for generating this constitutively active fusion tyrosine kinase, wherein a ~800kb interstitial deletion within 4q12 fuses the 5′ portion of *FIP1L1* to the 3′ portion of *PDGFRA*.[57] *FIP1L1-PDGFRA* occurs in a very small subset of patients who present with the phenotypic features of either SM or HES, but the presence of the mutation reliably predicts complete hematologic and molecular response to imatinib therapy.

The association between eosinophilic myeloid malignancies and *PDGFRB* rearrangement was first characterized and published in 1994 where fusion of the tyrosine kinase encoding region of *PDGFRB* to the *ets*- like gene, *ETV6* (*ETV6-PDGFRB*, t(5;12)(q33;p13) was demonstrated. The fusion protein was transforming to cell lines and resulted in constitutive activation of PDGFRB signaling. Since then, several other *PDGFRB* fusion transcripts with similar disease phenotypes have been described, cell line transformation and MPD-induction in mice has been demonstrated, and imatinib therapy was effective when employed.

FGFR1 Mutated Eosinophilia The 8p11 myeloproliferative syndrome (EMS) (also known as human stem cell leukemic/lymphoma syndrome) constitutes a clinical phenotype with features of both lymphoma and eosinophilic MPN and characterized by a fusion mutation that involves the gene for fibroblast growth factor receptor-1 (*FGFR1*), which is located on chromosome 8p11. In EMS, both myeloid and lymphoid lineage cells exhibit the 8p11 translocation, thus demonstrating the stem cell origin of the disease. The disease features several 8p11-linked chromosome translocations and some of the corresponding fusion *FGFR1* mutants have been shown to transform cell lines and induce EMS- or CML-like disease in mice depending on the specific *FGFR1* partner gene, *ZNF 198* or *BCR*, respectively. Consistent with this laboratory observation, some patients with *BCR-FGFR1* mutation manifest a more indolent CML-like disease. The mechanism of FGFR1 activation in EMS is similar to that seen with PDGFRB-associated MPD; the tyrosine kinase domain of FGFR1 is juxtaposed to a dimerization domain from the partner gene. EMS is aggressive and requires combination chemotherapy followed by ASCT.

PCM1-JAK2 Associated Myeloid/Lymphoid Neoplasm with Eosinophilia The 2016 revised WHO document includes a provisional entity under myeloid/lymphoid neoplasms with eosinophilia referred to as "myeloid/lymphoid neoplasms with *PCM1-JAK2*." The entity is characterized by the t(8;9)(p22;p24.1) cytogenetic abnormality and a phenotype that displays marked male predominance, organomegaly, eosinophilia, and hetereogenous morphologic features similar to MPN, MDS, or MDS/MPN. Current drug therapy for *PCM1-JAK2*-associated disease is suboptimal, although some affected patients have displayed transient responses to ruxolutinib therapy.

Hypereosinophilic Syndrome Blood eosinophilia that is neither secondary nor clonal is operationally labeled as being "idiopathic." HES is a sub-category of idiopathic eosinophilia with persistent increase of the AEC to $\geq 1.5 \times 10^9$/L and presence of eosinophil-mediated organ damage, including cardiomyopathy, gastroenteritis, cutaneous lesions, sinusitis, pneumonitis, neuritis, and vasculitis. In addition, some patients manifest thromboembolic complications, hepatosplenomegaly, and either cytopenia or cytosis.

BM histological and cytogenetic/molecular studies should be examined before a working diagnosis of HES is made. Additional blood studies that are currently recommended during the evaluation of "HES" include serum tryptase (an increased level suggests mastocytosis and warrants molecular studies to detect *FIP1L1-PDGFRA*), T-cell immunophenotyping, as well as T-cell receptor antigen gene rearrangement analysis (a positive test suggests an underlying clonal or phenotypically abnormal T-cell disorder). In addition, initial evaluation in HES should include echocardiogram and measurement of serum troponin levels to screen for myocardial involvement by the disease.

Initial evaluation of the patient with eosinophilia should include tests that facilitate assessment of target organ damage: complete blood count, chest x-ray, echocardiogram, and serum troponin level. Increased level of serum cardiac troponin has been shown to correlate with the presence of cardiomyopathy in HES. Typical echocardiographic findings in HES include ventricular apical thrombus, posterior mitral leaflet or tricuspid valve abnormality, endocardial thickening, dilated left ventricle, and pericardial effusion.

In a Mayo Clinic study of 98 consecutive patients with idiopathic eosinophilia, including HES, median age was 53 years (55% males), and overt organ involvement was seen >80% of the cases including 54% involving organs other than the skin. The frequencies of cardiac involvement, hepatosplenomegaly, increased serum tryptase and interleukin-5 levels were 8, 4, 24, and 31%, respectively. The study also revealed that 11% of the affected patients harbored pathogenetic mutations including *TET2*, *ASXL1*, and *KIT*; the presence of such mutations did not appear to influence phenotype and the number of informative cases was too small to assess prognostic relevance. Instead, the study identified anemia and presence of cardiac involvement or hepatosplenomegaly as risk factors for survival.

Glucocorticoids are the cornerstone of therapy in HES. Treatment with oral prednisone is usually started at 1mg/kg/d and continued for 1 to 2 weeks before the dose is tapered slowly over the ensuing 2 to 3 months. If symptoms recur at a prednisone dose level of >10 mg/d, either hydroxyurea or interferon α is used as steroid-sparing agent. In patients who do not respond to usual therapy as outlined above, mepolizumab or alemtuzumab might be considered. Mepolizumab targets IL-5, a well-recognized survival factor for eosinophils. Alemtuzumab targets the CD52 antigen, which has been shown to be expressed by eosinophils but not by neutrophils.

MASTOCYTOSIS

Mast cell disease (MCD) is defined as tissue infiltration by morphologically as well as immunophenotypically abnormal mast cells. MCD is classified into two broad categories; cutaneous and systemic mastocytosis (SM). MCD in adults is usually systemic and the clinical course can be either indolent or aggressive, depending on the respective absence or presence of impaired organ function. Symptoms and signs of MCD include urticaria pigmentosa, mast cell mediator release symptoms (e.g., headache, flushing, lightheadedness, syncope, anaphylaxis, pruritus, urticaria, angioedema, nausea, diarrhea, abdominal cramps), and organ damage (lytic bone lesions, osteoporosis, hepatosplenomegaly, cytopenia). Aggressive SM can be associated with another myeloid malignancy, including MPN, MDS, MDS/MPN overlap (e.g., CMML), or present as overt mast cell leukemia (MCL). In general, life expectancy is near normal in indolent SM but significantly shortened in aggressive SM.

Diagnosis of SM is based on BM examination that shows clusters of morphologically abnormal, spindle-shaped mast cells that are best evaluated by the use of immunohistochemical stains that are specific to mast cells (tryptase, CD117). In addition, mast cell immunophenotyping reveals aberrant CD25 expression by neoplastic mast cells. Other laboratory findings in SM include increased levels of serum tryptase, histamine and urine histamine metabolites and prostaglandins. SM is associated with *KIT* mutations, usually *KIT*D816V, in the majority of patients. Accordingly, mutation screening for *KIT*D816V is diagnostically useful. However, the ability to detect *KIT*D816V depends on assay

sensitivity and mast cell content of the test sample. The 2016 WHO classification of mastocytosis includes (1) cutaneous mastocytosis (CM), (2) SM, and (3) mast cell sarcoma (MCS). SM is further classified into (a) indolent SM (ISM), (b) smoldering SM (SSM), (c) SM with an associated hematological neoplasm (SM-AHN), (d) aggressive SM (ASM), and (e) MCL.

Both indolent and aggressive SM patients might experience mast cell mediator release symptoms, which are usually managed by both H-1 and H-2 histamine receptor blockers as well as cromolyn sodium. In addition, patients with propensity to vasodilatory shock should wear a medical alert bracelet as well as carry an Epi-Pen self-injector for self-administration of subcutaneous epinephrine. Urticaria pigmentosa shows variable response to both topical and systemic corticosteroid therapy. Cytoreductive therapy is not recommended for indolent SM. In aggressive SM, either interferon α or cladribine is considered first-line therapy and benefits the majority of patients. In contrast, imatinib is ineffective in the treatment of *PDGFR*-unmutated SM. A controlled study of patients with ISM or SSM demonstrated marginal value of masitinib (oral tyrosine kinase inhibitor that inhibits KIT and LYN) with reported cumulative symptomatic response rate of 18.7% vs 7.4% for placebo. Treatment responses were more impressive in another study that used the multikinase inhibitor midostaurin in patients with the more aggressive forms of SM, with 45% of the patients achieving major response.

DENDRITIC AND HISTIOCYTIC NEOPLASMS

DC and histiocyte/macrophage neoplasms are extremely rare. DCs are antigen-presenting cells, whereas histiocyte/macrophages are antigen-processing. BM myeloid stem cells (CD34+) give rise to monocyte (CD14+, CD68+, CD11c+, CD1a–) and DC (CD14-, CD11c+/–, CD1a+/c) precursors. Monocyte precursors, in turn, give rise to macrophages (CD14+, CD68+, CD11c+, CD163+, lysozyme+) and interstitial DCs (CD68+, CD1a–). DC precursors give rise to Langerhans cell DCs (Birbeck granules, CD1a+, S100+, langerin+) and plasmacytoid DCs (CD68+, CD123+). Follicular DCs (CD21+, CD23+, CD35+) originate from mesenchymal stem cells. Dendritic and histiocytic neoplasms are operationally classified into macrophage/histiocyte-related and DC-related. The former includes histiocytic sarcoma/malignant histiocytosis (MH) and the latter Langerhans cell (LC) histiocytosis, LC sarcoma, interdigitating DC sarcoma, and follicular DC sarcoma.

Histiocytic Sarcoma/Malignant Histiocytosis Histiocytic sarcoma represents malignant proliferation of mature tissue histiocytes and is often localized. Median age at diagnosis is estimated at 46 years with slight male predilection. Some patients might have history of lymphoma, MDS, or germ cell tumors at time of disease presentation. The three typical disease sites are lymph nodes, skin, and the gastrointestinal system. Patients may or may not have systemic symptoms including fever and weight loss, and other symptoms include hepatosplenomegaly, lytic bone lesions, and pancytopenia. Immunophenotype includes presence of histiocytic markers (CD68, lysozyme, CD11c, CD14) and absence of myeloid or lymphoid markers. Prognosis is poor and treatment often ineffective. The term MH refers to a disseminated disease and systemic symptoms. Lymphoma-like treatment induces complete remissions in some patients and median survival is estimated at 2 years.

Langerhans Cell Histiocytosis LCs are specialized DCs that reside in mucocutaneous tissue and upon activation become specialized for antigen presentation to T cells. LC histiocytosis (LCH; also known as histiocytosis X) represents neoplastic proliferation of LCs (S-100+, CD1a+, and Birbeck granules on electron microscopy). LCH incidence is estimated at 5 per million and the disease typically affects children with a male predilection. Presentation can be either uni- (eosinophilic granuloma) or multi-focal. The former usually affects bones and less frequently lymph nodes, skin, and lung, while the latter is more disseminated. Unifocal disease often affects older children and adults while multisystem disease affects infants. LCH of the lung in adults is characterized by bilateral nodules. Prognosis depends on organs involved. Only 10% of patients progress from unifocal to multiorgan disease. LCH of the lung might improve upon cessation of smoking. Approximately 55% of patients with LCH harbor *BRAF*V600E gain-of-function mutations, which indicates high-risk disease and resistance to first-line therapy, while responses to targeted therapy with vemurafenib have been reported.

Langerhans Cell Sarcoma Langerhans cell sarcoma (LCS) also represents neoplastic proliferation of LCs with overtly malignant morphology. The disease can present de novo or progress from antecedent LCH. There is a female predilection and median age at diagnosis is estimated at 41 years. Immunophenotype is similar to that seen in LCH and liver, spleen, lung, and bone are the usual sites of disease. Prognosis is poor and treatment generally ineffective.

Interdigitating Dendritic Cell Sarcoma Interdigitating DC sarcoma (IDCS), also known as reticulum cell sarcoma, represents neoplastic proliferation of IDCs. The disease is extremely rare and affects elderly adults with no sex predilection. Typical presentation is asymptomatic solitary lymphadenopathy. Immunophenotype includes S-100+ and negative for vimentin and CD1a. Prognosis ranges from benign local disease to widespread lethal disease.

Follicular Dendritic Cell Sarcoma FDC reside in B-cell follicles and present antigen to B cells. FDC neoplasms (FDCN) are usually localized and often affect adults. FDCN might be associated with Castleman's disease in 10–20% of cases and increased incidence in schizophrenia has been reported. Cervical lymph nodes are the most frequent site of involvement in FDCN and other sites include maxillary, mediastinal, and retroperitoneal lymph nodes, oral cavity, the gastrointestinal system, skin, and breast. Sites of metastasis include lung and liver. Immunophenotype includes CD21, CD35, and CD23. Clinical course is typically indolent, and treatment includes surgical excision followed by regional radiotherapy and sometimes systemic chemotherapy.

Hemophagocytic Syndromes HPS represents non-neoplastic proliferation and activation of macrophages that induces cytokine-mediated BM suppression and features of intense phagocytosis in BM and liver. HPS may result from genetic or acquired disorders of macrophages. The former entail genetically determined inability to regulate macrophage proliferation and activation. Acquired HPS is often precipitated by viral infections, most notably Epstein-Barr virus. HPS might also accompany certain malignancies such as T-cell lymphoma. It is characterized by pancytopenia and elevated ferritin levels. Interferon γ is thought to play a role. Clinical course is often fulminant and fatal.

107 Plasma Cell Disorders

Nikhil C. Munshi, Dan L. Longo, Kenneth C. Anderson

The *plasma cell disorders* are monoclonal neoplasms related to each other by virtue of their development from common progenitors in the late B-lymphocyte lineage. Multiple myeloma (MM), Waldenström's macroglobulinemia, primary amyloidosis **(Chap. 108)**, and the heavy chain diseases comprise this group and may be designated by a variety of synonyms such as *monoclonal gammopathies, paraproteinemias, plasma cell dyscrasias*, and *dysproteinemias*. Mature B lymphocytes destined to produce IgG bear surface immunoglobulin molecules of both μ and γ heavy chain isotypes with both isotypes having identical idiotypes (variable regions). Under normal circumstances, maturation to antibody-secreting plasma cells and their proliferation is stimulated by exposure to the antigen for which the surface immunoglobulin is specific; however, in the plasma cell disorders, the control over this process is lost. The clinical manifestations of all the plasma cell disorders relate to the expansion of the neoplastic cells, to the secretion of cell products (immunoglobulin molecules or subunits, lymphokines), and to some extent to the host's response to the tumor. **Normal development of B lymphocytes is discussed in Chap. 342 and depicted in Fig. 104-2.**

Three categories of structural variation are present among immunoglobulin molecules that form antigenic determinants, and these are used to classify immunoglobulins. *Isotypes* are those determinants that distinguish among the main classes of antibodies of a given species and are the same in all normal individuals of that species. Therefore, isotypic determinants are, by definition, recognized by antibodies from a distinct species (heterologous sera) but not by antibodies from the same species (homologous sera). There are five heavy chain isotypes (M, G, A, D, E) and two light chain isotypes (κ, λ). *Allotypes* are distinct determinants that reflect regular small differences between individuals of the same species in the amino acid sequences of otherwise similar immunoglobulins. These differences are determined by allelic genes; by definition, they are detected by antibodies made in the same species. *Idiotypes* are the third category of antigenic determinants. They are unique to the molecules produced by a given clone of antibody-producing cells. Idiotypes are formed by the unique structure of the antigen-binding portion of the molecule.

Antibody molecules **(Fig. 107-1)** are composed of two heavy chains (~50,000 mol wt) and two light chains (~25,000 mol wt). Each chain has a constant portion (limited amino acid sequence variability) and a variable region (extensive sequence variability). The light and heavy chains are linked by disulfide bonds and are aligned so that their variable regions are adjacent to one another. This variable region forms the antigen recognition site of the antibody molecule; its unique structural features form idiotypes that are reliable markers for a particular clone of cells because each antibody is formed and secreted by a single clone. Because of the mechanics of the gene rearrangements necessary to specify the immunoglobulin variable regions (VDJ joining for the heavy chain, VJ joining for the light chain), a particular clone rearranges only one of the two chromosomes to produce an immunoglobulin molecule of only one light chain isotype and only one allotype (allelic exclusion) (Fig. 107-1). After exposure to antigen, the variable region may become associated with a new heavy chain isotype (class switch). Each clone of cells performs these sequential gene arrangements in a unique way. This results in each clone producing a unique immunoglobulin molecule. In most plasma cells, light chains are synthesized in slight excess, secreted as free light chains, and cleared by the kidney, but <10 mg of such light chains is excreted per day.

Electrophoretic analysis permits separation of components of the serum proteins **(Fig. 107-2)**. The immunoglobulins move heterogeneously in an electric field and form a broad peak in the gamma region, which is usually increased in the sera of patients with plasma cell tumors. There is a sharp spike in this region called an *M component* (M for monoclonal). Less commonly, the M component may appear in the β_2 or α_2 globulin region. The monoclonal antibody must be present at a concentration of at least 5 g/L (0.5 g/dL) to be accurately quantitated by this method. This corresponds to ~10^9 cells producing the antibody. Confirmation of the type of immunoglobulin and that it is truly monoclonal is determined by immunoelectrophoresis that reveals a single heavy and/or light chain type. Hence immunoelectrophoresis and electrophoresis provide qualitative and quantitative assessment of the M component, respectively. Once the presence of an M component has been confirmed, the amount of M component in the serum is a reliable measure of the tumor burden, making M component an excellent tumor marker to manage therapy, yet it is not specific enough to be used to screen asymptomatic patients. In addition to the plasma cell disorders, M components may be detected in other lymphoid neoplasms such as chronic lymphocytic leukemia (CLL) and lymphomas of B- or T-cell origin; nonlymphoid neoplasms such as chronic myeloid leukemia, breast cancer, and colon cancer; a variety of nonneoplastic conditions such as cirrhosis, sarcoidosis, parasitic diseases, Gaucher's disease, and pyoderma gangrenosum; and a number of autoimmune conditions, including rheumatoid arthritis, myasthenia gravis, and cold agglutinin disease. Monoclonal proteins are also observed in immunosuppressed patients after organ transplant and, rarely, allogeneic transplant. At least two very rare skin diseases—lichen myxedematosus (also known as papular mucinosis) and necrobiotic xanthogranuloma—are associated with a monoclonal gammopathy. In papular mucinosis, highly cationic IgG is deposited in the dermis of patients. This organ specificity may reflect the specificity of the antibody for some antigenic component of the dermis. Necrobiotic xanthogranuloma is a histiocytic infiltration of the skin, usually of the face, that produces red or yellow nodules that can enlarge to plaques. Approximately 10% progress to myeloma. Five percent of patients with sensory motor neuropathy also have a monoclonal paraprotein.

The nature of the M component is variable in plasma cell disorders. It may be an intact antibody molecule of any heavy chain subclass, or it may be an altered antibody or fragment. Isolated light or heavy chains may be produced. In some plasma cell tumors such as extramedullary or solitary bone plasmacytomas, less than one-third of patients will have an M component. In ~20% of myelomas, only light chains are produced and, in most cases, are secreted in the urine as Bence Jones proteins. The frequency of myelomas of a particular heavy chain class is roughly proportional to the serum concentration, and therefore, IgG myelomas are more common than IgA and IgD myelomas. In ~1% of patients with myeloma, biclonal or triclonal gammopathy is observed.

MULTIPLE MYELOMA

DEFINITION

MM represents a malignant proliferation of plasma cells derived from a single clone. The tumor, its products, and the host response to it result in a number of organ dysfunctions and symptoms, including bone pain or fracture, renal failure, susceptibility to infection, anemia, hypercalcemia, and occasionally clotting abnormalities, neurologic symptoms, and manifestations of hyperviscosity.

ETIOLOGY

The cause of myeloma is not known. Myeloma occurred with increased frequency in those exposed to the radiation of nuclear warheads in World War II after a 20-year latency. Myeloma has been seen more commonly than expected among farmers, wood workers, leather workers, and those exposed to petroleum products. A variety of chromosomal alterations have been found in patients with myeloma: hyperdiploidy, 13q14 deletions, translocations t(11;14)(q13;q32), t(4;14)(p16;q32), and t(14;16), 1q amplification or 1p deletion, and 17p13 deletions. Evidence is strong that errors in switch recombination—the genetic mechanism to change antibody heavy chain isotype—participate in the early transformation process. However, no single common molecular pathogenetic pathway has yet emerged. Genome sequencing studies have failed to identify any recurrent

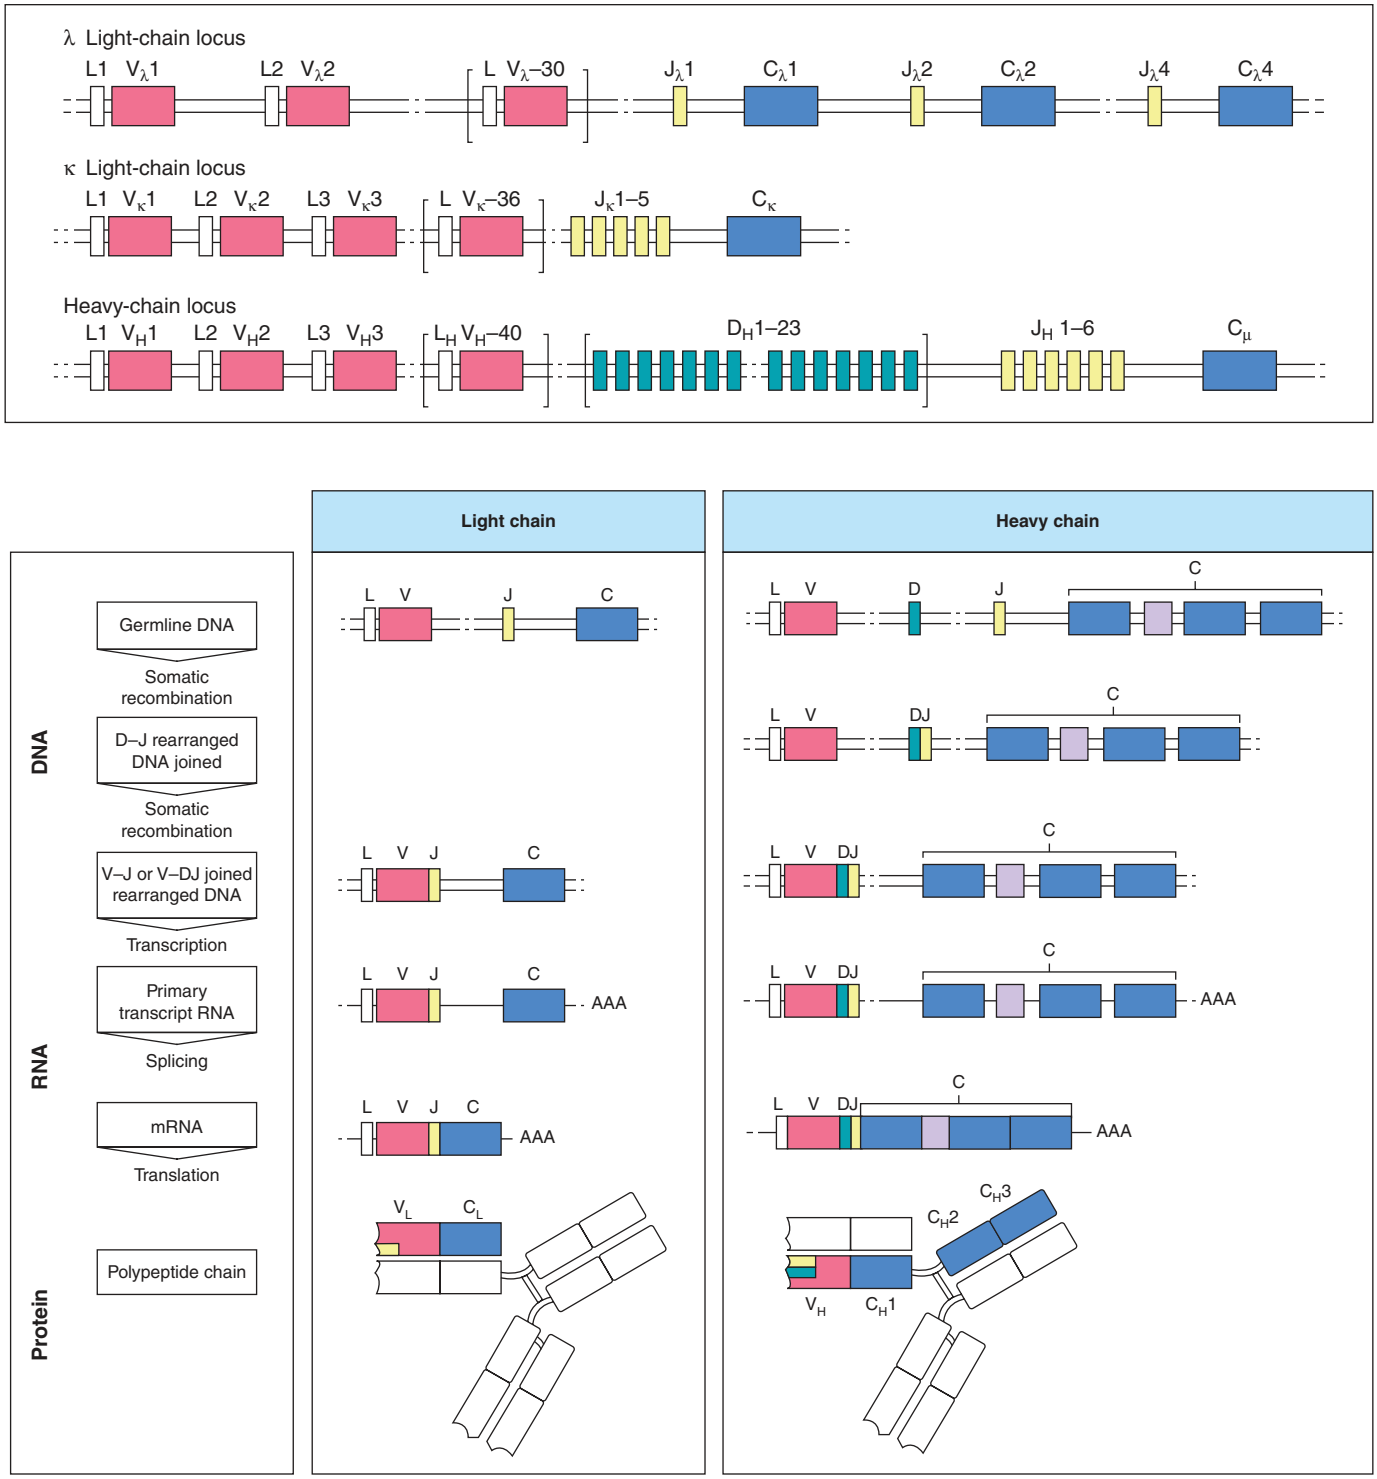

FIGURE 107-1 Immunoglobulin genetics and the relationship of gene segments to the antibody protein. The *top* portion of the figure is a schematic of the organization of the immunoglobulin genes, λ on chromosome 22, κ on chromosome 2, and the heavy chain locus on chromosome 14. The heavy chain locus is >2 megabases, and some of the D region gene segments are only a few bases long, so the figure depicts the schematic relationship among the segments, not their actual size. The *bottom* portion of the figure outlines the steps in going from the noncontiguous germline gene segments to an intact antibody molecule. Two recombination events juxtapose the V-D-J (or V-J for light chains) segments. The rearranged gene is transcribed, and RNA splicing cuts out intervening sequences to produce an mRNA, which is then translated into an antibody light or heavy chain. The sites on the antibody that bind to antigen (the so-called CDR3 regions) are encoded by D and J segments for heavy chains and the J segments for light chains. *(From K Murphy: Janeway's Immunobiology, 8th ed. Garland Science, 2011.)*

mutation with frequency >20%; *N-ras*, *K-ras*, and *B-raf* mutations are most common and combined occur in >40% of patients. Evidence of complex clusters of subclonal variants is present at diagnosis, acquires additional mutations over time, indicative of genomic evolution that may drive disease progression. Interleukin (IL) 6 may play a role in driving myeloma cell proliferation. It remains difficult to distinguish benign from malignant plasma cells based on morphologic criteria in all but a few cases **(Fig. 107-3)**.

INCIDENCE AND PREVALENCE

An estimated 30,280 new cases of myeloma were diagnosed in 2017, and 12,590 people died from the disease in the United States. Myeloma increases in incidence with age. The median age at diagnosis is 69 years; it is uncommon under age 40. Males are more commonly affected than females, and blacks have nearly twice the incidence of whites. Myeloma accounts for 1.3% of all malignancies in whites and 2% in blacks, and 13% of all hematologic cancers in whites and 33% in blacks.

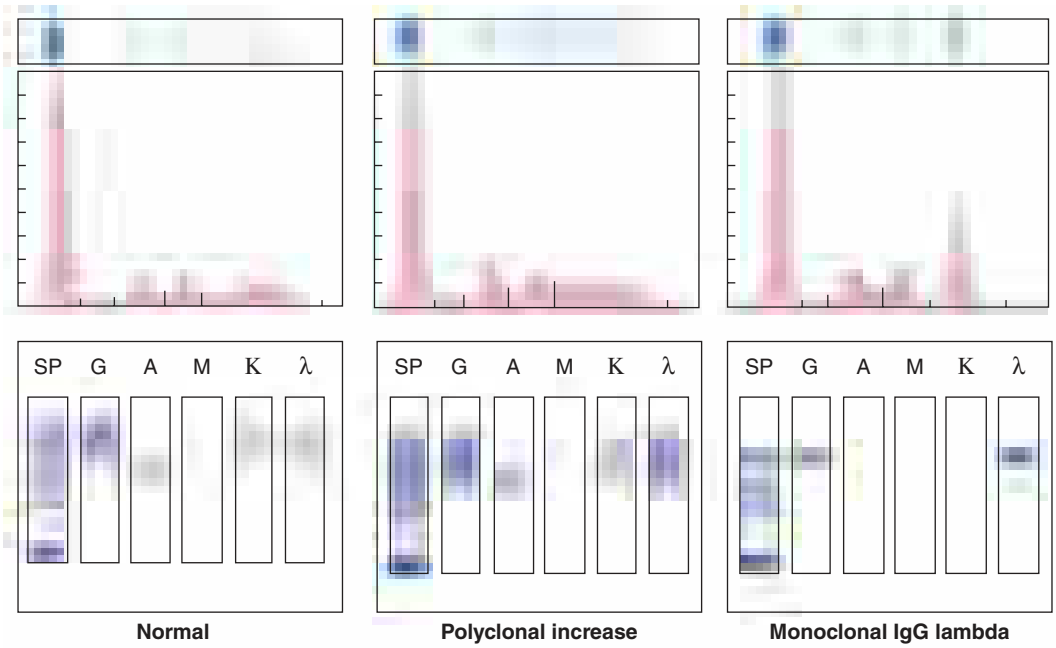

FIGURE 107-2 Representative patterns of serum electrophoresis and immunofixation. The *upper panels* represent agarose gel, middle panels are the densitometric tracing of the gel, and *lower panels* are immunofixation patterns. Panel on the *left* illustrates the normal pattern of serum protein on electrophoresis. Because there are many different immunoglobulins in the serum, their differing mobilities in an electric field produce a broad peak. In conditions associated with increases in polyclonal immunoglobulin, the broad peak is more prominent (*middle panel*). In monoclonal gammopathies, the predominance of a product of a single cell produces a "church spire" sharp peak, usually in the γ globulin region (*right panel*). The immunofixation (*lower panel*) identifies the type of immunoglobulin. For example, normal and polyclonal increase in immunoglobulins produce no distinct bands; however, the *right panel* shows distinct bands in IgG and lambda protein lanes, confirming the presence of IgG lambda monoclonal protein. *(Courtesy of Dr. Neal I. Lindeman; with permission.)*

GLOBAL CONSIDERATIONS

The incidence of myeloma is highest in African Americans and Pacific Islanders; intermediate in Europeans and North American whites; and lowest in people from developing countries including Asia. The higher incidence in more developed countries may result from the combination of a longer life expectancy and more frequent medical surveillance. Incidence of MM in other ethnic groups including native Hawaiians, female Hispanics, American Indians from New Mexico, and Alaskan natives is higher relative to U.S. whites in the same geographic area. Chinese and Japanese populations have a lower incidence than whites. Immunoproliferative small-intestinal disease (IPSID) with alpha heavy chain disease is most prevalent in the Mediterranean area. Despite these differences in prevalence, the characteristics, response to therapy, and prognosis of myeloma are similar worldwide.

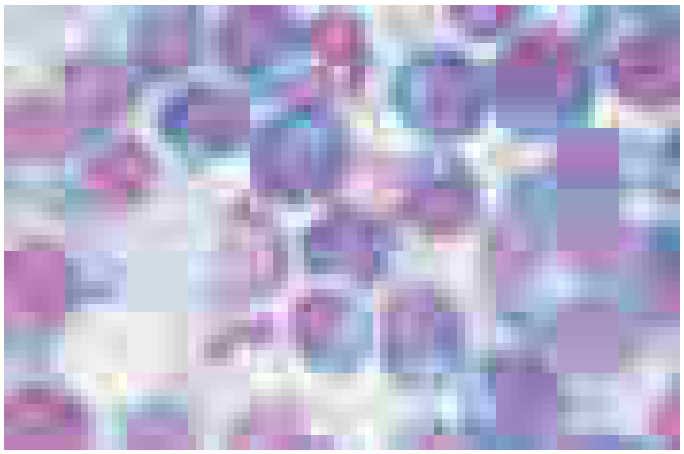

FIGURE 107-3 Multiple myeloma (marrow). The cells bear characteristic morphologic features of plasma cells, round or oval cells with an eccentric nucleus composed of coarsely clumped chromatin, a densely basophilic cytoplasm, and a perinuclear clear zone containing the Golgi apparatus. Binucleate and multinucleate malignant plasma cells can be seen.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

MM cells bind via cell-surface adhesion molecules to bone marrow stromal cells (BMSCs) and extracellular matrix (ECM), which triggers MM cell growth, survival, drug resistance, and migration in the bone marrow milieu **(Fig. 107-4)**. These effects are due both to direct MM cell–BMSC binding via adhesion molecules and to induction of various cytokines, including IL-6, insulin-like growth factor type I (IGF-I), vascular endothelial growth factor (VEGF), and stromal cell–derived growth factor (SDF)-1α. Growth, drug resistance, and migration are mediated via Ras/Raf/mitogen-activated protein kinase, PI3K/Akt, and protein kinase C signaling cascades, respectively.

Bone pain is the most common symptom in myeloma, affecting nearly 70% of patients. Persistent localized pain usually signifies a pathologic fracture. The bone lesions of myeloma are caused by the proliferation of tumor cells, activation of osteoclasts that destroy bone, and suppression of osteoblasts that form new bone. The increased osteoclast activity is mediated by osteoclast activating factors (OAFs) produced by the myeloma cells (mediated by several cytokines, including IL-1, lymphotoxin, VEGF, receptor activator of NF-κB [RANK] ligand, macrophage inhibitory factor [MIP]-1α, and tumor necrosis factor [TNF]). The bone lesions are lytic in nature **(Fig. 107-5)** and are rarely associated with osteoblastic new bone formation due to their suppression by dickhoff-1 (DKK-1) produced by myeloma cells. Therefore, radioisotopic bone scanning is less useful in diagnosis than is plain radiography. The bony lysis results in substantial mobilization of calcium from bone, and serious acute and chronic complications of hypercalcemia may dominate the clinical picture (see below). Localized bone lesions may cause the collapse of vertebrae leading to spinal cord compression. The next most common clinical problem in patients with myeloma is susceptibility to bacterial infections. The most common infections are pneumonias and pyelonephritis, and the most frequent pathogens are *Streptococcus pneumoniae, Staphylococcus aureus*, and *Klebsiella pneumoniae* in the lungs and *Escherichia coli* and other gram-negative organisms in the urinary tract. In ~25% of patients, recurrent infections are the presenting features, and >75% of patients will have a serious infection at some time in their course. The susceptibility to infection has several contributing causes. First, patients with myeloma have diffuse hypogammaglobulinemia if

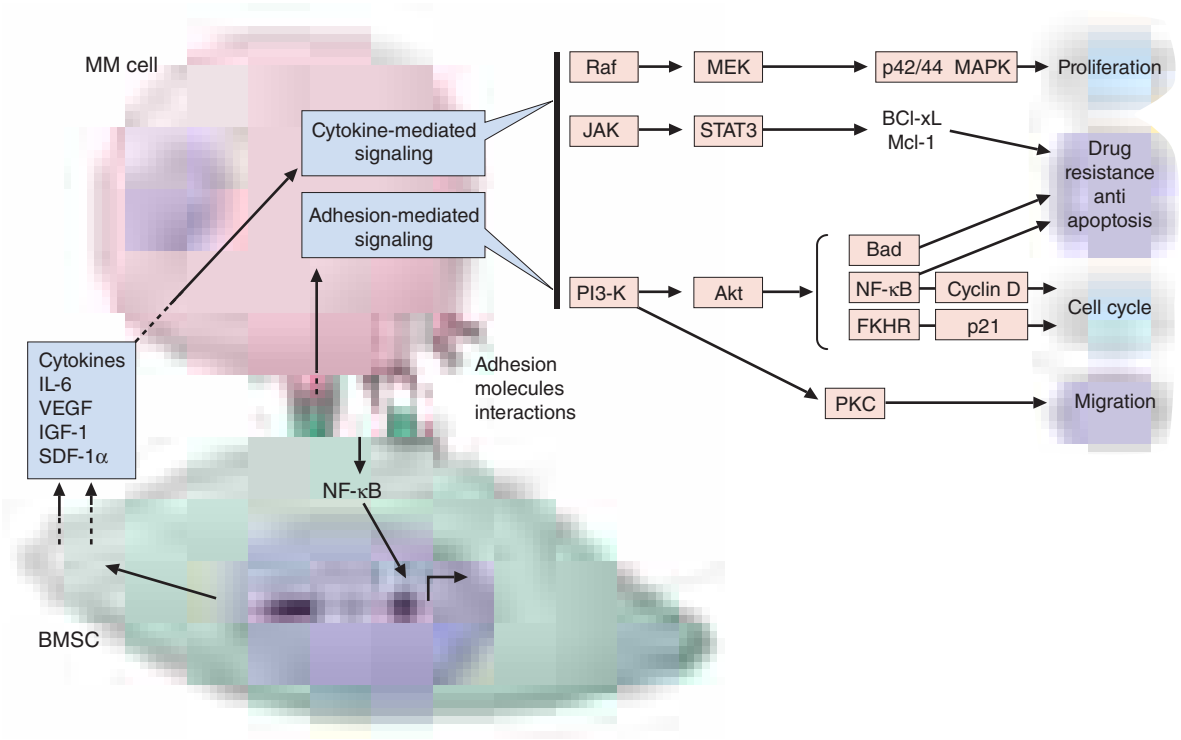

FIGURE 107-4 Pathogenesis of multiple myeloma. Multiple myeloma (MM) cells interact with bone marrow stromal cells (BMSCs) and extracellular matrix proteins via adhesion molecules, triggering adhesion-mediated signaling as well as cytokine production. This triggers cytokine-mediated signaling that provides growth, survival, and antiapoptotic effects as well as development of drug resistance.

the M component is excluded. The hypogammaglobulinemia is related to both decreased production and increased destruction of normal antibodies. The large M component results in fractional catabolic rates of 8–16% instead of the normal 2%. Moreover, some patients generate a population of circulating regulatory cells in response to their myeloma that can suppress normal antibody synthesis. These patients have very poor antibody responses, especially to polysaccharide antigens such as those on bacterial cell walls. Various abnormalities in T-cell function are also observed including decreased Th_1 response, increase in Th17 cells producing proinflammatory cytokines, and aberrant T_{reg} cell function. Granulocyte lysozyme content is low, and granulocyte migration is not as rapid as normal in patients with myeloma, probably the result of a tumor product. There are also a variety of abnormalities in complement functions in myeloma patients. All these factors contribute to the immune deficiency in these patients. Some commonly used therapeutic agents, e.g., dexamethasone, suppress immune responses and increase susceptibility to bacterial and fungal infection, and bortezomib predisposes to herpesvirus reactivation.

Renal failure occurs in nearly 25% of myeloma patients, and some renal pathology is noted in >50%. Of many contributing factors, hypercalcemia is the most common cause of renal failure. Glomerular deposits of amyloid, hyperuricemia, recurrent infections, frequent use of nonsteroidal anti-inflammatory agents for pain control, use of iodinated contrast dye for imaging, bisphosphonate use, and occasional infiltration of the kidney by myeloma cells all may contribute to renal dysfunction. However, tubular damage associated with the excretion of light chains is almost always present. Normally, light chains are filtered, reabsorbed in the tubules, and catabolized. With the increase in the amount of light chains presented to the tubule, the tubular cells become overloaded with these proteins, and tubular damage results either directly from light chain toxic effects or indirectly from the release of intracellular lysosomal enzymes. The earliest manifestation of this tubular damage is the adult Fanconi's syndrome (a type 2 proximal renal tubular acidosis), with loss of glucose and amino acids, as well as defects in the ability of the kidney to acidify and concentrate the urine. The proteinuria is not accompanied by hypertension, and the protein is nearly all light chains. Generally, very little albumin is in the urine because glomerular function is usually normal. When the glomeruli are involved, nonselective proteinuria is also observed. Patients with myeloma also have a decreased anion gap [i.e., $Na^+ - (Cl^- + HCO_3^-)$] because the M component is cationic, resulting in retention of chloride. This is often accompanied by hyponatremia that is felt to be artificial (pseudohyponatremia) because each volume of serum has less water as a result of the increased protein. Renal dysfunction due to light chain deposition disease, light chain cast nephropathy, and amyloidosis is partially reversible with effective therapy. Myeloma patients are susceptible to developing acute renal failure if they become dehydrated.

Normocytic and normochromic anemia occurs in ~80% of myeloma patients. It is usually related to the replacement of normal marrow by expanding tumor cells, to the inhibition of hematopoiesis by factors made by the tumor, to reduced production of erythropoietin by the kidney, and to the effects of long-term therapy. In addition, mild hemolysis may contribute to the anemia. A larger than expected fraction of patients may have megaloblastic anemia due to either folate or vitamin B_{12} deficiency. Granulocytopenia and thrombocytopenia are rare except when therapy-induced. Clotting abnormalities may be seen due to the failure of antibody-coated platelets to function properly; the interaction of the M component with clotting factors I, II, V, VII, or VIII; antibody to clotting factors; or amyloid damage of endothelium. Deep venous thrombosis is also observed with use of thalidomide, lenalidomide, or pomalidomide in combination with dexamethasone. Raynaud's phenomenon and impaired circulation may result if the M component forms cryoglobulins, and hyperviscosity syndromes may develop depending on the physical properties of the M component (most common with IgM, IgG3, and IgA paraproteins). Hyperviscosity is defined based on the relative viscosity of serum as compared with water. Normal relative serum viscosity is 1.8 (i.e., serum is normally almost twice as viscous as water). Symptoms of hyperviscosity occur at a level greater than 4 centipoise (cP), which is usually reached at paraprotein concentrations of ~40 g/L (4 g/dL) for IgM, 50 g/L (5 g/dL) for IgG3, and 70 g/L (7 g/dL) for IgA; however, depending on chemical and physical properties of the paraprotein molecule, it can occasionally be observed at lower levels.

B

FIGURE 107-5 Bony lesions in multiple myeloma (MM). ***A.*** The skull demonstrates the typical "punched out" lesions characteristic of MM. The lesion represents a purely osteolytic lesion with little or no osteoblastic activity (above). ***B.*** PET/CT showing multiple fluorodeoxyglucose (FDG)-avid lesions in skeleton (left panel) with their resolution on achieving complete response (CR) (right panel). *(Part A courtesy of Dr. Geraldine Schechter; with permission. Part B courtesy of Dr. Sundar Jagannath; with permission.)*

Although neurologic symptoms occur in a minority of patients, they may have many causes. Hypercalcemia may produce lethargy, weakness, depression, and confusion. Hyperviscosity may lead to headache, fatigue, shortness of breath, exacerbation or precipitation of heart failure, visual disturbances, ataxia, vertigo, retinopathy, somnolence, and coma. Bony damage and collapse may lead to cord compression, radicular pain, and loss of bowel and bladder control. Infiltration of peripheral nerves by amyloid can be a cause of carpal tunnel syndrome and other sensorimotor mono- and polyneuropathies. Neuropathy associated with monoclonal gammopathy of undetermined significance (MGUS) and myeloma is more frequently sensory than motor neuropathy and is associated with IgM more than other isotypes. In >50% of patients with neuropathy, the IgM monoclonal protein is directed against myelin-associated globulin (MAG). Sensory neuropathy is also a side effect of therapy, specifically thalidomide and bortezomib.

Many of the clinical features of myeloma, e.g., cord compression, pathologic fractures, hyperviscosity, sepsis, and hypercalcemia, can present as medical emergencies. Despite the widespread distribution of plasma cells in the body, tumor expansion is dominantly within bone and bone marrow and, for reasons unknown, rarely causes enlargement of spleen, lymph nodes, or gut-associated lymphatic tissue.

DIAGNOSIS AND STAGING

The diagnosis of myeloma requires marrow plasmacytosis (>10%), a serum and/or urine M component, and at least one of the myeloma defining events detailed in **Table 107-1**. Bone marrow plasma cells are CD138+ and either monoclonal kappa or lambda light chain positive. The most important differential diagnosis in patients with myeloma involves their separation from individuals with MGUS or smoldering multiple myeloma (SMM). MGUS is vastly more common than myeloma, occurring in 1% of the population aged >50 years and in up to 10% of individuals aged >75 years. The diagnostic criteria for MGUS, SMM, and myeloma are described in Table 107-1. Although ~1% of patients per year with MGUS go on to develop myeloma, all cases of myeloma are preceded by MGUS. Non-IgG subtype, abnormal kappa/lambda free light chain ratio, and serum M protein >15 g/L (1.5 g/dL) are associated with higher incidence of progression of MGUS to myeloma. Absence of all three features predicts a 5% chance of progression, whereas higher risk MGUS with the presence of all three features predicts a 60% chance of progression >20 years. The features responsible for higher risk of progression from SMM to MM are bone marrow plasmacytosis >10%, abnormal kappa/lambda free light chain ratio, and serum M protein >30 g/L (3 g/dL). Patients with only one of these three features have a 25% chance of progression to MM in 5 years, whereas patients with high-risk SMM with all three features have a 76% chance of progression. There are two important variants of myeloma—solitary bone plasmacytoma and solitary extramedullary plasmacytoma. These lesions are associated with an M component in <30% of the cases, they may affect younger individuals, and both are associated with median survivals of ≥10 years. Solitary bone plasmacytoma is a single lytic bone lesion without marrow plasmacytosis. Extramedullary plasmacytomas usually involve the submucosal lymphoid tissue of the nasopharynx or paranasal sinuses without marrow plasmacytosis. Both tumors are highly responsive to local radiation therapy. If an M component is present, it should disappear after treatment. Solitary bone plasmacytomas may recur in other bony sites or evolve into myeloma. Extramedullary plasmacytomas rarely recur or progress.

Serum protein electrophoresis and measurement of serum immunoglobulins and free light chains are useful for detecting and characterizing M spikes, supplemented by immunoelectrophoresis, which is especially sensitive for identifying low concentrations of M components not detectable by protein electrophoresis. A 24-h urine specimen is necessary to quantitate Bence Jones protein excretion. Serum alkaline phosphatase is usually normal even with extensive bone involvement because of the absence of osteoblastic activity. It is also important to quantitate serum β_2-microglobulin and albumin (see below).

The serum M component will be IgG in 53% of patients, IgA in 25%, and IgD in 1%; 20% of patients will have only light chains in serum and urine. Dipsticks for detecting proteinuria are not reliable at identifying light chains, and the heat test for detecting Bence Jones protein is falsely negative in ~50% of patients with light chain myeloma. Fewer than 1% of patients have no identifiable M component; these patients usually have light chain myeloma in which renal catabolism has made the light chains undetectable in the urine. In most of these patients, light chains can now be detected by serum free light chain assay. IgD myeloma may also present with light chain disease. About two-thirds of patients with serum M components also have urinary light chains. The light chain isotype may have an impact on disease behavior. Whether this is due to some genetically important determinant of cell proliferation or because lambda light chains are more likely to cause renal damage and form amyloid than are kappa light chains is unclear. The heavy chain

TABLE 107-1 Diagnostic Criteria for Multiple Myeloma, Myeloma Variants, and Monoclonal Gammopathy of Undetermined Significance

Monoclonal Gammopathy of Undetermined Significance (MGUS)
Serum monoclonal protein (non-IgM type) <30 g/L
Clonal bone marrow plasma cells <10%*
Absence of myeloma defining events or amyloidosis that can be attributed to the plasma cell proliferative disorder
Smoldering Multiple Myeloma (Asymptomatic Myeloma)
Both criteria must be met: • Serum monoclonal protein (IgG or IgA) ≥30 g/L or urinary monoclonal protein ≥500 mg per 24 h and/or clonal bone marrow plasma cells 10–60% • Absence of myeloma defining events or amyloidosis
Symptomatic Multiple Myeloma

Clonal bone marrow plasma cells or biopsy-proven bony or extramedullary plasmacytoma[a] and any one or more of the following myeloma defining events:
• Evidence of one or more end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:
  • Hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)
  • Renal insufficiency: creatinine clearance <40 mL per min[b] or serum creatinine >177 μmol/L (>2 mg/dL)
  • Anemia: hemoglobin value of >20 g/L below the lower limit of normal, or a hemoglobin value <100 g/L
  • Bone lesions: one or more osteolytic lesions on skeletal radiography, CT, or PET-CT[c]
  • Any one or more of the following biomarkers of malignancy:
  • Clonal bone marrow plasma cell percentage[a] ≥60%
  • Involved: uninvolved serum free light chain ratio[d] ≥100
  • >1 focal lesions on MRI studies[e]

Nonsecretory Myeloma
No M protein in serum and/or urine with immunofixation[f] Bone marrow clonal plasmacytosis ≥10% or plasmacytoma[a] Myeloma-related organ or tissue impairment (end-organ damage, as described above)
Solitary Plasmacytoma
Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells Normal bone marrow with no evidence of clonal plasma cells[a] Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion) Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lymphoplasma cell proliferative disorder
POEMS Syndrome
All of the following four criteria must be met: 1. Polyneuropathy 2. Monoclonal plasma cell proliferative disorder 3. Any one of the following: (a) sclerotic bone lesions; (b) Castleman's disease; (c) elevated levels of vascular endothelial growth factor (VEGF) 4. Any one of the following: (a) organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy); (b) extravascular volume overload (edema, pleural effusion, or ascites); (c) endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, and pancreatic); (d) skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, and white nails); (e) papilledema; (f) thrombocytosis/polycythemia[g]

PET-CT=^{18}F-fluorodeoxyglucose PET with CT. [a]Clonality should be established by showing κ/λ-light-chain restriction on flow cytometry, immunohistochemistry, or immunofluorescence. Bone marrow plasma cell percentage should preferably be estimated from a core biopsy specimen; in case of a disparity between the aspirate and core biopsy, the highest value should be used. [b]Measured or estimated by validated equations. [c]If bone marrow has less than 10% clonal plasma cells, more than one bone lesion is required to distinguish from solitary plasmacytoma with minimal marrow involvement. [d]These values are based on the serum Freelite assay (The Binding Site Group, Birmingham, UK). The involved free light chain must be ≥100 mg/L. [e]Each focal lesion must be 5 mm or more in size. [f]A small M component may sometimes be present. [g]These features should have no attributable other causes and have temporal relation with each other.

Abbreviation: POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes.

isotype may have an impact on patient management as well. About half of patients with IgM paraproteins develop hyperviscosity compared with only 2–4% of patients with IgA and IgG M components. Among IgG myelomas, it is the IgG3 subclass that has the highest tendency to form both concentration- and temperature-dependent aggregates, leading to hyperviscosity and cold agglutination at lower serum concentrations. A standard workup directed at detecting monoclonal plasma cells and myeloma-defining events as well as prognosis is detailed in **Table 107-2**. A complete blood count with differential may reveal anemia. Erythrocyte sedimentation rate is elevated. Rare patients (~1%) may have plasma cell leukemia with >2000 plasma cells/μL. This may be seen in disproportionate frequency in IgD (12%) and IgE (25%) myelomas. Serum calcium, urea nitrogen, creatinine, and uric acid levels may be elevated.

The clinical evaluation of patients with myeloma includes a careful physical examination searching for tender bones and masses. Chest and bone radiographs may reveal lytic lesions or diffuse osteopenia. Magnetic resonance imaging (MRI) offers a sensitive means to document extent of bone marrow infiltration and cord or root compression in patients with pain syndromes. ^{18}F-fluorodeoxyglucose (^{18}F-FDG) PET/CT is a valuable tool to assess bone damage and detect extramedullary sites of the disease (Fig. 107-5). The use of ^{18}F-FDG PET/CT is recommended to distinguish between smoldering and active MM and to confirm a suspected diagnosis of solitary plasmacytoma. It is also a valuable tool to evaluate response in patients with oligo- or nonsecretory myeloma.

PROGNOSIS

Serum β_2-microglobulin is the single most powerful predictor of survival and can substitute for staging. β_2-Microglobulin is the light chain of the class I major histocompatibility antigens (HLA-A, -B, -C) on the surface of every cell. Combination of serum β_2-microglobulin and albumin levels forms the basis for a three-stage International Staging System (ISS) **(Table 107-3)** that predicts survival. With the use of high-dose therapy and the newer agents, the Durie-Salmon staging system is unable to predict outcome and thus is no longer used. High labeling

TABLE 107-2 Standard Investigative Workup in MM

Investigations to Evaluate for Clonal Plasma Cells
Bone marrow aspirate and biopsy (fine needle aspiration of plasmacytoma if indicated)
- Histology
- Clonality by kappa/lambda immunostaining by flow cytometry or immunohistochemistry
Investigations to Evaluate Clonal Paraprotein
Serum protein electrophoresis and immunofixation
Quantitative serum immunoglobulin levels (IgG, IgA, and IgM)
24-h Urine protein electrophoresis and immunofixation
Serum free light chain and ratio
Immunofixation for IgD or IgE in select cases
Investigation to Evaluate End-Organ Damage
Hemogram to assess for anemia
Chemistry panel for renal function and calcium
Skeletal survey to evaluate bone lesions
- PET/CT or MRI if SMM or solitary plasmacytoma with no other MDE or extramedullary disease
Investigation for Risk Stratification
- β-2 microglobulin and serum albumin for ISS stage
- Fluorescent in situ hybridization for hyperdipoidy, del17p, t(4;14); t(14;16), amp1q34, and del 13 on bone marrow sample
- LDH
Specialized Investigation in Selected Cases
Abdominal fat pad for amyloid
Serum viscosity if IgM component or high IgA levels or serum M-component >7 g/dL

Abbreviations: ISS, International Staging System; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET/CT, positron emission tomography/computerized tomography.

TABLE 107-3 Risk Stratification in Myeloma

CHROMOSOMAL ABNORMALITIES		
METHOD	**STANDARD RISK (80%) (EXPECTED SURVIVAL 6–7+ YEARS)**	**HIGH RISK (20%) (EXPECTED SURVIVAL 2–3 YEARS)**
Karyotype	No chromosomal aberration	Any abnormality on conventional karyotype
FISH	t(11;14) t(6:14) Del(13)	Del(17p) t(4:14) t(14:16) t(14;20) amp 1q34

index, circulating plasma cells, performance status, and high levels of lactate dehydrogenase are also associated with poor prognosis.

Other factors that may influence prognosis are the presence of cytogenetic abnormalities and hypodiploidy by karyotype, fluorescent in situ hybridization (FISH)–identified chromosome 17p deletion, and translocations t(4;14), (14;16), and t(14;20) and 1q34 amplification. Chromosome 13q deletion, previously thought to predict poor outcome, is not a predictor following the use of newer agents. The ISS system, along with cytogenetic changes, is the most widely used method for assessing prognosis (Table 107-3). Microarray profiling has formed the basis for RNA-based prognostic staging systems. Genome sequencing efforts have allowed for characterization of critical genes, pathways, and clonal heterogeneity in myeloma. The median number of mutations per transcribed genome in myeloma is around 58. A very heterogeneous mutational landscape with no unifying mutation has been observed. The most frequently mutated genes are *KRAS* and *NRAS* (about 20% each), followed by *TP53, DIS3, FAM46C*, and *BRAF*, all mutated in 5–10% of the patients. All other mutations were observed in <5% of the patients. These results are now being applied to develop new targeted personalized therapies in myeloma.

TREATMENT

Multiple Myeloma

No specific intervention is indicated for patients with MGUS. Follow-up once a year or less frequently is adequate except in higher risk MGUS, where serum protein electrophoresis, complete blood count, creatinine, and calcium should be repeated every 6 months. A patient with MGUS and severe polyneuropathy is considered for therapeutic intervention if a causal relationship can be assumed, especially in the absence of any other potential causes for neuropathy. Therapy can include plasmapheresis and occasionally rituximab in patients with IgM MGUS or myeloma-like therapy in those with IgG or IgA disease. About 10% of patients have smoldering MM (SMM) and will have an indolent course demonstrating only slow progression of disease over many years. For patients with SMM, no specific therapeutic intervention is indicated, although early intervention with lenalidomide and dexamethasone may prevent progression from high-risk SMM to active MM. At present, patients with SMM only require antitumor therapy when myeloma-defining events are identified. Patients with solitary bone plasmacytomas and extramedullary plasmacytomas may be expected to enjoy prolonged disease-free survival after local radiation therapy at a dose of around 40 Gy. Occult marrow involvement may occur at low incidence in patients with solitary bone plasmacytoma. Such patients are usually identified because their serum M component falls slowly or disappears initially after local therapy, only to return after a few months. These patients respond well to systemic therapy.

Patients with symptomatic and/or progressive myeloma require therapeutic intervention. In general, such therapy has two purposes: (1) systemic therapy to control myeloma; and (2) supportive care to control symptoms of the disease, its complications, and adverse effects of therapy. Therapy can significantly prolong survival and improve the quality of life for myeloma patients.

The therapy of myeloma includes an initial induction regimen followed by consolidation and/or maintenance therapy and, on subsequent progression, management of relapsed disease. A number of agents available for use at various stages of the therapy and their doses, schedules, and combinations are detailed in **Table 107-4**. Therapy is partly dictated by the patient's age and comorbidities, which may affect a patient's ability to undergo high-dose therapy and transplantation (**Fig. 107-6**).

Thalidomide, when combined with dexamethasone, achieved responses in two-thirds of newly diagnosed MM patients. Subsequently, lenalidomide, an immunomodulatory derivative of thalidomide, and bortezomib, a proteasome inhibitor, have each been combined with dexamethasone with high response rates (>80%) in newly diagnosed patients with MM. Importantly, their lower toxicity profile with improved efficacy has made them the preferred agents for induction therapy. Efforts to improve the depth of response and the fraction of patients responding have involved using three-drug

TABLE 107-4 Standard Therapeutic Agents in Myeloma

CLASS	AGENT	STANDARD DOSAGE AND ADMINISTRATION	COMBINATION	MYELOMA INDICATION
Immunomodulatory agents	Thalidomide (T)	Oral 50–200 mg qd	TD, VTD	Newly diagnosed and relapsed
	Lenalidomide (R)	Oral 5–25 mg daily × 21 days q 4 week	RD, RVD, DaRD, ERD, KRD, IRD	Relapsed
	Pomalidomide (P)	Oral 2–4 mg daily × 21 days q 4 week	PD	Relapsed
Proteasome inhibitor	Bortezomib (V)	IV or SC 1.3 mg/m^2 days 1, 4, 8, 11 OR 1, 8, 15	VD, VTD, VRD, DaVD, VCD	Newly diagnosed and relapsed
	Carfilzomib (K)	IV 20–56 mg/m^2 days 1, 2, 8, 9, 15, 16 q 4 weeks	KD, KRD	Relapsed
	Ixazomib (I)	Oral 4 mg days 1,8,15	IRD	Relapsed
Antibodies	Daratumumab (Da)	IV 16 mg/kg/week for 8 weeks then every 2 weeks for 16 weeks and then every 4 weeks thereafter	Dara, DaRD, DaVD	Relapsed
	Elotuzumab (E)	IV 10 mg/kg days 1, 8, 15, and 22 for first two cycles then on days 1 and 15. Along with RD	EloRD	Relapsed
Histone deacetylase inhibitor	Panobinostat (Pa)		PaVD	Relapsed
Alkylating agents	Melphalan (M)	Oral melphalan, 0.25 mg/kg per day for 4 days (with Pred) every 4–6 weeks	MP, MPT, MPR, MPV, high-dose M	Newly diagnosed and relapsed conditioning
	Cyclophosphamide (C)	IV—300–500 mg/m^2 weekly × 2 q 4 weeks Oral—50 mg qd × 21 days	VCD	Newly diagnosed and relapsed
	Bendamustine (B)	IV 70–90 mg days 1, 2 or days 1, 8 q 4 weeks	BD or BVD	Relapsed
Steroid	Dexamethasone (D) Prednisone (P)	Oral 10–40 mg q week Oral 1 mg/kg		All stages

regimens. The combination of lenalidomide, bortezomib, and dexamethasone achieves close to a 100% response rate and 30% complete response (CR) rate, making it one of the preferred induction regimens in transplant-eligible patients. Other similar three-drug combinations (bortezomib, thalidomide, and dexamethasone or bortezomib, cyclophosphamide, and dexamethasone) also achieve >90% response rate. Herpes zoster prophylaxis is indicated if bortezomib is used, and neuropathy attendant to bortezomib can be decreased both by its subcutaneous administration and administration on a weekly schedule. Lenalidomide use requires prophylaxis for deep-vein thrombosis (DVT) with either aspirin or if patients are at a greater risk of DVT, warfarin or low-molecular-weight heparin.

In patients receiving lenalidomide, stem cells should be collected within 6 months, because the continued use of lenalidomide may compromise the ability to collect adequate numbers of stem cells. Initial therapy is continued until maximal cytoreduction. In patients who are transplant candidates, alkylating agents such as melphalan should be avoided because they damage stem cells, leading to decreased ability to collect stem cells for autologous transplant.

In patients who are not transplant candidates due to physiologic age >70 years, significant cardiopulmonary problems, or other comorbid illnesses, the same two- or three-drug combinations described above are considered standard of care as induction therapy. Previously, therapy consisting of intermittent pulses of

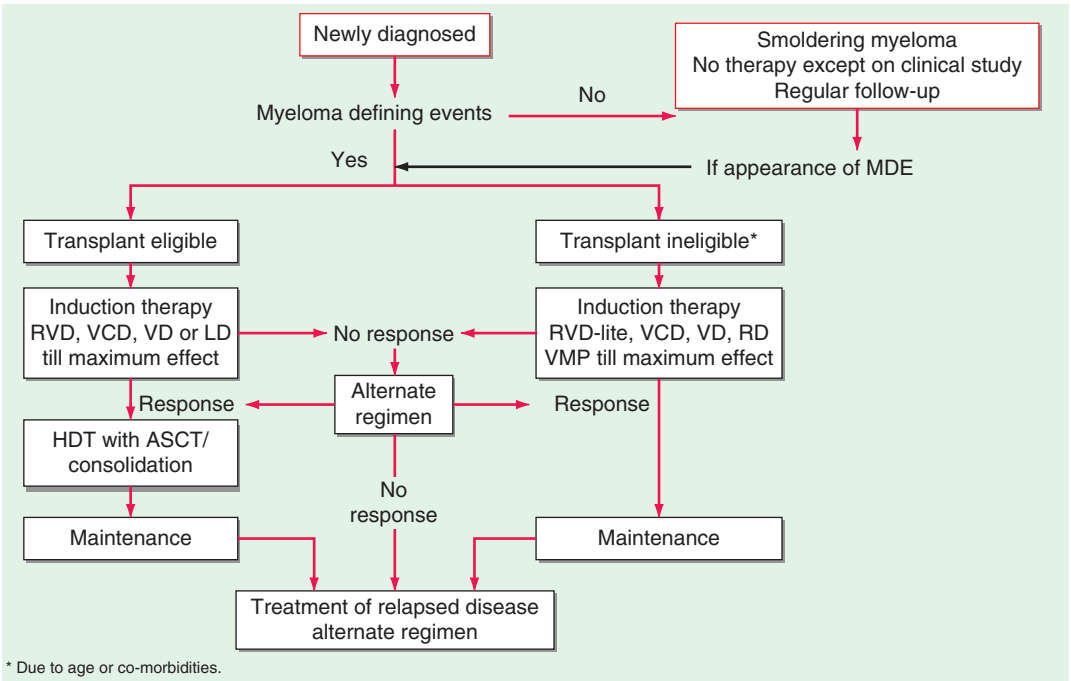

FIGURE 107-6 Treatment algorithm for multiple myeloma. C, cyclophosphamide; D, dexamethasone; M, melphalan; P, prednisone; R, lenalidomide; RVD-lite, weekly regimen; V, bortezomib. Alternate regimen-combinations including daratumumab; elotuzumab; panobinostat; carfilzomib; ixazomib, pomalidomide or agents; ASCT, autologous stem cell transplantation; HDT, high-dose therapy; MDE, myeloma defining events.

melphalan, an alkylating agent, with prednisone (MP) was used. However, a number of studies have combined novel agents with MP and reported superior response and survival outcomes. In patients >65 years old, combining thalidomide with MP (MPT) obtains higher response rates and overall survival compared with MP alone. Similarly, significantly improved response (71 vs 35%) and overall survival (3-year survival 72 vs 59%) were observed with the combination of bortezomib and MP compared with MP alone. Lenalidomide added to MP followed by lenalidomide maintenance also prolonged progression-free survival compared with MP alone. These combinations of novel agents with MP also achieve high CR rates (MPT, ~15%; MP plus bortezomib, ~30%; MP plus lenalidomide, ~20%; and MP, ~2–4%). Continuous use of the lenalidomide and dexamethasone combination appears to be superior to the MPT regimen, making it a standard of care for older adults with myeloma.

High-dose therapy (HDT) and consolidation/maintenance are standard practice in the majority of eligible patients. Randomized studies comparing standard-dose therapy to high-dose melphalan therapy with hematopoietic stem cell support have shown that HDT can achieve high overall response rates, with up to 25–40% additional CRs and prolonged progression-free and overall survival; however, few, if any, patients are cured. Although two successive HDTs (tandem transplantations) are more effective than single HDT, the benefit is only observed in the subset of patients who do not achieve a complete or very good partial response to the first transplantation, which is rare. Moreover, a randomized study failed to show any significant difference in overall survival between early transplantation after induction therapy versus delayed transplantation at relapse. These data allow an option to delay transplantation, especially with the availability of more agents and combinations. Allogeneic transplantations may also produce high response rates, but with significant toxicities. Nonmyeloablative allogeneic transplantation can reduce toxicity but is recommended only under the auspices of a clinical trial to exploit an immune graft-versus-myeloma effect while avoiding attendant toxicity.

Maintenance therapy prolongs remissions following standard-dose regimens as well as HDT. Two phase 3 studies have demonstrated improved progression-free survival, and one study showed prolonged overall survival in patients receiving lenalidomide compared to placebo as maintenance therapy after HDT. In nontransplant candidates, two phase 3 studies showed prolonged progression-free survival with lenalidomide maintenance after MP plus lenalidomide or lenalidomide with dexamethasone induction therapy. Although concern arises regarding an increased incidence of second primary malignancies in patients receiving lenalidomide maintenance, its benefits in reducing the risk of progressive disease and death from myeloma far outweigh the small increased risk of second cancers. In patients with high-risk cytogenetics, lenalidomide and bortezomib have been combined and show promise as maintenance therapy after transplantation.

Relapsed myeloma can be treated with a number of agents including lenalidomide and/or bortezomib, if previously not used. These agents in combination with dexamethasone can achieve a partial response rate of up to 60% and a 10–15% CR rate in patients with relapsed disease. The combination of bortezomib and liposomal doxorubicin is active in relapsed myeloma. Thalidomide, if not used as initial therapy, can achieve responses in refractory cases. The second-generation proteasome inhibitor carfilzomib and immunomodulatory agent pomalidomide have shown efficacy in relapsed and refractory MM, even MM refractory to lenalidomide and bortezomib. An oral proteasome inhibitor, ixazomib has also been approved in combination with lenalidomide and dexamethasone as an all-oral regimen for relapsed MM. Two antibodies are approved for treatment of relapsed MM. Daratumumab targeting CD38 achieves high response rates and improved progression-free survival as a single agent with further improvement in response and survival when added to bortezomib and dexamethasone, or lenalidomide and dexamethasone. Elotuzumab targeting SLAMF7 has shown significant activity in combination with lenalidomide and dexamethasone in relapsed/refractory myeloma but not as a single agent. Panobinostat, a histone deacetylase inhibitor, in combination with bortezomib and dexamethasone has been approved for treatment of relapsed refractory myeloma based on superior response and progression-free survival compared to bortezomib and dexamethasone alone. Incorporation of the large number of active agents at various stages of therapies including in the newly diagnosed patients is improving survival as well as quality of life.

Improvement in the serum M component may lag behind the symptomatic improvement due to longer half-life (~3 weeks) of the immunoglobulin. The fall in M component depends on the rate of tumor kill and the fractional catabolic rate of immunoglobulin. Light chain excretion, with a functional half-life of ~6 h, may fall within the first week of treatment. Because urine light chain levels may relate to renal tubular function, they are not a reliable measure of tumor cell kill in patients with renal dysfunction; however, improvements in serum free light chain measurement are often seen sooner. Sequencing- and multicolor flow cytometry-based methods are now used to assess minimal residual disease (MRD) in bone marrow. Absence of MRD predicts longer survival. Although patients may not achieve complete remission, clinical responses may last for long periods of time.

The median overall survival of patients with myeloma is 8+ years, with subsets of younger patients surviving >10 years. The major causes of death are progressive myeloma, renal failure, sepsis, or therapy-related myelodysplasia. Nearly a quarter of patients die of myocardial infarction, chronic lung disease, diabetes, or stroke—all intercurrent illnesses related more to the age of the patient group than to the tumor.

Supportive care directed at the anticipated complications of the disease may be as important as primary antitumor therapy. Hypercalcemia generally responds well to bisphosphonates, glucocorticoid therapy, hydration, and natriuresis, and rarely requires calcitonin as well. Bisphosphonates (e.g., pamidronate 90 mg or zoledronate 4 mg initially once a month and later less frequently) reduce osteoclastic bone resorption and preserve performance status and quality of life, decrease bone-related complications, and may also have antitumor effects. Osteonecrosis of the jaw and renal dysfunction can occur in a minority of patients receiving bisphosphonate therapy. Treatments aimed at strengthening the skeleton such as fluorides, calcium, and vitamin D, with or without androgens, have been suggested, but are not of proven efficacy. Kyphoplasty or vertebroplasty should be considered in patients with painful collapsed vertebra. Iatrogenic worsening of renal function may be prevented by maintaining a high fluid intake to prevent dehydration and enhance excretion of light chains and calcium. In the event of acute renal failure, plasmapheresis is ~10 times more effective at clearing light chains than peritoneal dialysis; however, its role in reversing renal failure remains controversial. Importantly, reducing the protein load by effective antitumor therapy with agents such as bortezomib may result in improvement in renal function in over half of the patients. Use of lenalidomide in renal failure is possible but requires dose modification, as it is renally excreted. Urinary tract infections should be watched for and treated early. Plasmapheresis may be the treatment of choice for hyperviscosity syndromes. Although the pneumococcus is a dreaded pathogen in myeloma patients, pneumococcal polysaccharide vaccines may not elicit an antibody response. The pneumococcal conjugate vaccines may be more protective. Prophylactic administration of intravenous γ globulin preparations is used in the setting of recurrent serious infections. Chronic oral antibiotic prophylaxis is not warranted. Patients developing neurologic symptoms in the lower extremities, severe localized back pain, or problems with bowel and bladder control may need emergency MRI and local radiation therapy and glucocorticoids if cord compression is identified. In patients in whom neurologic deficit is increasing or substantial, emergent surgical decompression may be necessary. Most bone lesions respond to analgesics and systemic therapy, but certain painful lesions may respond most promptly to localized

radiation. The anemia associated with myeloma may respond to erythropoietin along with hematinics (iron, folate, cobalamin). The pathogenesis of the anemia should be established and specific therapy instituted, whenever possible.

WALDENSTRÖM'S MACROGLOBULINEMIA

In 1948, Waldenström described a malignancy of lymphoplasmacytoid cells that secreted IgM. In contrast to myeloma, the disease was associated with lymphadenopathy and hepatosplenomegaly, but the major clinical manifestation was hyperviscosity syndrome. The disease resembles the related diseases CLL, myeloma, and lymphocytic lymphoma. It originates from a postgerminal center B cell that has undergone somatic mutations and antigenic selection in the lymphoid follicle and has the characteristics of an IgM-bearing memory B cell. Waldenström's macroglobulinemia (WM) and IgM myeloma follow a similar clinical course, but therapeutic options are different. The diagnosis of IgM myeloma is usually reserved for patients with lytic bone lesions and predominant infiltration with CD138+ plasma cells in the bone marrow. Such patients are at greater risk of pathologic fractures than patients with WM.

A familial occurrence is common in WM, but its molecular bases are yet unclear. A distinct *MYD88* L265P somatic mutation is present in >90% of patients with WM and the majority of IgM MGUS. Other commonly occurring mutations include *CXCR4* (30–40%), *ARID1A* (17%), and *CD79B* (8–15%). Presence of *MYD88* mutation status is now used as a diagnostic test to discriminate WM from marginal zone lymphomas (MZLs), IgM-secreting myeloma, and CLL with plasmacytic differentiation. This mutation also explains the molecular pathogenesis of the disease, with involvement of Toll-like receptor (TLR) and interleukin 1 receptor (IL-1R) signaling leading to activation of IL-1R–associated kinase (IRAK) 4 and IRAK1 followed by nuclear factor-κB (NF-κB) activation. *MYD88* mutation also triggers Burton's tyrosine kinase (BTK), hemopoietic cell kinase (HCK) growth, and survival signaling, which are now important therapeutic targets in WM. *CXCR4* mutations induce AKT and extracellular regulated kinase-1/2 (ERK 1/2) signaling. This pathway can lead to development of drug resistance in the presence of its ligand CXCL12.

The disease is similar to myeloma in being slightly more common in men and occurring with increased incidence with increasing age (median 64 years). The IgM in some patients with macroglobulinemia may have specificity for myelin-associated glycoprotein (MAG), a protein that has been associated with demyelinating disease of the peripheral nervous system and may be lost earlier and to a greater extent than the better known myelin basic protein in patients with multiple sclerosis. Sometimes patients with macroglobulinemia develop a peripheral neuropathy, and half of these patients are positive for anti-MAG antibody. The neuropathy may precede the appearance of the neoplasm. The whole process may begin with a viral infection that may elicit an antibody response that cross-reacts with a normal tissue component.

Like myeloma, the disease involves the bone marrow, but unlike myeloma, it does not cause bone lesions or hypercalcemia. Bone marrow shows >10% infiltration with lymphoplasmacytic cells (surface IgM+, CD19+, CD20+, and CD22+, rarely CD5+, but CD10− and CD23−) with an increase in number of mast cells. Like myeloma, an M component is present in the serum in excess of 30 g/L (3 g/dL), but unlike myeloma, the size of the IgM paraprotein results in little renal excretion, and only ~20% of patients excrete light chains. Therefore, renal disease is not common. The light chain isotype is kappa in 80% of the cases. Patients present with weakness, fatigue, and recurrent infections similar to myeloma patients, but epistaxis, visual disturbances, and neurologic symptoms such as peripheral neuropathy, dizziness, headache, and transient paresis are much more common in macroglobulinemia. Presence of *MYD88* and *CXCR4* mutations also affects disease presentation. Presence of *CXCR4* mutations is associated with higher bone marrow disease burden and higher incidence of hyperviscosity. Patients with wild-type *MYD88* show lower bone marrow disease burden.

Physical examination reveals adenopathy and hepatosplenomegaly, and ophthalmoscopic examination may reveal vascular segmentation and dilation of the retinal veins characteristic of hyperviscosity states. Patients may have a normocytic, normochromic anemia, but rouleaux formation and a positive Coombs' test are much more common than in myeloma. Malignant lymphocytes are usually present in the peripheral blood. About 10% of macroglobulins are cryoglobulins. These are pure M components and are not the mixed cryoglobulins seen in rheumatoid arthritis and other autoimmune diseases. Mixed cryoglobulins are composed of IgM or IgA complexed with IgG, for which they are specific. In both cases, Raynaud's phenomenon and serious vascular symptoms precipitated by the cold may occur, but mixed cryoglobulins are not commonly associated with malignancy. Patients suspected of having a cryoglobulin based on history and physical examination should have their blood drawn into a warm syringe and delivered to the laboratory in a container of warm water to avoid errors in quantitating the cryoglobulin.

TREATMENT

Waldenström's Macroglobulinemia

Control of serious hyperviscosity symptoms such as an altered state of consciousness or paresis can be achieved acutely by plasmapheresis because 80% of the IgM paraprotein is intravascular. The median survival of affected individuals is ~50 months. However, many patients with WM have indolent disease that does not require therapy. Pretreatment parameters including older age, male sex, general symptoms, and cytopenias define a high-risk population. Treatment is usually not initiated unless the disease is symptomatic or increasing anemia, hyperviscosity, lymphadenopathy, or hepatosplenomegaly is present. Ibrutinib is approved by the U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for use in patients with symptomatic WM. It targets the constitutively activated BTK. In patients with one prior line of therapy, the overall response to ibrutinib was 91%. Best responses to ibrutinib are observed in patients with mutated *MYD88* and wild-type *CXCR4* status, while delayed and lower response rates to ibrutinib are observed in patients with mutated *CXCR4*. The other first line treatments include rituximab (anti-CD20) alone or combined with alkylators (bendamustine and cyclophosphamide), or proteasome inhibitors (bortezomib). Rituximab can produce IgM flare, so either plasmapheresis should be used before rituximab or its use should be initially withheld in patients with high IgM levels. Fludarabine (25 mg/m^2 per day for 5 days every 4 weeks) and cladribine (0.1 mg/kg per day for 7 days every 4 weeks) are also highly effective single agents. With identification of the *MYD88* mutation, inhibitors targeting IRAK1/4 and BCL2 are being evaluated. Although high-dose therapy plus autologous transplantation is an option, its use has declined due to the availability of other effective agents.

POEMS SYNDROME

The features of this syndrome are *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, and *s*kin changes (POEMS). Diagnostic criteria are described in Table 107-1. Patients usually have a severe, progressive sensorimotor polyneuropathy associated with sclerotic bone lesions from myeloma. Polyneuropathy occurs in ~1.4% of myelomas, but the POEMS syndrome is only a rare subset of that group. Unlike typical myeloma, hepatomegaly and lymphadenopathy occur in about two-thirds of patients, and splenomegaly is seen in one-third. The lymphadenopathy frequently resembles Castleman's disease histologically, a condition that has been linked to IL-6 overproduction. The endocrine manifestations include amenorrhea in women and impotence and gynecomastia in men. Hyperprolactinemia due to loss of normal inhibitory control by the hypothalamus may be associated with other central nervous system manifestations such as papilledema and elevated cerebrospinal fluid pressure and protein. Type 2 diabetes mellitus occurs in about one-third of patients. Hypothyroidism and adrenal insufficiency are occasionally noted. Skin changes are diverse: hyperpigmentation, hypertrichosis, skin thickening, and digital clubbing. Other manifestations include peripheral edema, ascites, pleural effusions, fever, and

thrombocytosis. Not all the components of POEMS syndrome may be present initially.

The pathogenesis of the disease is unclear, but high circulating levels of the proinflammatory cytokines IL-1, IL-6, VEGF, and TNF have been documented, and levels of the inhibitory cytokine transforming growth factor β are lower than expected. Treatment of the myeloma may result in an improvement in the other disease manifestations.

Patients are often treated similarly to those with myeloma. Plasmapheresis does not appear to be of benefit in POEMS syndrome. Patients presenting with isolated sclerotic lesions may have resolution of neuropathic symptoms after local therapy for plasmacytoma with radiotherapy. Similar to MM, novel agents and high-dose therapy with autologous stem cell transplantation have been pursued in selected patients and have been associated with prolonged progression-free survival.

HEAVY CHAIN DISEASES

The heavy chain diseases are rare lymphoplasmacytic malignancies. Their clinical manifestations vary with the heavy chain isotype. Patients have absence of light chain and secrete a defective heavy chain that usually has an intact Fc fragment and a deletion in the Fd region. Gamma, alpha, and mu heavy chain diseases have been described, but no reports of delta or epsilon heavy chain diseases have appeared. Molecular biologic analysis of these tumors has revealed structural genetic defects that may account for the aberrant chain secreted.

GAMMA HEAVY CHAIN DISEASE (FRANKLIN'S DISEASE)

This disease affects individuals of widely different age groups and countries of origin. It is characterized by lymphadenopathy, fever, anemia, malaise, hepatosplenomegaly, and weakness. It is frequently associated with autoimmune diseases, especially rheumatoid arthritis. Its most distinctive symptom is palatal edema, resulting from involvement of nodes in Waldeyer's ring, and this may progress to produce respiratory compromise. The diagnosis depends on the demonstration of an anomalous serum M component (often <20 g/L [<2 g/dL]) that reacts with anti-IgG but not antilight chain reagents. The M component is typically present in both serum and urine. Most of the paraproteins have been of the γ_1 subclass, but other subclasses have been seen. The patients may have thrombocytopenia, eosinophilia, and nondiagnostic bone marrow that may show increased numbers of lymphocytes or plasma cells that do not stain for light chain. Patients usually have a rapid downhill course and die of infection; however, some patients have survived 5 years with chemotherapy. Therapy is indicated when symptomatic and involves chemotherapeutic combinations used in low-grade lymphoma. Rituximab has also been reported to show efficacy.

ALPHA HEAVY CHAIN DISEASE (SELIGMANN'S DISEASE)

This is the most common of the heavy chain diseases. It is closely related to a malignancy known as Mediterranean lymphoma, a disease that affects young persons in parts of the world where intestinal parasites are common, such as the Mediterranean, Asia, and South America. The disease is characterized by an infiltration of the lamina propria of the small intestine with lymphoplasmacytoid cells that secrete truncated alpha chains. Demonstrating alpha heavy chains is difficult because the alpha chains tend to polymerize and appear as a smear instead of a sharp peak on electrophoretic profiles. Despite the polymerization, hyperviscosity is not a common problem in alpha heavy chain disease. Without J chain–facilitated dimerization, viscosity does not increase dramatically. Light chains are absent from serum and urine. The patients present with chronic diarrhea, weight loss, and malabsorption and have extensive mesenteric and paraaortic adenopathy. Respiratory tract involvement occurs rarely. Patients may vary widely in their clinical course. Some may develop diffuse aggressive histologies of malignant lymphoma. Chemotherapy may produce long-term remissions. Rare patients appear to have responded to antibiotic therapy, raising the question of the etiologic role of antigenic stimulation, perhaps by some chronic intestinal infection. Chemotherapy plus antibiotics may be more effective than chemotherapy alone. IPSID is recognized as an infectious pathogen–associated human lymphoma that has association with *Campylobacter jejuni*. It involves mainly the proximal small intestine resulting in malabsorption, diarrhea, and abdominal pain. IPSID is associated with excessive plasma cell differentiation and produces truncated alpha heavy chain proteins lacking the light chains as well as the first constant domain. Early-stage IPSID responds to antibiotics (30–70% complete remission). Most untreated IPSID patients progress to lymphoplasmacytic and immunoblastic lymphoma. Patients not responding to antibiotic therapy are considered for treatment with combination chemotherapy used to treat low-grade lymphoma.

MU HEAVY CHAIN DISEASE

The secretion of isolated mu heavy chains into the serum appears to occur in a very rare subset of patients with CLL. The only features that may distinguish patients with mu heavy chain disease are the presence of vacuoles in the malignant lymphocytes and the excretion of kappa light chains in the urine. The diagnosis requires ultracentrifugation or gel filtration to confirm the nonreactivity of the paraprotein with the light chain reagents because some intact macroglobulins fail to interact with these serums. The tumor cells seem to have a defect in the assembly of light and heavy chains because they appear to contain both in their cytoplasm. Such patients are not treated differently from other patients with CLL **(Chap. 104)**.

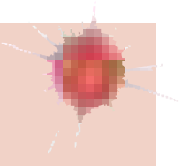
108 Amyloidosis

John L. Berk, Vaishali Sanchorawala



GENERAL PRINCIPLES

Amyloidosis is the term for a group of protein misfolding disorders characterized by the extracellular deposition of insoluble polymeric protein fibrils in tissues and organs. A robust cellular machinery exists to chaperone proteins during the process of synthesis and secretion, to ensure that they achieve correct tertiary conformation and function, and to eliminate proteins that misfold. However, genetic mutation, incorrect processing, and other factors may favor misfolding, with consequent loss of normal protein function and intracellular or extracellular aggregation. Many diseases, ranging from cystic fibrosis to

Alzheimer's disease, are now known to involve protein misfolding. In the amyloidoses, the aggregates are typically extracellular, and the misfolded protein subunits assume a common antiparallel, β-pleated sheet–rich structural conformation that leads to the formation of higher-order oligomers and then fibrils with unique staining properties. The term *amyloid* was coined around 1854 by the pathologist Rudolf Virchow, who thought that these deposits resembled starch (Latin *amylum*) under the microscope.

Amyloid diseases, defined by the biochemical nature of the protein composing the fibril deposits, are classified according to whether they are systemic or localized, whether they are acquired or inherited, and their clinical patterns **(Table 108-1)**. The standard nomenclature is *AX*, where *A* indicates amyloidosis and *X* represents the protein present in the fibril. This chapter focuses primarily on the systemic forms. *AL* refers to amyloid composed of immunoglobulin light chains (LCs); this disorder, formerly termed *primary systemic amyloidosis*, arises from a clonal B cell or plasma cell disorder and can be associated with myeloma or lymphoma. *ATTR* refers to the most prevalent of the *familial amyloidoses*, which are most commonly due to mutations in transthyretin (TTR), the transport protein for thyroid hormone and retinol-binding protein. *AA* amyloid is composed of the acute-phase reactant protein serum amyloid A (SAA) and occurs in the setting of chronic inflammatory or infectious diseases; for this reason, this type was formerly known as *secondary amyloidosis*. *$A\beta_2M$* amyloid results from misfolded β_2-microglobulin, occurring in individuals with long-standing renal disease who have undergone dialysis, typically for years. *Aβ*, the most common form of localized amyloidosis, is found in the brain of patients with Alzheimer's disease after abnormal proteolytic processing and aggregation of polypeptides derived from the amyloid precursor protein.

Diagnosis and treatment of the amyloidoses rest upon the histopathologic identification of amyloid deposits and immunohistochemical, biochemical, or genetic determination of amyloid type **(Fig. 108-1)**. In the systemic amyloidoses, the clinically involved organs can be biopsied, but amyloid deposits may be found in any tissue of the body. Historically, blood vessels of the gingiva or rectal mucosa were often examined, but the most easily accessible tissue—positive in more than 80% of patients with systemic amyloidosis—is abdominal fat. After local anesthesia, fat is aspirated from the abdominal pannus with a 16-gauge needle. Fat globules expelled onto a glass slide can be stained, thus avoiding a surgical procedure. If this material is negative, more invasive biopsies of the kidney, heart, liver, or gastrointestinal tract can be considered in patients in whom amyloidosis is suspected. The regular β-sheet structure of amyloid deposits exhibits a unique "apple green" birefringence by polarized light microscopy when stained with Congo red dye; other regular protein structures (e.g., collagen) appear white under these conditions. The 10-nm-diameter fibrils can also be visualized by electron microscopy of paraformaldehyde-fixed tissue. Once amyloid is found, the precursor protein type must be determined by immunohistochemistry, immunoelectron microscopy, or extraction and biochemical analysis employing mass spectrometry; gene sequencing is used to identify mutants causing hereditary amyloidosis. The patient's history, physical findings, and clinical presentation, including age and ethnic origin, organ system involvement, underlying diseases, and family history, may provide helpful clues as to the type of amyloidosis. However, there can be considerable overlap in clinical presentations, and accurate typing is essential to guide appropriate therapy.

The mechanisms of fibril formation and tissue toxicity remain controversial. The "amyloid hypothesis," as it is currently understood, proposes that precursor proteins undergo a process of reversible unfolding or misfolding; misfolded proteins form oligomeric aggregates, higher-order polymers, and then fibrils that deposit in tissues. Accumulating evidence suggests that the oligomeric intermediates may constitute the most toxic species. Oligomers are more capable than large fibrils of interacting with cells and inducing formation of reactive oxygen species and stress signaling. Ultimately, the fibrillar tissue deposits are likely to interfere with normal organ function. A more sophisticated understanding of the mechanisms leading to amyloid formation and cell and tissue dysfunction will continue to provide new targets for therapies.

The clinical syndromes of the amyloidoses are associated with relatively nonspecific alterations in routine laboratory tests. Blood counts are usually normal, although the erythrocyte sedimentation rate is frequently elevated. Patients with glomerular kidney involvement generally have proteinuria, often in the nephrotic range, leading to

TABLE 108-1 Amyloid Precursor Proteins and Their Clinical Syndromes

DESIGNATION	PRECURSOR	CLINICAL SYNDROME	CLINICAL INVOLVEMENT
Systemic Amyloidoses			
AL	Immunoglobulin light chain	Primary or myeloma-associated[a]	Any
AH	Immunoglobulin heavy chain	Rare variant of primary or myeloma-associated	Any
AA	Serum amyloid A protein	Secondary; reactive[b]	Renal, heart, other
$A\beta_2M$	β_2-Microglobulin	Hemodialysis-associated	Synovial tissue, bone
ATTR	Transthyretin	Familial (mutant)	Cardiac, peripheral and autonomic nerves
		Age-related (wild type)	
AApoAI	Apolipoprotein AI	Familial	Hepatic, renal
AApoAII	Apolipoprotein AII	Familial	Renal
AGel	Gelsolin	Familial	Cornea, cranial nerves, skin, renal
AFib	Fibrinogen Aα	Familial	Renal
ALys	Lysozyme	Familial	Renal, hepatic
ALECT2	Leukocyte chemotactic factor 2	Undefined	Renal
Localized Amyloidoses			
Aβ	Amyloid β protein	Alzheimer's disease; Down's syndrome	Central nervous system
ACys	Cystatin C	Cerebral amyloid angiopathy	Central nervous system, vascular
APrP	Prion protein	Spongiform encephalopathies	Central nervous system
AIAPP	Islet amyloid polypeptide (amylin)	Diabetes-associated	Pancreas
ACal	Calcitonin	Medullary carcinoma of the thyroid	Thyroid
AANF	Atrial natriuretic factor	Atrial fibrillation	Cardiac atria
APro	Prolactin	Endocrinopathy	Pituitary
ASgl	Semenogelin I	Age-related; incidental autopsy or biopsy finding	Seminal vesicles

[a]Localized AL deposits can occur in skin, conjunctiva, urinary bladder, and the tracheobronchial tree. [b]Secondary to chronic inflammation or infection or to a hereditary periodic fever syndrome such as familial Mediterranean fever.

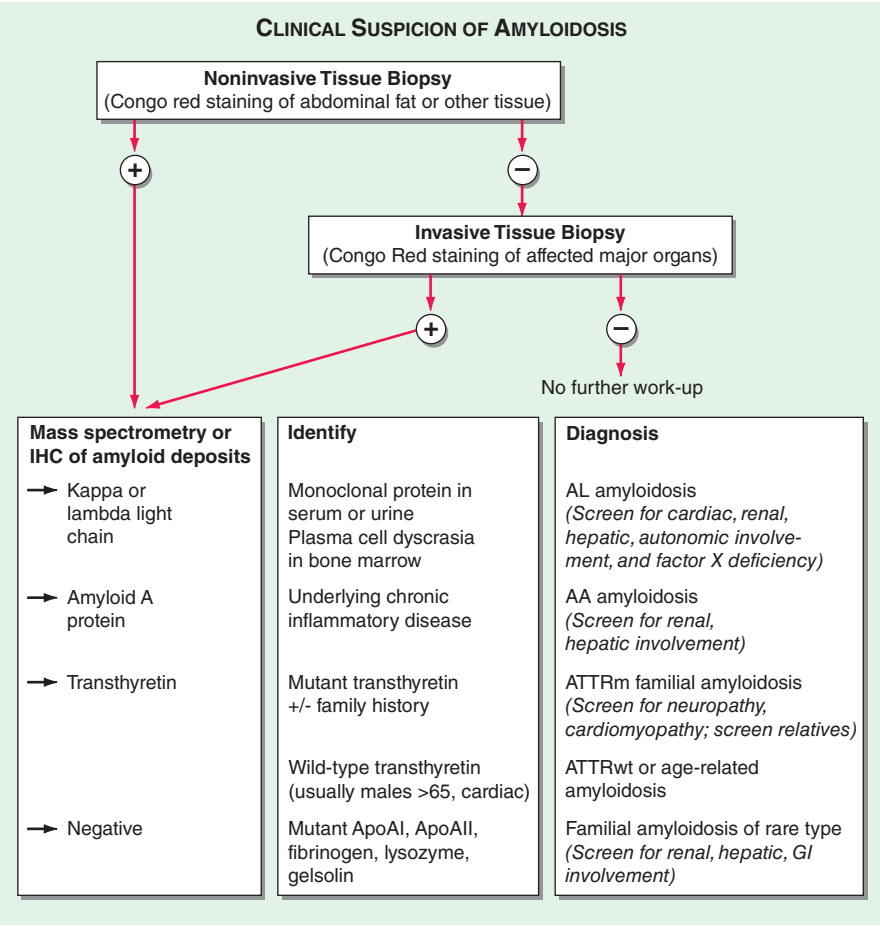


FIGURE 108-1 Algorithm for the diagnosis of amyloidosis and determination of type. Clinical suspicion: unexplained nephropathy, cardiomyopathy, neuropathy, enteropathy, arthropathy, and macroglossia. ApoAI, apolipoprotein AI; ApoAII, apolipoprotein AII; GI, gastrointestinal.

hypoalbuminemia that may be severe; patients with serum albumin levels <2 g/dL generally have pedal edema or anasarca. Amyloid cardiomyopathy is characterized by concentric ventricular hypertrophy and diastolic dysfunction associated with elevation of brain natriuretic peptide or N-terminal pro–brain natriuretic peptide as well as troponin. These cardiac biomarkers can be used for disease staging, prognostication, and disease activity monitoring in patients with AL amyloidosis. Notably, renal insufficiency can falsely elevate levels of these biomarkers. Recently, biomarkers of cardiac remodeling—that is, matrix metalloproteinases and tissue inhibitors of metalloproteinases—have been found to be altered in the serum of patients with amyloid cardiomyopathy. Electrocardiographic and echocardiographic features of amyloid cardiomyopathy are described below. Patients with liver involvement, even when advanced, usually develop cholestasis with an elevated alkaline phosphatase concentration with minimal alteration of the aminotransferases and preservation of synthetic function. In AL amyloidosis, endocrine organs may be infiltrated with fibrils, and hypothyroidism, hypoadrenalism, or even hypopituitarism can occur. Although none of these findings is specific for amyloidosis, the presence of abnormalities in multiple organ systems should raise suspicion regarding this diagnosis.

AL AMYLOIDOSIS

Etiology and Incidence AL amyloidosis is most frequently caused by a clonal expansion of bone-marrow plasma cells that secrete a monoclonal immunoglobulin LC depositing as amyloid fibrils in tissues. Whether the clonal plasma cells produce a LC that misfolds and leads to AL amyloidosis or an LC that folds properly, allowing the cells to inexorably expand over time and develop into multiple myeloma (Chap. 107), may depend upon primary sequence of the clonal LC or other genetic or epigenetic factors. AL amyloidosis can occur with multiple myeloma or other B lymphoproliferative diseases, including non-Hodgkin's lymphoma (Chap. 104) and Waldenström's macroglobulinemia (Chap. 107). AL amyloidosis is the most common type of systemic amyloidosis diagnosed in North America. Its incidence has been estimated at 4.5 cases/100,000 population; however, ascertainment continues to be inadequate, and the true incidence may be much higher. AL amyloidosis, like other plasma cell diseases, usually occurs after age 40 and is often rapidly progressive and fatal if untreated.

Pathology and Clinical Features Amyloid deposits are usually widespread in AL amyloidosis and can be present in the interstitium of any organ outside the central nervous system. The amyloid fibril deposits are composed of full-length 23-kDa monoclonal immunoglobulin LCs as well as fragments. Accessory molecules co-deposited with LC fibrils (as well as with other amyloid fibrils) include serum amyloid P component, apolipoproteins e and AIV, glycosaminoglycans, and metal ions. Although all kappa and lambda LC subtypes have been identified in AL amyloid fibrils, lambda subtypes predominate. The lambda 6 subtype appears to have unique structural properties that predispose it to fibril formation, often in the kidney.

AL amyloidosis is often a rapidly progressive disease that presents as a pleiotropic set of clinical syndromes, recognition of which is key for initiation of the appropriate workup. Nonspecific symptoms of fatigue and weight loss are common; however, the diagnosis is rarely considered until symptoms referable to a specific organ develop. The kidneys are the most frequently involved organ and are affected in 70–80% of patients. Renal amyloidosis usually manifests as proteinuria, often in the nephrotic range and associated with hypoalbuminemia, secondary hypercholesterolemia and hypertriglyceridemia, and edema or anasarca. In some patients, interstitial rather than glomerular amyloid deposition can produce azotemia without proteinuria. The heart is the second most commonly affected organ (50–60% of patients), and cardiac involvement is the leading cause of death from AL amyloidosis. Early on, the electrocardiogram may show low voltage in the limb leads with a pseudo-infarct pattern. Echocardiographic features of disease include concentrically thickened ventricles and diastolic dysfunction with an abnormal global longitudinal strain pattern; a "sparkly" appearance has been described but is often not seen with modern high-resolution echocardiographic techniques. Poor atrial contractility occurs even in sinus rhythm, and patients with cardiac amyloidosis are at risk for development of atrial thrombi and stroke. Cardiac MRI can show increased wall thickness, and characteristic delayed enhancement of the subendocardium has been described following injection of gadolinium contrast. Nervous system symptoms include peripheral sensorimotor neuropathy and/or autonomic dysfunction manifesting as gastrointestinal motility disturbances (early satiety, diarrhea, constipation), dry eyes and mouth, impotence, orthostatic hypotension, and/or neurogenic bladder. Macroglossia (Fig. 108-2*A*), a pathognomonic sign of AL amyloidosis, is seen in only ~10% of patients. Liver involvement causes cholestasis and hepatomegaly. The spleen is frequently involved, and there may be functional hyposplenism in the absence of significant splenomegaly. Many patients experience "easy bruising" due to amyloid deposits in capillaries or deficiency of clotting factor X due to binding to amyloid fibrils; cutaneous ecchymoses appear, particularly around the eyes,

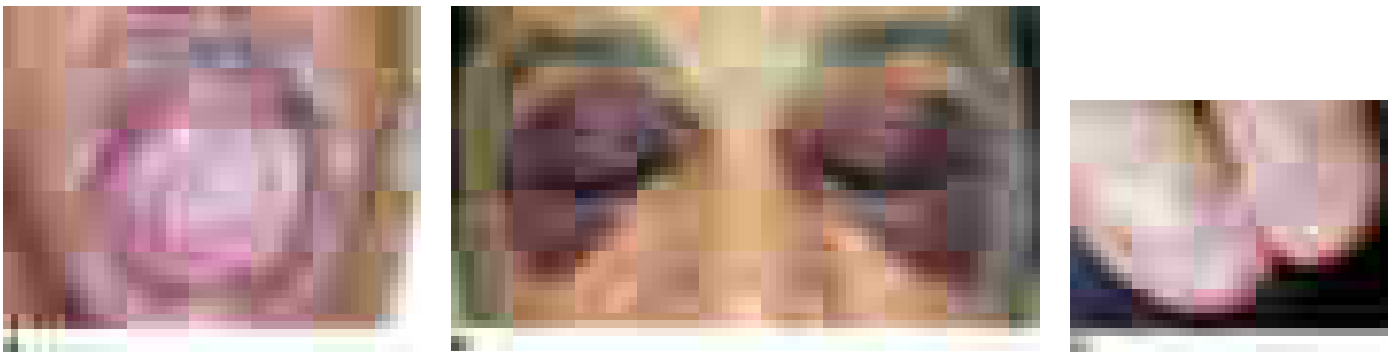

FIGURE 108-2 Clinical signs of AL amyloidosis. *A.* Macroglossia. ***B.*** Periorbital ecchymoses. ***C.*** Fingernail dystrophy.

producing another uncommon but pathognomonic finding, the "raccoon-eye" sign (Fig. 108-2*B*). Other findings include nail dystrophy (Fig. 108-2*C*), alopecia, and amyloid arthropathy with thickening of synovial membranes in the wrists and shoulders. The presence of a multisystemic illness or general fatigue along with any of these clinical syndromes should prompt a workup for amyloidosis.

Diagnosis Identification of an underlying clonal plasma cell or B lymphoproliferative process and a clonal LC are key to the diagnosis of AL amyloidosis. Serum protein electrophoresis and urine protein electrophoresis, although of value in multiple myeloma, are *not* useful screening tests if AL amyloidosis is suspected because the clonal LC or whole immunoglobulin often is not present in sufficient amounts to produce a monoclonal "M-spike" in the serum or LC (Bence Jones) protein in the urine. However, more than 90% of patients with AL amyloidosis have serum or urine monoclonal LC or whole immunoglobulin detectable by immunofixation electrophoresis of serum (SIFE) or urine (UIFE) (Fig. 108-3*A*) or by

A

B

FIGURE 108-3 Laboratory features of AL amyloidosis. *A.* Serum immunofixation electrophoresis reveals an IgGκ monoclonal protein in this example; serum protein electrophoresis is often normal. ***B.*** Bone-marrow biopsy sections stained by immunohistochemistry with antibody to CD138 (syndecan, highly expressed on plasma cells) (*left*) or by in situ hybridization with fluorescein-tagged probes (Ventana Medical Systems) binding to κ mRNA (*center*) and λ mRNA (*right*) in plasma cells. *(Photomicrograph courtesy of C. O'Hara; with permission.)*

nephelometric measurement of serum "free" LCs (i.e., LCs circulating in monomeric form rather than in an immunoglobulin tetramer with heavy chain). Examining the ratio as well as the absolute amount of serum-free LCs is essential, as renal insufficiency reduces LC clearance, nonspecifically elevating both isotypes. In addition, an increased percentage of plasma cells in the bone marrow—typically 5–30% of nucleated cells—is found in ~90% of patients. Kappa or lambda clonality should be demonstrated by flow cytometry, immunohistochemistry, or in situ hybridization for LC mRNA **(Fig. 108-3*B*)**.

A monoclonal serum protein by itself is not diagnostic of amyloidosis, since monoclonal gammopathy of uncertain significance is common in older patients **(Chap. 107)**. However, when monoclonal gammopathy of uncertain significance is found in patients with biopsy-proven amyloidosis, the AL type should be ruled out. Similarly, patients thought to have "smoldering myeloma" because of a modest elevation of bone-marrow plasma cells should be screened for AL amyloidosis if they have signs or symptoms of renal, cardiac, or neurologic disease. Accurate tissue amyloid typing is essential for appropriate treatment. Immunohistochemical staining of the amyloid deposits is useful if they selectively bind one LC antibody in preference to the other; some AL deposits bind antibodies nonspecifically. Immunoelectron microscopy is more reliable, while mass spectrometry–based microsequencing of small amounts of protein extracted from fibril deposits has become the diagnostic standard. In ambiguous cases, other forms of amyloidosis should be thoroughly excluded with appropriate genetic and other testing.

TREATMENT

AL Amyloidosis

Extensive multisystemic involvement typifies AL amyloidosis, and the median survival period without treatment is usually only ~1–2 years from the time of diagnosis. Current therapies target the clonal bone-marrow plasma cells, using approaches employed for multiple myeloma. Treatment with oral melphalan and prednisone can decrease the plasma cell burden but rarely leads to complete hematologic remission, meaningful organ responses, or improved survival and is no longer widely used. The substitution of dexamethasone for prednisone produces a higher response rate and more durable remissions, although dexamethasone is not always well tolerated by patients with significant edema or cardiac disease. High-dose IV melphalan followed by autologous stem cell transplantation (HDM/SCT) produces complete hematologic responses in ~40% of treated patients, as determined by loss of clonal plasma cells in the bone marrow and disappearance of the amyloidogenic monoclonal LC, as determined by SIFE/UIFE and free LC quantitation. Six to 12 months after achieving a hematologic responses, improvements in organ function and quality of life may occur. Hematologic responses appear to be more durable after HDM/SCT than in multiple myeloma, with remissions continuing in some patients beyond 15 years without additional treatment. Unfortunately, only about 30–40% of all AL amyloidosis patients are suitable for aggressive treatment, and, even at specialized treatment centers, transplantation-related mortality rates are higher than those for other hematologic diseases because of impaired organ function at initial presentation. Amyloid cardiomyopathy, poor nutritional and performance status, and multiorgan disease contribute to excess morbidity and mortality. A bleeding diathesis resulting from adsorption of clotting factor X to amyloid fibrils also increases mortality rates; however, this syndrome occurs in only 5–10% of patients. A randomized multicenter trial conducted in France compared oral melphalan and dexamethasone with HDM/SCT and failed to show a benefit of dose-intensive treatment, although the transplantation-related mortality rate in this study was very high. It has become clear that careful selection of patients and expert peritransplantation management are essential in reducing transplantation-related mortality.

For patients with AL amyloidosis and impaired cardiac function or arrhythmias due to involvement of the myocardium, the median survival period is only ~6 months without treatment. In these patients, cardiac transplantation can be performed and followed by HDM/SCT to eliminate the noxious LC clone and prevent amyloid deposition in the transplanted heart or other organs.

Novel anti–plasma cell agents have been investigated for treatment of plasma cell diseases. The immunomodulators thalidomide, lenalidomide, and pomalidomide display activity; dosing may need to be adjusted compared to their usage for myeloma. The proteasome inhibitor bortezomib has also been found to be effective in single-center and multicenter trials. Anti-fibril small molecules and humanized monoclonal antibodies are also being tested. Clinical trials are essential in improving therapy for this rare disease.

Supportive care is important for patients with any type of amyloidosis. For nephrotic syndrome, diuretics and supportive stockings can ameliorate edema; angiotensin-converting enzyme inhibitors should be used with caution and have not been shown to slow renal disease progression. Effective diuresis can be facilitated with albumin infusions to raise intravascular oncotic pressure. Congestive heart failure due to amyloid cardiomyopathy is best treated with diuretics; it is important to note that digitalis, calcium channel blockers, and beta blockers are relatively contraindicated as they can interact with amyloid fibrils and produce heart block and worsening heart failure. Amiodarone has been used for atrial and ventricular arrhythmias. Automatic implantable defibrillators appear to have reduced effectiveness due to the thickened myocardium, but they may benefit some patients. Atrial ablation is an effective approach for atrial fibrillation. For conduction abnormalities, ventricular pacing may be indicated. Atrial contractile dysfunction is common in amyloid cardiomyopathy and associated with increased thromboembolic complications, prompting considerations of anticoagulation even in the absence of atrial fibrillation. Autonomic neuropathy can be treated with α agonists such as midodrine to support postural blood pressure; gastrointestinal dysfunction may respond to motility or bulk agents. Nutritional supplementation, either oral or parenteral, is also important.

In localized AL amyloidosis, amyloid deposits can be produced by clonal plasma cells infiltrating local sites in the airways, bladder, skin, or lymph nodes (Table 108-1). These deposits may respond to surgical intervention or elimination of the responsible plasma cell clone by low-dose radiation therapy (typically only 20 Gy); systemic treatment generally is not appropriate. Patients should be referred to a center familiar with management of these rare manifestations of amyloidosis.

AA AMYLOIDOSIS

Etiology and Incidence AA amyloidosis can occur in association with almost any chronic inflammatory state (e.g., rheumatoid arthritis, inflammatory bowel disease, familial Mediterranean fever **[Chap. 362]**, or other periodic fever syndromes) or chronic infections such as tuberculosis or subacute bacterial endocarditis. In the United States and Europe, AA amyloidosis has become less common, occurring in fewer than 2% of patients with these diseases, presumably because of advances in anti-inflammatory and antimicrobial therapies. It has also been described in association with Castleman's disease, lymphomas, renal cell carcinoma, emphasizing the diagnostic importance of CT scanning to look for such tumors as well as serologic and microbiologic studies. In up to 30% of patients, AA amyloidosis can also be seen without any identifiable underlying disease. AA is the most frequent systemic amyloidosis that occurs in children.

Pathology and Clinical Features Organ involvement in AA amyloidosis usually begins in the kidneys. Hepatomegaly, splenomegaly, and autonomic neuropathy can also occur as the disease

progresses; cardiomyopathy occurs in later disease. The symptoms and signs of AA disease cannot be reliably distinguished from those of AL amyloidosis. AA amyloid fibrils are usually composed of an 8-kDa, 76-amino-acid *N*-terminal portion of the 12-kDa precursor protein SAA. This acute-phase apoprotein is synthesized in the liver and transported by high-density lipoprotein (HDL3) in the plasma. Several years of an underlying inflammatory disease causing chronic elevation of SAA levels usually precede fibril formation, although infections can lead to AA deposition more rapidly.

TREATMENT

AA Amyloidosis

Primary therapy for AA amyloidosis consists of treatment of the underlying inflammatory or infectious disease. Treatment that suppresses or eliminates the inflammatory state or infection decreases the SAA concentration and rate of amyloid fibril formation. For familial Mediterranean fever, colchicine at a dose of 1.2–1.8 mg/d is the standard treatment. However, colchicine has not been helpful for AA amyloidosis of other causes or for other amyloidoses. Tumor necrosis factor and interleukin 1 antagonists can be effective in syndromes related to cytokine elevation. Efforts to develop a fibril-specific agent (eprodisate) that interferes with the interaction of serum amyloid A protein and glycosaminoglycans to prevent or disrupt fibril formation failed in phase III trials.

ATTR AND AF AMYLOIDOSIS

The familial amyloidoses are autosomal dominant diseases in which, beginning in midlife, a variant (FINE) plasma protein forms amyloid deposits. These diseases are rare, with an estimated incidence of <1 case/100,000 population in the United States, although founder effects in isolated areas of Portugal, Sweden, and Japan have led to a much higher incidence. The most common form of AF amyloidosis is ATTRm in the updated nomenclature, caused by mutation of the abundant plasma protein transthyretin (TTR, also known as *prealbumin*). More than 120 TTR mutations are known, and most are associated with ATTR amyloidosis. One variant, V122I, has a carrier frequency of nearly 4% in the African-American population and is associated with late-onset cardiac amyloidosis. The actual incidence and penetrance of disease in the African-American population is the subject of ongoing research, but ATTR amyloidosis warrants consideration in the differential diagnosis of African-American patients who present with concentric cardiac hypertrophy and evidence of diastolic heart failure, particularly in the absence of a history of hypertension. Other familial amyloidoses, caused by variant apolipoproteins AI or AII, gelsolin, fibrinogen Aα, or lysozyme, are reported in only a few families worldwide. New amyloidogenic serum proteins continue to be identified periodically, including recently the leukocyte chemotactic factor LECT2, a cause of renal amyloidosis in Hispanic and Pakistani populations. To date, no mutation in the coding sequence for the LECT2 gene has been identified, so the heritability of ALECT2 remains uncertain.

Amyloid deposits composed of unmutated precursor protein (wild type TTR) occur with aging. Due to a rapidly aging world population, wild-type ATTR (ATTRwt) is being diagnosed with increasing frequency in Caucasian men >65 years of age with amyloid cardiomyopathy. Formerly termed senile systemic amyloidosis, ATTRwt has been found at autopsy in 25% of hearts from men older than age 80 years. Why a wild type protein becomes amyloidogenic, and why patients bearing mutant TTR genes do not express disease until adulthood, remains a mystery.

Clinical Features and Diagnosis AF amyloidosis has a presentation that is variable but is usually consistent within kindreds affected by the same mutant protein. A family history makes AF disease more likely, but many patients present with previously unrecognized familial disease or sporadically with new mutations. ATTRm amyloidosis typically presents as a syndrome of familial amyloidotic polyneuropathy or familial amyloidotic cardiomyopathy. Peripheral neuropathy begins as a small-fiber length-dependent lower-extremity sensorimotor neuropathy and progresses to the upper extremities. Autonomic neuropathy manifests as diarrhea with weight loss and orthostatic hypotension. Patients with ATTR V30M, the most common mutation, often develop conduction defects late in the disease. Patients with ATTR T60A and several other mutations have myocardial thickening similar to that caused by AL amyloidosis, although heart failure is less common and long-term untreated survival rates are usually better. Vitreous opacities caused by amyloid deposits are pathognomonic for ATTR amyloidosis.

Typical syndromes associated with other forms of AF disease include renal amyloidosis with mutant fibrinogen, lysozyme, or apolipoproteins; hepatic amyloidosis with apolipoprotein AI; and amyloidosis of cranial nerves and cornea with gelsolin. Patients with AF amyloidosis can present with clinical syndromes that mimic those of patients with AL disease. Rarely, AF carriers can develop AL disease or AF patients may have monoclonal gammopathy without AL. Thus, it is important to screen both for plasma cell disorders and for mutations in patients with amyloidosis. Variant TTRs can usually be detected by isoelectric focusing, but DNA sequencing is now standard for diagnosis of ATTRm and other AF mutations.

TREATMENT

ATTR Amyloidosis

Without intervention, the survival period after onset of ATTR disease is 5–15 years. Orthotopic liver transplantation replaces the major source of variant TTR production with one producing normal TTR. While liver transplantation can slow disease progression and improve chances of survival, it does not reverse sensorimotor neuropathy. Liver transplants are most successful in young patients with early peripheral neuropathy; older patients with familial amyloidotic cardiomyopathy or advanced polyneuropathy often experience end-organ disease progression despite successful liver transplantation. Post-transplant ATTR disease progression results from deposition of wild-type TTR onto pre-existing fibrillar deposits principally composed of mutant TTR.

The rate-limiting step in ATTR amyloidosis is dissociation of the TTR tetramer into monomeric protein followed by misfolding, oligomerization, and fibril aggregation. TTR tetramers can be stabilized by thyroxine binding or by thyroxine-mimetic small molecules such as the non-steroidal anti-inflammatory drug diflunisal or the rationally designed small-molecule therapeutic tafamidis. A placebo-controlled randomized trial of diflunisal demonstrated a significant reduction in the progression of polyneuropathy and maintenance of quality of life in patients with a wide variety of ATTR mutations who received the "repurposed" diflunisal. Tafamidis tested in a similar fashion in patients with the V30M ATTR mutation failed to meet its primary endpoints but was approved for marketing by the European Medicines Agency since most secondary endpoints favored the drug. These agents are now being investigated for effects on ATTR cardiomyopathy. In vitro data and serendipitous observations in patients suggest that ATTRm disease can be ameliorated by "transsuppression," in which a T119M TTR variant stabilizes tetramers that also contain amyloidogenic subunits. Interestingly, in a large population study in Denmark, 0.5% of participants were heterozygous for the T119M allele, and this small group had higher levels of TTR in their blood, a reduced incidence of cerebrovascular disease, and a 5- to 10-year survival advantage compared with participants lacking this allele. The newest approach to controlling ATTR disease, TTR gene silencing, involves nearly complete suppression of TTR production by the liver, effectively preventing amyloid fibril formation by eliminating the precursor protein. TTR gene silencers including RNA interference and anti-sense oligonucleotide agents directed against TTR RNA are in phase III clinical trials to determine their effect on progression of ATTR polyneuropathy and cardiomyopathy.

Aβ$_2$M AMYLOIDOSIS

Aβ$_2$M amyloid is composed of β$_2$-microglobulin, the invariant chain of class I human leukocyte antigens, and produces rheumatologic manifestations in patients undergoing long-term hemodialysis. β$_2$-Microglobulin is excreted by the kidney, and levels become elevated in end-stage renal disease. The molecular mass of β$_2$M is 11.8 kDa—above the cutoff of some dialysis membranes. The incidence of this disease appears to be declining with the use of newer membranes in high-flow dialysis techniques. Aβ$_2$M amyloidosis usually presents as carpal tunnel syndrome, persistent joint effusions, spondyloarthropathy, or cystic bone lesions. Carpal tunnel syndrome is often the first symptom. In the past, persistent joint effusions accompanied by mild discomfort were found in up to 50% of patients who had undergone dialysis for >12 years. Involvement is bilateral, and large joints (shoulders, knees, wrists, and hips) are most frequently affected. The synovial fluid is noninflammatory, and β$_2$M amyloid can be found if the sediment is stained with Congo red. Although less common, visceral β$_2$M amyloid deposits do occasionally occur in the gastrointestinal tract, heart, tendons, and subcutaneous tissues of the buttocks. There is no specific therapy for Aβ$_2$M amyloidosis, but cessation of dialysis after renal allografting may lead to symptomatic improvement.

THERAPEUTIC FRONTIERS

To date, treatment strategies have focused on limiting formation of amyloidogenic proteins. Disruption of existing amyloid by targeting ubiquitous components of the tissue deposits may offer means to improving major end organ function. Two antibody approaches—one involving an epitope exposed during immunoglobulin light chain misfolding (AL disease) and the other directed against serum amyloid P component—are undergoing evaluation in early phase III studies.

SUMMARY

A diagnosis of amyloidosis should be considered in patients with unexplained nephropathy, cardiomyopathy (particularly with diastolic dysfunction), neuropathy (either peripheral or autonomic), enteropathy, or the pathognomonic soft tissue findings of macroglossia or periorbital ecchymoses. Pathologic identification of amyloid fibrils can be made with Congo red staining of aspirated abdominal fat or of an involved-organ biopsy specimen. Accurate typing by a combination of immunologic, biochemical, and genetic testing is essential in selecting appropriate therapy (Fig. 108-1). Systemic amyloidosis should not be considered an untreatable condition, as anti–plasma cell chemotherapy is highly effective in AL disease and targeted therapies are being developed for AA and ATTR disease. The combination of precursor and end organ amyloid therapeutics may permit not only disease control but also functional improvement to patients with amyloidosis. Tertiary referral centers can provide specialized diagnostic techniques and access to clinical trials for patients with these rare diseases.

109 Transfusion Biology and Therapy

Jeffery S. Dzieczkowski, Pierre Tiberghien, Kenneth C. Anderson

BLOOD GROUP ANTIGENS AND ANTIBODIES

Antigens systems important in transfusion medicine comprise red blood cell (RBC), platelet, neutrophil, and the widely distributed human leukocytes (HLA) antigens.

The study of RBC antigens and antibodies forms the foundation of transfusion medicine. Serologic studies initially characterized these antigens, but now the molecular composition and structure of many are known. Antigens, either carbohydrate or protein, are assigned to a blood group system based on the structure and similarity of the determinant epitopes. Other cellular blood elements such as platelets and plasma proteins are also antigenic and can result in alloimmunization, the production of antibodies directed against antigenic determinants of another individual. These antibodies, called alloantibodies, can comprise anti-RBC Abs, anti-human platelet antigens (HPA) Abs, as well as anti-human leukocytes antigens (HLA) Ab.

Antibodies directed against RBC antigens may result from "natural" exposure, particularly to carbohydrates that mimic some blood group antigens that are present in the environment, particularly saprophyte bacteria. Those antibodies that occur via natural stimuli are usually produced by a T cell–independent response (thus, generating no immune memory) and are mainly IgM isotype. *Autoantibodies* (antibodies against autologous blood group antigens) arise spontaneously or as the result of infectious sequelae (e.g., from *Mycoplasma pneumoniae*) and are also often IgM. These antibodies are often clinically insignificant due to their low affinity for antigen at body temperature. However, IgM antibodies can activate the complement cascade and result in hemolysis. Autoantibodies can also arise in an autoimmune setting with most often an IgG isotype. Antibodies that result from allogeneic exposure, such as transfusion or pregnancy, are usually IgG. IgG antibodies commonly bind to antigen at warmer temperatures and may hemolyze RBCs. Unlike IgM antibodies, IgG antibodies can cross the placenta and bind fetal erythrocytes bearing the corresponding antigen, resulting in hemolytic disease of the newborn, or *hydrops fetalis*. The same holds true for IgG directed against HPA antigens on platelets that can lead to fetal or neonatal immunization and result in intracranial hemorrhage.

Recipient alloimmunization to leukocytes, platelets, and plasma proteins may also result in transfusion complications such as fevers and urticaria as well as platelet transfusion refractoriness, but generally does not cause hemolysis. Such an alloimmunization in the blood donor may also result in a severe lung disorder called transfusion-related acute lung injury (TRALI). Assay for these non-hemolytic alloantibodies is not routinely performed; however, they may be detected using special assays.

ABO ANTIGENS AND ANTIBODIES

The first blood group antigen system, recognized in 1900, was ABO, the most important in transfusion medicine. The major blood groups of this system are A, B, AB, and O. O type RBCs lack A or B antigens. These antigens are carbohydrates attached to a precursor backbone, may be found on the cellular membrane either as glycosphingolipids or glycoproteins, and are secreted into plasma and body fluids as glycoproteins. H substance is the immediate precursor on which the A and B antigens are added. This H substance is formed by the addition of fucose to the glycolipid or glycoprotein backbone. The subsequent addition of *N*-acetylgalactosamine creates the A antigen, while the addition of galactose produces the B antigen.

The genes that determine the A and B phenotypes are found on chromosome 9p and are expressed in a Mendelian codominant manner. The gene products are glycosyl transferases, which confer the enzymatic

capability of attaching the specific antigenic carbohydrate. Individuals who lack the "A" and "B" transferases are phenotypically type "O," while those who inherit both transferases are type "AB." Rare individuals lack the H gene, which codes for fucose transferase, and cannot form H substance. These individuals are homozygous for the silent h allele (hh) and have Bombay phenotype (O_h).

The ABO blood group system is important because essentially all individuals produce antibodies to the ABH carbohydrate antigen that they lack. The "naturally" occurring anti-A and anti-B antibodies are termed *isoagglutinins*. Thus, type A individuals produce anti-B, while type B individuals make anti-A. Neither isoagglutinin is found in type AB individuals, while type O individuals produce both anti-A and anti-B. Thus, persons with type AB are considered "universal recipients" with regard to RBC transfusion because they do not have antibodies against any ABO phenotype, while persons with type O blood can donate to essentially all recipients because their cells are not recognized by any ABO isoagglutinins. The rare individuals with Bombay phenotype produce antibodies to H substance (which is present on all red cells except those of *hh* phenotype) as well as to both A and B antigens and are therefore compatible only with other *hh* donors.

In most people (80%), A, B, and H antigens are secreted by the cells and are present in the circulation as well as in various secretions such as saliva (*Se* phenotype). Others, called "nonsecretors" do not secrete A, B, and H antigens (*se* phenotype). ABO and Se/se systems influence the susceptibility to a variety of diseases. For example, malaria is less severe in O than non O patients. Conversely, group O is associated with enhanced susceptibility to *Helicobacter pylori* (and gastric ulcer) as well as to cholera bacillus or to norovirus. Furthermore, group O individuals exhibit a lesser procoagulation phenotype when compared to non O individuals.

RH SYSTEM

The Rh system is the second most important blood group system in pretransfusion testing. The Rh antigens are found on a 30- to 32-kDa RBC membrane protein that has no defined function. Although >40 different antigens in the Rh system have been described, five determinants account for the vast majority of phenotypes. The two RH genes are located on chromosome 1. The RHD gene codes for the RhD protein. The RHCE gene codes for RhCE proteins expressing C and/or c, and E and/or e antigens. The presence of the D antigen confers Rh "positivity," while persons who lack the D antigen are Rh negative. Two allelic antigen pairs, E/e and C/c, are also found on the Rh protein. These two Rh genes, RHD and RHCE, determine eight main haplotypes (DCe, DcE, Dce, DCE, dce, dCe, dcE, and dCE) whose frequencies differ among different populations. The high diversity of the RH antigens includes weak or partial expression. Identifying individuals (especially young female of childbearing potential and multi-transfused patients) with a weak or RhD antigen is important to adequately select RhD positive or negative RBC. Molecular biology is now routinely applied to resolve such situations.

The D antigen is a potent alloantigen. About 15% of individuals lack this antigen. Exposure of these Rh-negative people to even small amounts of Rh-positive cells, by either transfusion or pregnancy, can result in the production of anti-D alloantibody.

OTHER BLOOD GROUP SYSTEMS AND ALLOANTIBODIES

Thirty-six RBC group systems, six collections (related set of antigens not sufficiently distinct from existing systems to qualify as systems) and two series (low frequency ["private"] and high frequency ["public"] individual antigens) are presently recognized, composed of more than 350 antigens. The presence or absence of certain antigens has been associated with various diseases and anomalies; antigens also act as receptors for infectious agents. Alloantibodies of importance in routine clinical practice are listed in **Table 109-1**.

Antibodies to *Lewis system* carbohydrate antigens are the most common cause of incompatibility during pretransfusion screening. The Lewis gene product is a fucosyl transferase and maps to chromosome 19. The antigen is not an integral membrane structure but is adsorbed to the RBC membrane from the plasma. Antibodies to Lewis antigens are usually IgM and cannot cross the placenta. Lewis antigens may be adsorbed onto tumor cells and may be targets of therapy.

TABLE 109-1 RBC Blood Group Systems and Alloantigens

BLOOD GROUP SYSTEM	ANTIGEN	ALLOANTIBODY	CLINICAL SIGNIFICANCE
Rh (D, C/c, E/e)	RBC protein	IgG	HTR, HDN
Lewis (Le^a, Le^b)	Oligosaccharide	IgM/IgG	Rare HTR
Kell (K/k)	RBC protein	IgG	HTR, HDN
Duffy (Fy^a/Fy^b)	RBC protein	IgG	HTR, HDN
Kidd (Jk^a/Jk^b)	RBC protein	IgG	HTR (often delayed), HDN (mild)
I	Carbohydrate	IgM	None
MNS	RBC protein	IgM/IgG	Anti-M rare HDN, anti-S, -s, and -U HDN, HTR

Abbreviations: HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; RBC, red blood cell.

I system antigens are also oligosaccharides related to H, A, B, and Le. I and i are not allelic pairs but are carbohydrate antigens that differ only in the extent of branching. The i antigen is an unbranched chain that is converted by the I gene product, a glycosyltransferase, into a branched chain. The branching process affects all the ABH antigens, which become progressively more branched in the first 2 years of life. Some patients with cold agglutinin disease or lymphomas can produce anti-I autoantibodies that cause RBC destruction. Occasional patients with mononucleosis or *Mycoplasma* pneumonia may develop cold agglutinins of either anti-I or anti-i specificity. Most adults lack i expression; thus, finding a donor for patients with anti-i is not difficult. Even though most adults express I antigen, binding is generally low at body temperature. Thus, administration of warm blood prevents isoagglutination.

The *P system* is another group of carbohydrate antigens controlled by specific glycosyltransferases. The very rare individuals lacking the P antigen produce an anti-P antibody. Finding a compatible donor for such individuals is difficult. P antigen is also the target of auto-antibodies in diseases such as syphilis and viral diseases in children, and can result in paroxysmal cold hemoglobinuria. In the latter case, an autoantibody to P binds to RBCs in the cold and fixes complement upon warming. Antibodies with these biphasic properties are called *Donath-Landsteiner antibodies*. The P antigen is the cellular receptor of parvovirus B19 and also may be a receptor for *Escherichia coli* binding to urothelial cells.

The *MNS system* is regulated by genes on chromosome 4. M and N are determinants on glycophorin A, an RBC membrane protein, and S and s are determinants on glycophorin B. Anti-S and anti-s IgG antibodies may develop after pregnancy or transfusion and lead to hemolysis. Glycophorin B expresses a public antigen named U. Anti-U antibodies can occur in the rare individuals lacking the U antigen. Such occurrence is problematic; virtually every donor is incompatible because nearly all persons express U.

The *Kell* protein is very large (720 amino acids), and its secondary structure contains many different antigenic epitopes. The immunogenicity of Kell is third behind the ABO and Rh systems. The Kell protein is linked to another blood group protein termed Kx. The rare absence of this protein (controlled by a gene on X) is associated with weak KEL antigen, acanthocytosis, shortened RBC survival, and a progressive form of muscular dystrophy that includes cardiac defects. This rare condition is called the *McLeod phenotype*. The K_x gene is linked to the 91-kDa component of the NADPH-oxidase on the X chromosome, deletion or mutation of which accounts for about 60% of cases of chronic granulomatous disease. Such individuals can produce an anti-Kx antibody that makes finding a compatible blood product difficult.

The *Duffy* antigens are codominant alleles, Fy^a and Fy^b, that also serve as receptors for *Plasmodium vivax*. More than 70% of persons in sub-Saharan Africa lack these antigens, probably from selective

influences of malaria infection on the population. For unknown reasons, the lack of the Duffy antigen receptor for cytokines (DARC) is associated with mild neutropenia.

The *Kidd* antigens, Jk^a and Jk^b, may elicit antibodies transiently. A delayed hemolytic transfusion reaction (DHTR) that occurs with blood tested as compatible is often related to delayed appearance of anti-Jk^a.

PRETRANSFUSION TESTING

Pretransfusion testing of a potential recipient consists of the "type and screen." The "forward type" determines the ABO and Rh phenotype of the recipient's RBC by using antisera directed against the A, B, and D antigens. The "reverse type" detects isoagglutinins in the patient's serum and should correlate with the ABO phenotype, or forward type. Additional typing for other main Rh antigens (CcEe), the K antigen, and more rarely Duffy, Kidd and Ss antigens, can be required depending on the clinical setting. Molecular typing is increasingly used to predict the RBC phenotype and facilitate the selection of a compatible blood component.

The alloantibody screen identifies antibodies directed against other RBC antigens. The alloantibody screen is performed by mixing patient serum with type O RBCs that contain the major antigens of most blood group systems and whose extended phenotype is known. The specificity of the alloantibody is identified by correlating the presence or absence of antigen with the results of the agglutination. Special attention should be given to patients receiving monoclonal antibody treatment that may bind to RBC (such as anti-CD38 treatment for myeloma) and therefore interfere with alloantibody screening.

Cross-matching is ordered when there is a high probability that the patient will require a packed RBC (PRBC) transfusion. In the setting of a systematic alloantibody screen, such a crossmatch can be restricted to alloimmunized patients as well as patients at high risk of alloimmunization (prior pregnancies, transfusions). Blood selected for cross-matching must be ABO compatible and lack antigens for which the patient has alloantibodies. Nonreactive cross-matching confirms the absence of any major incompatibility and reserves that unit for the patient.

In the case of Rh (D) -negative patients, every attempt must be made to provide Rh-negative blood components to prevent alloimmunization to the D antigen. In an emergency, Rh-positive blood can be safely transfused to an Rh-negative patient who lacks anti-D; however, the recipient is likely to become alloimmunized and produce anti-D. Rh-negative women of childbearing age who are transfused with products containing Rh-positive RBCs should receive passive immunization with anti-D (RhoGam or WinRho) to reduce or prevent sensitization.

BLOOD COMPONENTS

Blood products intended for transfusion are routinely collected as whole blood (450 mL) in various anticoagulants. Most donated blood is processed into components: PRBCs, platelets, and fresh-frozen plasma (FFP) or cryoprecipitate **(Table 109-2)**. Whole blood can be first separated into PRBCs and platelet-rich plasma by slow centrifugation. The platelet-rich plasma is then centrifuged at high speed to yield one unit of random donor (RD) platelets (subsequently pooled) and one unit of FFP. Alternatively, whole blood can undergo high speed centrifugation to separate a PRBC, a FFP and a "buffy-coat" containing leukocytes and platelets. The buffy coat then undergoes pooling and is centrifuged at low speed to produce pooled platelets. The leukocyte level of blood products can be lowered by an additional filtration step after which they are referred to as leukoreduced (or leukodepleted) (<1 to 5×10^6 leukocytes per product). Cryoprecipitate is produced by thawing FFP to precipitate the plasma proteins, then separated by centrifugation.

Apheresis technology is used for the collection of multiple units of platelets from a single donor. These single-donor apheresis platelets (SDAP) contain the equivalent of at least five units of RD platelets and before eventual leukoreduced, have fewer contaminating leukocytes than pooled RD platelets.

Plasma as well as RBCs and granulocytes may also be collected by apheresis. Plasma-derived products such as albumin, intravenous immunoglobulin, antithrombin, and coagulation factor concentrates are prepared from pooled plasma from many donors. Plasma fractionation includes steps that eliminate infectious agents.

TABLE 109-2 Characteristics of Selected Blood Components

COMPONENT	VOLUME, mL	CONTENT	CLINICAL RESPONSE
PRBC	250–300 (including additive solution)	RBCs with variable leukocyte content and small amount of plasma	Increase hemoglobin 10 g/L and hematocrit 3%
Platelets (from whole blood)	50–70 /RD unit pool of 4 to 6 RD unit	5.5×10^{10}/RD unit	Increase platelet count 5000–10,000/μL/ RD unit
Platelets (from apheresis)	200–400	$\geq 2 \times 10^{11}$/SDAP product	For pooled RD and SDAP: CCI $\geq 10 \times 10^9$/L within 1 h and $\geq 7.5 \times 10^9$/L within 24 h posttransfusion
FFP	200–250	Plasma proteins—coagulation factors, proteins C and S, antithrombin	Increases coagulation factors about 2%
Cryoprecipitate (may be used as topical fibrin glue as well)	10–15 /unit, pool of 4 to 5 units	Cold-insoluble plasma proteins, fibrinogen, factor VIII, factor XIII, vWF fibronectin	Increased plasma fibrinogen 0,3-1 g/L, increased factor VIII

Abbreviations: CCI, corrected count increment; FFP, fresh-frozen plasma; PRBC, packed red blood cells; RBC, red blood cell; RD, random donor; SDAP, single-donor apheresis platelets; vWF, von Willebrand factor.

WHOLE BLOOD

Whole blood provides both oxygen-carrying capacity and volume expansion. It is the ideal component for patients who have sustained acute hemorrhage of ≥25% total blood volume loss. Whole blood is stored at 4°C to maintain erythrocyte viability, but platelet dysfunction and degradation of some coagulation factors occur. In addition, 2,3-bisphosphoglycerate levels fall over time, leading to an increase in the oxygen affinity of the hemoglobin and a decreased capacity to deliver oxygen to the tissues, a problem with all red cell storage. Fresh whole blood avoids these problems, but it is typically used only in emergency settings (i.e., military). Whole blood is not readily available, since it is routinely processed into components.

PACKED RBCS

This product increases oxygen-carrying capacity in the anemic patient. PRBC are stored in additive solution up to 35–42 days at 4°C. Adequate oxygenation can be maintained with a hemoglobin content of 70 g/L in the normovolemic patient without cardiac disease; however, comorbid factors may necessitate transfusion at a higher threshold. The decision to transfuse should be guided by the clinical situation and not by an arbitrary laboratory value. In the critical care setting, liberal use of transfusions to maintain near-normal levels of hemoglobin has not proven advantageous. In most patients requiring transfusion, levels of hemoglobin of 80 g/L are sufficient to keep oxygen supply from being critically low.

PRBCs may be modified to prevent certain adverse reactions. The majority of cellular blood products are now leukocyte-reduced and universal prestorage leukocyte reduction has been recommended. Prestorage filtration appears superior to bedside filtration as smaller amounts of cytokines are generated in the stored product. These PRBC units contain <1 to 5.10^6 donor leukocytes, and their use lowers the incidence of posttransfusion fever and chills, cytomegalovirus (CMV) infections, and alloimmunization. Other theoretical benefits include less immunosuppression in the recipient and lower risk of infections with intracellular pathogens (in addition to CMV). Plasma, which may cause allergic reactions, can be removed from cellular blood components by washing. Patients with hemoglobinopathies such as sickle cell disease may undergo RBC exchange, an apheresis procedure by which sickled RBCs are replaced by donor RBCs.

PLATELETS

Thrombocytopenia is a risk factor for hemorrhage, and platelet transfusion reduces the incidence of bleeding. Platelets are stored in plasma or in additive solution up to 5–7 days at 20–24°C and under permanent motion. The threshold for prophylactic platelet transfusion is 10,000/μL. In patients without fever or infections, a threshold of 5000/μL may be sufficient to prevent spontaneous hemorrhage. For invasive procedures, 50,000/μL platelets is the usual target level.

Platelets are given either as pools of 4 to 6 prepared RDs or as SDAPs from a single donor. In an unsensitized patient without increased platelet consumption (splenomegaly, fever, disseminated intravascular coagulation [DIC]), two units of transfused RD per square-meter body surface area (BSA) is anticipated to increase the platelet count by ~10,000/uL. Patients who have received multiple transfusions may be alloimmunized to many HLA- and platelet-specific antigens and have little or no increase in their posttransfusion platelet counts. Patients who may require multiple transfusions are best served by receiving leukocyte-reduced components to lower the risk of alloimmunization.

Refractoriness to platelet transfusion may be evaluated using the corrected count increment (CCI):

$$\text{CCI} = \frac{\text{posttransfusion count}\,(/\mu\text{L}) - \text{pretransfusion count}\,(/\mu\text{L})}{\text{number of platelets transfused} \times 10^{-11}} \times \text{BSA}\ (\text{m}^2)$$

where BSA is body surface area measured in square meters. The platelet count performed 1 h after the transfusion is acceptable if the CCI is 10×10^9/mL, and after 18–24 h an increment of 7.5×10^9/mL is expected. Patients who have suboptimal responses are likely to have received multiple transfusions and have antibodies directed against class I HLA antigens. Refractoriness can be investigated by detecting anti-HLA antibodies in the recipient's serum. Patients who are sensitized will often react with 100% of the lymphocytes used for the HLA-antibody screen, and HLA-matched SDAPs should be considered for those patients who require transfusion. Although ABO-identical HLA-matched SDAPs provide the best chance for increasing the platelet count, locating these products is difficult. Platelet cross-matching is available in some centers. Additional clinical causes for a low platelet CCI include fever, bleeding, splenomegaly, DIC, or medications in the recipient.

FRESH-FROZEN PLASMA

FFP contains stable coagulation factors and plasma proteins: fibrinogen, antithrombin, albumin, as well as proteins C and S. Indications for FFP include correction of coagulopathies, including the rapid reversal of warfarin; supplying deficient plasma proteins; and treatment of auto-antibody-mediated thrombotic thrombocytopenic purpura (TTP). In the latter case, therapeutic plasma exchange allows both the removal of the autoantibody and the supplementation of the depleted enzyme (ADAMTS13). Other auto-immune diseases such as Guillain-Barré syndrome and myasthenia gravis may benefit from plasma exchange. FFP should not be routinely used to expand blood volume. FFP is an acellular component and does not transmit intracellular infections, e.g., CMV. In addition to FFP, pre-thawed or never frozen plasma as well as freeze-dried plasma are increasingly used to insure immediate availability when required. Patients who are IgA-deficient and require plasma support should receive FFP from IgA-deficient donors to prevent anaphylaxis (see below).

CRYOPRECIPITATE

Cryoprecipitate is a source of fibrinogen, factor VIII, and von Willebrand factor (vWF). It is ideal for supplying fibrinogen to the volume-sensitive patient. When factor VIII concentrates are not available, cryoprecipitate may be used since each unit contains ~80 units of factor VIII. Cryoprecipitate may also supply vWF to patients with dysfunctional (type II) or absent (type III) von Willebrand disease.

PLASMA DERIVATIVES

Plasma from thousands of donors may be pooled to derive specific protein concentrates, including albumin, intravenous immunoglobulin, antithrombin, and coagulation factors. In addition, donors who have high-titer antibodies to specific agents or antigens provide hyperimmune globulins, such as anti-D (RhoGam, WinRho), and antisera to hepatitis B virus (HBV), varicella-zoster virus, CMV, and other infectious agents.

ADVERSE REACTIONS TO BLOOD TRANSFUSION

Adverse reactions to transfused blood components occur despite multiple tests, inspections, and checks. Fortunately, the most common reactions are not life threatening, although serious reactions can present with mild symptoms and signs. Some reactions can be reduced or prevented by modified (filtered, washed, or irradiated) blood components. Blood product pathogen reduction is an option for platelets and plasma, and underway for whole blood and PRBC. When an adverse reaction is suspected, the transfusion should be stopped and reported to the blood bank for investigation.

Transfusion reactions may result from immune and nonimmune mechanisms. Immune-mediated reactions are often due to preformed donor or recipient antibody; however, cellular elements may also cause adverse effects. Nonimmune causes of reactions are due to the chemical and physical properties of the stored blood component and its additives.

Transfusion-transmitted viral infections are increasingly rare due to improved screening and testing. As the risk of viral infection is reduced, the relative risk of other reactions increases, such as hemolytic transfusion reactions and sepsis from bacterially contaminated components. However, one must remain concerned by novel or previously unidentified viral risks. Pretransfusion quality assurance improvements further increase the safety of transfusion therapy. Infections, like any adverse transfusion reaction, must be brought to the attention of the blood bank for appropriate actions **(Table 109-3)**.

IMMUNE-MEDIATED REACTIONS

Acute Hemolytic Transfusion Reactions Immune-mediated hemolysis occurs when the recipient has preformed antibodies that lyse donor erythrocytes. The anti-A or anti-B antibodies are responsible for the majority of these reactions. However, alloantibodies directed against other RBC antigens, i.e., Rh, Kell, and Duffy, are responsible for fatal hemolytic transfusion reactions as well.

Acute hemolytic reactions may present with hypotension, tachypnea, tachycardia, fever, chills, hemoglobinemia, hemoglobinuria, chest and/or flank pain, and discomfort at the infusion site. Monitoring the patient's vital signs before and during the transfusion is important to identify reactions promptly. When acute hemolysis is suspected, the transfusion must be stopped immediately, intravenous access maintained, and the reaction reported to the blood bank. A correctly labeled posttransfusion blood sample and any untransfused blood should be sent to the blood bank for analysis. The laboratory evaluation for hemolysis includes the measurement of serum haptoglobin, lactate dehydrogenase (LDH), and indirect bilirubin levels.

The immune complexes that result in RBC lysis can cause renal dysfunction and failure. Diuresis should be induced with intravenous fluids and furosemide or mannitol. Tissue factor released from the lysed erythrocytes may initiate DIC. Coagulation studies including prothrombin time (PT), activated partial thromboplastin time (aPTT), fibrinogen, and platelet count should be monitored in patients with hemolytic reactions.

Errors at the patient's bedside, such as mislabeling the sample or transfusing the wrong patient, are responsible for the majority of these reactions. The blood bank investigation of these reactions includes examination of the pre- and posttransfusion samples for hemolysis and repeat typing of the patient samples; direct antiglobulin test (DAT), sometimes called the *direct Coombs test*, of the posttransfusion sample; repeating the cross-matching of the blood component; and checking all clerical records for errors. DAT detects the presence of antibody or complement bound to RBCs in vivo **(Fig. 109-1)**.

Delayed Hemolytic and Serologic Transfusion Reactions DHTRs are not completely preventable. These reactions occur in

TABLE 109-3 Risks of Transfusion Complications

	FREQUENCY, EPISODES: UNIT
Main Reactions	
Circulatory overload (TACO)	· 10.9:100,000
Febrile (FNHTR)	· 100–1000:100,000, frequently under reported
Allergic	· 100–400:100,000, product-dependent
TRALI	· 0,4–1:100,000, with mitigation, product-dependent
Delayed hemolytic	· 40:100,000
Acute hemolytic	· 2.5–7.9:100,000
Infections[a]	
Bacteria (septic transfusion reaction)	· 0,3–25:1,000,000 (product and detection- or pathogen-reduction-dependent
Hepatitis B	· 1:300,000 (<1:1,000,000*)
Hepatitis C*	· <0,1–1:1,000,000
HIV-1*, -2	· 0,1–1:1,000,000
HTLV-I and -II	· 1:3,000,000
Malaria	· 1:4,000,000
*: with nucleic acid testing (NAT) screening	
Other Complications	
RBC allosensitization	· 1:100
HLA allosensitization	· 1:10 (in the absence of leukodepletion)
Graft-versus-host disease	Extremely rare (with blood product irradiation in immunosuppressed patients)

[a]Other infectious agents associated with transfusion include arborvirus (West Nile virus, Dengue virus, Zika virus) hepatitis A and E virus, parvovirus B-19, *Babesia microti* and *Babesia duncani* (babesiosis), *Anaplasma phagocytophilum* (human granulocytic ehrlichiosis), *Trypanosoma cruzi* (Chagas disease), *Treponema pallidum*, and human herpesvirus-8. Frequency of infectious risks differ significantly world-wide.

Abbreviations: FNHTR, febrile nonhemolytic transfusion reaction; TRALI, transfusion-related acute lung injury; HTLV, human T lymphotropic virus; RBC, red blood cell; TACO, transfusion-associated circulatory overload.

patients previously sensitized to RBC alloantigens who have a negative alloantibody screen due to low antibody levels. When the patient is transfused with antigen-positive blood, an anamnestic response results in the early production of alloantibody that binds donor RBCs. The alloantibody is detectable 1–2 weeks following the transfusion, and the posttransfusion DAT may become positive due to circulating donor RBCs coated with antibody or complement. The transfused, alloantibody-coated erythrocytes are cleared by the reticuloendothelial system. These reactions are detected most commonly in the blood bank when a subsequent patient sample reveals a positive alloantibody screen or a new alloantibody in a recently transfused recipient.

No specific therapy is usually required, although additional RBC transfusions may be necessary. Delayed serologic transfusion reactions are similar to DHTR, as the DAT is positive and alloantibody is detected; however, RBC clearance is not increased.

Febrile Nonhemolytic Transfusion Reaction The most frequent reaction associated with the transfusion of cellular blood components is a febrile nonhemolytic transfusion reaction (FNHTR). These reactions are characterized by chills and rigors and a ≥1°C rise in temperature. FNHTR is diagnosed when other causes of fever in the transfused patient are ruled out. Antibodies directed against donor leukocyte and HLA antigens may mediate these reactions; thus, multiply transfused patients and multiparous women are felt to be at increased risk. Although anti-HLA antibodies may be demonstrated in the recipient's serum, investigation is not routinely done because of the mild nature of most FNHTRs. The use of leukocyte-reduced blood products may prevent or delay sensitization to leukocyte antigens and thereby reduce the incidence of these febrile episodes. Cytokines released from leukocytes within stored blood components may mediate FNHTR; thus, leukoreduction before storage may prevent these reactions. Likewise, cytokines and chemokines released from platelets components, released during storage may also mediate FNHTR.

Allergic Reactions Urticarial reactions are related to plasma proteins found in transfused components. Mild reactions may be treated symptomatically by temporarily stopping the transfusion and administering antihistamines (diphenhydramine, 50 mg orally or intramuscularly). The transfusion may be completed after the signs and/or symptoms resolve. Patients with a history of allergic transfusion reaction may be premedicated with an antihistamine. Cellular components can be washed to remove residual plasma for the extremely sensitized patient. Most of the allergic presentation may not depend on preformed antibodies and may be attributable to biological response modifiers triggering histamine and serotonin release from platelets and leukocytes.

Anaphylactic Reaction This severe allergic reaction presents after transfusion of only a few milliliters of the blood component. Symptoms and signs include difficulty breathing, coughing, nausea and vomiting, hypotension, bronchospasm, loss of consciousness, respiratory arrest, and shock. Treatment includes stopping the transfusion, maintaining vascular access, and administering epinephrine (0.5–1 mL of 1:1000 dilution subcutaneously). Glucocorticoids may be required in severe cases.

Patients who are IgA-deficient, <1% of the population, may be sensitized to this Ig class and are at risk for anaphylactic reactions associated with plasma transfusion. Individuals with severe IgA deficiency should therefore receive only IgA-deficient plasma and washed cellular blood components. Patients who have anaphylactic or repeated allergic reactions to blood components should be tested for IgA deficiency. Of note, the importance of the allergic risk associated with IgA deficiency may be overestimated and is currently debated.

Graft-Versus-Host Disease Graft-versus-host disease (GVHD) is a frequent complication of allogeneic stem cell transplantation, in which lymphocytes from the donor attack and cannot be eliminated by an immunodeficient host. Transfusion-related GVHD is mediated by donor T lymphocytes that recognize host HLA antigens as foreign and mount an immune response, which is manifested clinically by the development of fever, a characteristic cutaneous eruption, diarrhea, and liver function abnormalities. GVHD can also occur when blood components that contain viable T lymphocytes are transfused to immunodeficient recipients or to immunocompetent recipients who share HLA antigens with the donor (e.g., a family donor). In addition to the aforementioned clinical features of GVHD, transfusion-associated GVHD (TA-GVHD) is characterized by marrow aplasia and pancytopenia. TA-GVHD is highly resistant to treatment with immunosuppressive therapies, including glucocorticoids, cyclosporine, antithymocyte globulin, and ablative therapy followed by allogeneic bone marrow transplantation. Clinical manifestations appear at 8–10 days, and death occurs at 3–4 weeks posttransfusion.

TA-GVHD can be prevented by irradiation of cellular components (minimum of 2500 cGy) before transfusion to patients at risk. Recently, pathogen inactivation technologies have shown to prevent TA-GVHD as well. Patients at risk for TA-GVHD include fetuses receiving intrauterine transfusions, selected immunocompetent (e.g., lymphoma patients) or immunocompromised recipients, recipients of donor units known to be from a blood relative, and recipients who have undergone marrow transplantation. Directed donations by family members should be discouraged (they are not less likely to transmit infection); lacking other options, the blood products from family members should always be irradiated.

Transfusion-Related Acute Lung Injury TRALI is among the most common cause of transfusion related fatalities. The recipient develops symptoms of hypoxia ($PaO_2/FiO_2 < 300$ mmHg) and signs of noncardiogenic pulmonary edema, including bilateral interstitial infiltrates on chest x-ray, either during or within 6 h of transfusion. Treatment is

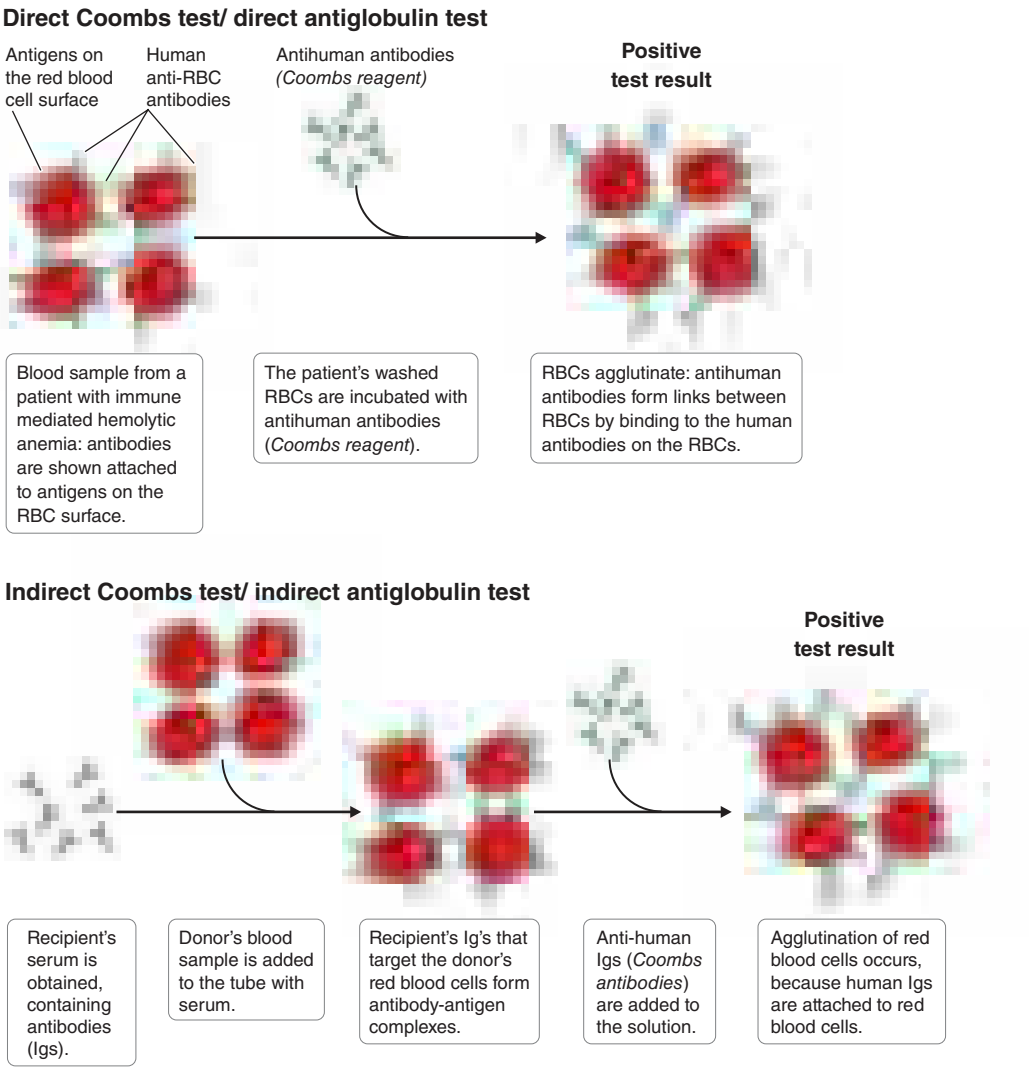

FIGURE 109-1 Direct and indirect Coombs test. The direct Coombs (antiglobulin) test detects the presence of antibodies (or complement) on the surface of erythrocytes. The indirect Coombs (antiglobulin) test detects antibodies in the serum that may bind to donor erythrocytes. RBC, red blood cell. *(Adapted from http://upload.wikimedia.org/wikipedia/commons/1/1c/coombs_test_schematic.png.)*

supportive, and patients usually recover without sequelae. TRALI usually results from the transfusion of donor plasma that contains high-titer anti-HLA class II antibodies that bind recipient leukocytes. Anti-HLA class I and anti-human neutrophil antigen (HNA) antibodies can be involved as well. The leukocytes aggregate in the pulmonary vasculature and release mediators that increase capillary permeability. Testing the donor's plasma for anti-HLA antibodies can support this diagnosis. The implicated donors are frequently multiparous women. The transfusion of plasma and platelets from male and nulliparous women donors reduces the risk of TRALI. Recipient factors that are associated with increased risk of TRALI include smoking, chronic alcohol use, shock, liver surgery (transplantation), mechanical ventilation with >30 cm H_20 pressure support and positive fluid balance.

Posttransfusion Purpura This reaction presents as thrombocytopenia 7–10 days after platelet transfusion and occurs predominantly in women. Platelet-specific antibodies are found in the recipient's serum, and the most frequently recognized antigen is HPA-1a found on the platelet glycoprotein IIIa receptor. The delayed thrombocytopenia is due to the production of antibodies that react to both donor and recipient platelets. Additional platelet transfusions can worsen the thrombocytopenia and should be avoided. Treatment with intravenous immunoglobulin may neutralize the effector antibodies, or plasmapheresis can be used to remove the antibodies.

Alloimmunization A recipient may become alloimmunized to a number of antigens on cellular blood elements and plasma proteins. Alloantibodies to RBC antigens are detected during pretransfusion testing, and their presence may delay finding antigen-negative cross-match-compatible products for transfusion. Women of childbearing age who are sensitized to certain RBC antigens (i.e., D, c, E, Kell, or Duffy) are at risk for bearing a fetus with hemolytic disease of the newborn. Matching for RBC antigen is the only pretransfusion selection test to prevent RBC alloimmunization.

Alloimmunization to antigens on leukocytes and platelets can result in refractoriness to platelet transfusions. Once alloimmunization has developed, HLA-compatible platelets from donors who share similar antigens with the recipient may be difficult to find. Hence, prudent transfusion practice is directed at preventing sensitization through the use of leukocyte-reduced cellular components, as well as limiting antigenic exposure by the judicious use of transfusions and use of SDAPs.

NONIMMUNOLOGIC REACTIONS

Fluid Overload Blood components are excellent volume expanders, and transfusion may quickly lead to transfusion-associated circulatory overload (TACO). Dyspnea with O_2% <90 on room air, bilateral infiltrates on CXR with systolic hypertension are found with TACO. Brain natriuretic peptide (BNP) is often elevated (>1.5) that of pre-transfusion levels. Monitoring the rate and volume of the transfusion and using a diuretic can minimize this problem.

Hypothermia Refrigerated (4°C) or frozen (−18°C or below) blood components can result in hypothermia when rapidly infused. Cardiac

dysrhythmias can result from exposing the sinoatrial node to cold fluid. Use of an in-line warmer will prevent this complication.

Electrolyte Toxicity RBC leakage during storage increases the concentration of potassium in the unit. Neonates and patients in renal failure are at risk for hyperkalemia. Preventive measures, such as using fresh or washed RBCs, are warranted for neonatal transfusions because this complication can be fatal.

Citrate, commonly used to anticoagulate blood components, chelates calcium and thereby inhibits the coagulation cascade. Hypocalcemia, manifested by circumoral numbness and/or tingling sensation of the fingers and toes, may result from multiple rapid transfusions. Because citrate is quickly metabolized to bicarbonate, calcium infusion is seldom required in this setting. If calcium or any other intravenous infusion is necessary, it must be given through a separate line.

Iron Overload Each unit of RBCs contains 200–250 mg of iron. Symptoms and signs of iron overload affecting endocrine, hepatic, and cardiac function are common after 100 units of RBCs have been transfused (total-body iron load of 20 g). Preventing this complication by using alternative therapies (e.g., erythropoietin) and judicious transfusion is preferable and cost effective. Chelating agents, such as deferoxamine and deferasirox, are available, but the response though is often suboptimal.

Hypotensive Reactions Transient hypotension may be noted among transfused patients who take angiotensin-converting enzyme (ACE) inhibitors. Since blood products contain bradykinin that is normally degraded by ACE, patients on ACE inhibitors may have increased bradykinin levels that cause hypotension in the recipient. The blood pressure typically returns to normal without intervention.

Immunomodulation Transfusion of allogeneic blood is immunosuppressive. Multiply transfused renal transplant recipients are less likely to reject the graft, and transfusion may result in poorer outcomes in cancer patients and increase the risk of infections. Transfusion-related immunomodulation is thought to be mediated by transfused leukocytes. Leukocyte-depleted cellular products may cause less immunosuppression, though controlled data are unlikely to be obtained as the blood supply becomes universally leukocyte-depleted.

INFECTIOUS COMPLICATIONS

The blood supply is initially screened by selecting healthy donors without high-risk lifestyles, medical conditions, or exposure to transmissible pathogens, such as intravenous drug use or visiting malaria endemic areas. Multiple tests performed on donated blood to detect the presence of infectious agents using nucleic acid amplification testing (NAT) or evidence of prior infections by testing for antibodies to pathogens and sterility of platelet products further reduce the risk of transfusion-acquired infections. Pathogen reduction of platelets and plasma offer an additional mean to reduce such risk.

Viral Infections • **HEPATITIS C VIRUS** Blood donations are tested for antibodies to HCV and HCV RNA. The risk of acquiring HCV through transfusion is now calculated to be 0,1 to 1 in 1,000,000 units. Infection with HCV may be asymptomatic or lead to chronic active hepatitis, cirrhosis, and liver failure.

HUMAN IMMUNODEFICIENCY VIRUS TYPE 1 Donated blood is tested for antibodies to HIV-1, HIV-1 p24 antigen, and HIV RNA using NAT. The risk of HIV-1 infection per transfusion episode is 0,1 to 1 in 1 million. Antibodies to HIV-2 are also measured in donated blood. No cases of HIV-2 infection in blood donors have been reported in the United States since 1992.

HEPATITIS B VIRUS Donated blood is screened for HBV using assays for hepatitis B surface antigen (HbsAg) most combined with NAT testing. The risk of transfusion-associated HBV infection is several times greater than for HCV. Vaccination of individuals who require long-term transfusion therapy can prevent this complication.

OTHER HEPATITIS VIRUSES Hepatitis A virus is rarely transmitted by transfusion; infection is typically asymptomatic and does not lead to chronic disease. Hepatitis E (HEV) can be transmitted by transfusion and may lead to chronic disease. Routine HEV RNA testing has been introduced in several European countries starting in 2015. West Nile virus (WNV) Transfusion-transmitted WNV infections were documented in 2002. This RNA virus can be detected using NAT; routine screening began in 2003. WNV infections range in severity from asymptomatic to fatal, with the older population at greater risk.

CYTOMEGALOVIRUS This ubiquitous virus infects ≥50% of the general population and is transmitted by the infected "passenger" leukocytes found in transfused PRBCs or platelet components. Cellular components that are leukocyte-reduced have a decreased risk of transmitting CMV, regardless of the serologic status of the donor. Groups at risk for CMV infections include immunosuppressed patients, CMV-seronegative transplant recipients, and neonates; these patients should receive leukocyte-depleted components or CMV seronegative products.

HUMAN T LYMPHOTROPIC VIRUS (HTLV) TYPE I Assays to detect HTLV-I and -II are used to screen all donated blood. HTLV-I is associated with adult T cell leukemia/lymphoma and tropical spastic paraparesis in a small percentage of infected persons (Chap. 196). The risk of transfusion-mediated HTLV-1 infection is further mitigated by blood product leukoreduction. HTLV-II is not clearly associated with any disease.

PARVOVIRUS B-19 Blood components and pooled plasma products can transmit this virus, the etiologic agent of erythema infectiosum, or fifth disease, in children. Parvovirus B-19 shows tropism for erythroid precursors and inhibits both erythrocyte production and maturation. Pure red cell aplasia, presenting either as acute aplastic crisis or chronic anemia with shortened RBC survival, may occur in individuals with an underlying hematologic disease, such as sickle cell disease or thalassemia (Chap. 94). The fetus of a seronegative woman is at risk for developing hydrops from this virus.

Bacterial Contamination The relative risk of transfusion-transmitted bacterial infection has increased as the absolute risk of viral infections has dramatically decreased.

Most bacteria do not grow well at cold temperatures; thus, PRBCs and FFP are not common sources of bacterial contamination. However, some gram-negative bacteria can grow at 1° to 6°C. *Yersinia*, *Pseudomonas*, *Serratia*, *Acinetobacter*, and *Escherichia* species have all been implicated in infections related to PRBC transfusion. Platelet concentrates, which are stored at room temperature, are more likely to contain skin contaminants such as gram-positive organisms, including coagulase-negative staphylococci. It is estimated that 1 in 1000–2000 platelet components is contaminated with bacteria. The risk of death due to transfusion-associated sepsis is estimated to be in the order of 1 in 200,000–400,000 platelets products. Since 2004, blood banks have instituted methods to detect contaminated platelet components. Pathogen-reduced platelets have been available and offer an alternative to prevent transfusion-transmitted bacterial infection.

Recipients of transfusion contaminated with bacteria may develop fever and chills, which can progress to septic shock and DIC. These reactions may occur abruptly, within minutes of initiating the transfusion, or after several hours. The onset of symptoms and signs is often sudden and fulminant, which distinguishes bacterial contamination from an FNHTR. The reactions, particularly those related to gram-negative contaminants, are the result of infused endotoxins formed within the contaminated stored component.

When these reactions are suspected, the transfusion must be stopped immediately. Therapy is directed at reversing any signs of shock, and broad-spectrum antibiotics should be given. The blood bank should be notified to identify any clerical or serologic error. The blood component bag should be sent for culture and Gram stain.

Other Infectious Agents Various parasites, including those causing malaria, babesiosis, and Chagas disease, can be transmitted by blood transfusion. Geographic migration and travel of donors shift the incidence of these infections. Other agents implicated in transfusion transmission include dengue, zika virus, variant Creutzfeldt-Jakob disease, *Anaplasma phagocytophilum*, and yellow fever vaccine virus

and the list will grow. Tests for some pathogens are available, such as *Trypanosoma cruzi*, but not universally required while others are being developed (Babesia microti). These infections should be considered in the transfused patient in the appropriate clinical setting.

ALTERNATIVES TO TRANSFUSION

Alternatives to allogeneic blood transfusions that avoid homologous donor exposures with attendant immunologic and infectious risks remain attractive. Autologous blood remains an option when transfusion is anticipated. However, the cost-benefit ratio of autologous transfusion remains high. No transfusion is a zero-risk event; clerical errors and bacterial contamination remain potential complications even with autologous transfusions. Additional methods of autologous transfusion in the surgical patient include preoperative hemodilution, recovery of shed blood from sterile surgical sites, and postoperative drainage collection. Directed or designated donation from friends and family of the potential recipient has not been safer than volunteer donor component transfusions. Such directed donations may in fact place the recipient at higher risk for complications such as GVHD and alloimmunization.

Granulocyte and granulocyte-macrophage colony-stimulating factors are clinically useful to hasten leukocyte recovery in patients with leukopenia related to high-dose chemotherapy. Erythropoietin stimulates erythrocyte production in patients with anemia of chronic renal failure and other conditions, thus avoiding or reducing the need for transfusion. This hormone can also stimulate erythropoiesis in the autologous donor to enable additional donation.

Gene therapy approaches in patients with sickle cell or major thalassemia offers the potential of dramatically reducing their transfusion needs. Stem cell-derived blood cells such as RBCs or platelets may in the future become a suitable alternative to very rare blood donors.

Lastly, optimizing the use of blood products through patient blood management programs can improve the therapeutic index of transfusion medicine.

ACKNOWLEDGMENT

We are pleased to acknowledge the assistance of Olivier Garaud, MD, PhD, and Jacques Chiaroni, MD, PhD, in the preparation of this chapter.

110 Hematopoietic Cell Transplantation

Frederick R. Appelbaum

Bone marrow transplantation was the original term used to describe the collection and transplantation of hematopoietic stem cells, but with the demonstration that peripheral blood and umbilical cord blood are also useful sources of stem cells, *hematopoietic cell transplantation* (HCT) has become the preferred generic term for this process. HCT is used to treat patients with an abnormal but nonmalignant lymphohematopoietic system by replacing it with one from a normal donor. HCT is also used to treat malignancy by allowing the administration of higher doses of myelosuppressive therapy than would otherwise be possible, and in the setting of allogeneic HCT, by conferring an immunologic graft-versus-tumor effect. The use of HCT has been increasing, both because of its efficacy in selected diseases and because of increasing availability of donors.

The Center for International Blood and Marrow Transplant Research (*http://www.cibmtr.org*) estimates that worldwide about 70,000 transplants were performed in 2016. The frequency of transplantation varied widely from country to country with a close association of transplant rates with Gross National Income (GNI)/capita. However, even among countries with similar GNIs/capita, there are substantial differences between countries and regions concerning the frequency of transplantation, disease indications, and choice of donor type.

THE HEMATOPOIETIC STEM CELL

Several features of the hematopoietic stem cell make transplantation clinically feasible, including its remarkable regenerative capacity, its ability to home to the marrow space following intravenous injection, and the ability of the stem cell to be cryopreserved **(Chap. 92)**. Transplantation of a single stem cell can replace the entire lymphohematopoietic system of an adult mouse. In humans, transplantation of a small percentage of a donor's bone marrow volume regularly results in complete and sustained replacement of the recipient's entire lymphohematopoietic system, including all red cells, granulocytes, B and T lymphocytes, and platelets, as well as cells comprising the fixed macrophage population, including Kupffer cells of the liver, pulmonary alveolar macrophages, osteoclasts, Langerhans cells of the skin, and brain microglial cells. The ability of the hematopoietic stem cell to home to the marrow following intravenous injection is mediated, in part, by an interaction between CXCL12, also known as stromal cell–derived factor 1, produced by marrow stromal cells and the alpha-chemokine receptor CXCR4 found on stem cells. Homing is also influenced by the interaction of cell-surface molecules, termed *selectins*, including E- and L-selectin, on bone marrow endothelial cells with ligands, termed *integrins*, such as VLA-4, on early hematopoietic cells. Human hematopoietic stem cells can survive freezing and thawing with little, if any, damage, making it possible to remove and store a portion of the patient's own bone marrow for later reinfusion following treatment of the patient with high-dose myelotoxic therapy.

CATEGORIES OF HCT

HCT can be described according to the relationship between the patient and the donor and by the anatomic source of stem cells. In ~1% of cases, patients have identical twins who can serve as donors. With the use of syngeneic donors, there is no risk of graft-versus-host disease (GVHD), and unlike the use of autologous marrow, there is no risk that the stem cells are contaminated with tumor cells.

Allogeneic transplantation involves a donor and a recipient who are not genetically identical. Following allogeneic transplantation, immune cells transplanted with the stem cells or developing from them can react against the patient, causing GVHD. Alternatively, if the immunosuppressive preparative regimen used to treat the patient before transplant is inadequate, immunocompetent cells of the patient can cause graft rejection. The risks of these complications are greatly influenced by the degree of matching between donor and recipient for human leukocyte antigen (HLA) molecules encoded by genes of the major histocompatibility complex.

HLA molecules are responsible for binding antigenic proteins and presenting them to T cells. The antigens presented by HLA molecules may derive from exogenous sources (e.g., during active infections) or may be endogenous proteins. If individuals are not HLA-matched, T cells from one individual will react strongly to the mismatched HLA, or "major antigens," of the second. Even if the individuals are HLA-matched, the T cells of the donor may react to differing endogenous or "minor antigens" presented by the HLA of the recipient. Reactions to minor antigens tend to be less vigorous. The genes of major relevance to transplantation

include HLA-A, -B, -C, and -D; they are closely linked and therefore tend to be inherited as haplotypes, with only rare crossovers between them. Thus, the odds that any one full sibling will match a patient are one in four, and the probability that the patient has an HLA-identical sibling is $1 - (0.75)^n$, where n equals the number of siblings.

With standard techniques, the risk of graft rejection is 1–3%, and the risk of severe, life-threatening acute GVHD is ~15% following transplantation between HLA-identical siblings. The incidence of graft rejection and GVHD increases progressively with the use of family member donors mismatched for one, two, or three antigens. Although survival following a one-antigen mismatched transplant is not markedly altered, survival following two- or three-antigen mismatched transplants is reduced. Since the formation of the National Marrow Donor Program and other registries, it has become possible to identify HLA-matched unrelated donors for many patients. The genes encoding HLA antigens are highly polymorphic, and thus the odds of any two unrelated individuals being HLA identical are extremely low, somewhat less than 1 in 10,000. However, by identifying and typing >25 million volunteer donors, HLA-matched donors can now be found for ~60% of patients for whom a search is initiated, with higher rates among whites and lower rates among minorities and patients of mixed race. It takes, on average, 3–4 months to complete a search and schedule and initiate an unrelated donor transplant. With improvements in HLA typing and supportive care measures, survival following matched unrelated donor transplantation is essentially the same as that seen with HLA-matched siblings. Methods have recently been developed that enable the selection of "permissive" single-antigen mismatched unrelated donors that result in transplant outcomes similar to those seen with full matches.

Allogeneic HCT can be carried out across ABO blood barriers by removing isoagglutinins and/or incompatible red blood cells from the donor graft. However, depending on the direction of the mismatch, hemolysis of donor cells by persistent isoagglutinins in the host, or hemolysis of recipient red cells by isoagglutinins in the graft or developing from it may occur despite appropriate manipulation of the donor cell product.

Autologous transplantation involves the removal and storage of the patient's own stem cells with subsequent reinfusion after the patient receives high-dose myeloablative therapy. Unlike allogeneic transplantation, there is no risk of GVHD or graft rejection with autologous transplantation. On the other hand, autologous transplantation lacks a graft-versus-tumor (GVT) effect, and the autologous stem cell product can be contaminated with tumor cells, which could lead to relapse. A variety of techniques have been developed to "purge" autologous products of tumor cells, but no prospective randomized trials have yet shown that any approach results in a decrease in relapse rates or improvement in disease-free or overall survival.

Bone marrow aspirated from the posterior and anterior iliac crests initially was the source of hematopoietic stem cells for transplantation. Typically, anywhere from 1.5 to 5×10^8 nucleated marrow cells per kilogram are collected for allogeneic transplantation. Several studies have found improved survival in the settings of both matched sibling and unrelated transplantation by transplanting higher numbers of bone marrow cells.

Hematopoietic stem cells circulate in the peripheral blood but in very low concentrations. Following the administration of a myeloid growth factor such as granulocyte colony-stimulating factor (G-CSF) and during recovery from intensive chemotherapy, the concentration of hematopoietic progenitor cells in blood, as measured either by colony-forming units or expression of the CD34 antigen, increases markedly. This has made it possible to harvest adequate numbers of stem cells from the peripheral blood for transplantation. Donors are typically treated with 4 or 5 days of hematopoietic growth factor, following which stem cells are collected in one or two 4-h pheresis sessions. In the autologous setting, transplantation of $>2.5 \times 10^6$ CD34 cells per kilogram, a number that can be collected in most circumstances, leads to rapid and sustained engraftment in virtually all cases. In the 10–20% of patients who fail to mobilize sufficient CD34+ cells with growth factor alone, the addition of plerixafor, an antagonist of CXCR4, may be useful. When compared to the use of autologous marrow, use of peripheral blood stem cells results in more rapid hematopoietic recovery. Although this more rapid recovery diminishes the morbidity rate of transplantation, no studies show improved survival.

TABLE 110-1 Probability of Identifying a Donor Based on Stem Cell Source and Patient Ethnicity

	UNRELATED ADULT %		UNRELATED CORD %

Hispanic	35	75	95
Black	18	70	90

[a]Matching for HLA-A, -B, -C, and DRB1. [b]Matching for HLA-A, -B, and DRB1.

Clinical trials have shown that the use of growth factor–mobilized peripheral blood stem cells from HLA-matched family members leads to faster engraftment without an increase in acute GVHD. Chronic GVHD may be increased with peripheral blood stem cells, but in trials conducted so far, this has been more than balanced by reductions in relapse rates and non-relapse mortality rates, with the use of peripheral blood stem cells resulting in improved overall survival. However, in the setting of matched unrelated donor transplantation, use of peripheral blood results in more chronic GVHD without a compensatory survival advantage, favoring the use of bone marrow in this setting.

Umbilical cord blood contains a high concentration of hematopoietic progenitor cells, allowing for its use as a source of stem cells for transplantation. Cord blood transplantation from family members has been explored in the setting where the immediate need for transplantation precludes waiting the 9 or so months generally required for the baby to mature to the point of donating marrow. Use of cord blood results in slower peripheral count recovery than seen with marrow but a lower incidence of GVHD, perhaps reflecting the low number of T cells in cord blood. Multiple cord blood banks have been developed to harvest and store cord blood for possible transplantation to unrelated patients from material that would otherwise be discarded. Currently more than 500,000 units are cryopreserved and available for use. The advantages of unrelated cord blood are rapid availability and decreased immune reactivity allowing for the use of partially matched units, which is of particular importance for those without matched unrelated donors. The risks of graft failure and transplant-related mortality are related to the dose of cord blood cells per kilogram, which previously limited the application of single cord blood transplantation to pediatric and smaller adult patients. Subsequent trials have found that for patients without suitable single cord units, the use of double cord transplants diminishes the risk of graft failure and early mortality even though only one of the donors ultimately engrafts. Survival rates are now similar with unrelated donor and cord blood transplantation with the result that a potential allogeneic donor can be found for almost every patient in need **(see Table 110-1)**.

THE TRANSPLANT PREPARATIVE REGIMEN

The treatment regimen administered to patients immediately preceding transplantation is designed to eradicate the patient's underlying disease and, in the setting of allogeneic transplantation, immunosuppress the patient adequately to prevent rejection of the transplanted marrow. The appropriate regimen therefore depends on the disease setting and source of marrow. For example, when transplantation is performed to treat severe combined immunodeficiency and the donor is a histocompatible sibling, no treatment is needed because no host cells require eradication and the patient is already too immunoincompetent to reject the transplanted marrow. For aplastic anemia, there is no large population of cells to eradicate, and high-dose cyclophosphamide plus antithymocyte globulin are sufficient to immunosuppress the patient adequately to accept the marrow graft. In the setting of thalassemia and sickle cell anemia, high-dose busulfan is frequently added to cyclophosphamide in order to eradicate hyperplastic host hematopoiesis. A variety of different regimens have been developed to treat malignant diseases. Most of these regimens include agents that have high activity against the tumor in question at conventional doses and have

myelosuppression as their predominant dose-limiting toxicity. Therefore, these regimens commonly include busulfan, cyclophosphamide, melphalan, thiotepa, carmustine, etoposide, and total-body irradiation in various combinations.

Although high-dose treatment regimens were the initial approach to transplantation for malignancies, the understanding that much of the antitumor effect of transplantation derives from an immunologically mediated GVT response led investigators to ask if reduced-intensity conditioning regimens might be effective and more tolerable. Evidence for a GVT effect comes from studies showing that post-transplant relapse rates are lowest in patients who develop acute and chronic GVHD, higher in those without GVHD, and higher still in recipients of T cell–depleted allogeneic or syngeneic marrow. The demonstration that complete remissions can be obtained in many patients who have relapsed after transplant by simply administering viable lymphocytes from the original donor further strengthens the argument for a potent GVT effect. Accordingly, a variety of alternative regimens have been studied, ranging from non-myeloablative that are the very minimum required to achieve engraftment (e.g., fludarabine plus 200 cGy total-body irradiation) and would cause only transient myelosuppression if no transplant were performed, to so-called reduced intensity regimens, which would cause significant but not necessarily fatal myelosuppression in the absence of transplantation (e.g., fludarabine plus melphalan). Studies to date document that engraftment can be readily achieved with less toxicity than seen with conventional transplantation. Complete sustained responses have been documented in many patients, particularly those with more indolent hematologic malignancies. In general, relapse rates are higher following reduced-intensity conditioning, but transplant-related mortality is lower, favoring the use of reduced-intensity conditioning in patients with significant comorbidities. High-dose regimens are favored in all those felt able to tolerate the treatment.

THE TRANSPLANT PROCEDURE

Marrow is usually collected from the donor's posterior and sometimes anterior iliac crests, with the donor under general or spinal anesthesia. Typically, 10–15 mL/kg of marrow is aspirated, placed in heparinized media, and filtered through 0.3- and 0.2-mm screens to remove fat and bony spicules. The collected marrow may undergo further processing depending on the clinical situation, such as the removal of red cells to prevent hemolysis in ABO-incompatible transplants, the removal of donor T cells to prevent GVHD, or attempts to remove possible contaminating tumor cells in autologous transplantation. Marrow donation is safe, with only very rare complications reported.

Peripheral blood stem cells are collected by leukapheresis after the donor has been treated with hematopoietic growth factors or, in the setting of autologous transplantation, sometimes after treatment with a combination of chemotherapy and growth factors. Stem cells for transplantation are infused through a large-bore central venous catheter. Such infusions are usually well tolerated, although occasionally patients develop fever, cough, or shortness of breath. These symptoms typically resolve with slowing of the infusion. When the stem cell product has been cryopreserved using dimethyl sulfoxide, patients more often experience short-lived nausea or vomiting due to the odor and taste of the cryoprotectant.

ENGRAFTMENT AND IMMUNE RECONSTITUTION

Peripheral blood counts usually reach their nadir several days to a week after transplant as a consequence of the preparative regimen; then cells produced by the transplanted stem cells begin to appear in the peripheral blood. The rate of recovery depends on the source of stem cells and the use of post-transplant growth factors. If marrow is the source of stem cells, recovery to 100 granulocytes/μL occurs on average by day 16 and to 500/μL by day 22. Use of G-CSF–mobilized peripheral blood stem cells speeds the rate of recovery by ~1 week when compared to marrow, whereas engraftment following cord blood transplantation is typically delayed by ~1 week compared to marrow. Use of a myeloid growth factor after transplant can accelerate recovery by 3–5 days. Platelet counts usually recover shortly after granulocytes.

While granulocytes and other components of innate immunity recover rapidly after HCT, adaptive immunity, which consists of cellular (T cell) and humoral (B cell) immunity, may take 1–2 years to fully recover. Survival and peripheral expansion of infused donor T cells is the dominant mechanism for T cell recovery in the first months after HCT and results in mostly CD8+ T cells with a limited repertoire. After several months, de novo generation of donor-derived CD4+ and CD8+ T cells becomes dominant providing a more diverse T cell repertoire. B cell counts recover by 6 months after autologous HCT and 9 months after allogeneic HCT. In general, immune recovery occurs more rapidly after autologous than allogeneic HCT and after receipt of unmodified grafts compared to the setting of in vivo or ex vivo T-cell depletion.

Following allogeneic transplantation, engraftment can be documented using fluorescence in situ hybridization of sex chromosomes if donor and recipient are sex-mismatched or by analysis of short tandem repeat polymorphisms after DNA amplification.

COMPLICATIONS FOLLOWING HEMATOPOIETIC CELL TRANSPLANT

Early Direct Chemoradiotoxicities The transplant preparative regimen may cause a spectrum of acute toxicities that vary according to intensity of the regimen and the specific agents used but frequently include nausea, vomiting, and mild skin erythema (Fig. 110-1). High-dose cyclophosphamide can result in hemorrhagic cystitis, which can usually be prevented by bladder irrigation or with the sulfhydryl compound mercaptoethanesulfonate (MESNA). Most high-dose preparative regimens will result in oral mucositis, which typically develops 5–7 days after transplant and often requires narcotic analgesia. Use of a patient-controlled analgesic pump provides the greatest patient satisfaction and results in a lower cumulative dose of narcotic. Keratinocyte growth factor (palifermin) can shorten the duration of mucositis by several days following autologous transplantation. Patients begin losing their hair 5–6 days after transplant and by 1 week are usually profoundly pancytopenic.

Depending on the intensity of the conditioning regimen, 3–10% of patients will develop sinusoidal obstruction syndrome (SOS) of the liver (formerly called venoocclusive disease), a syndrome that results from direct cytotoxic injury to hepatic-venular and sinusoidal endothelium, with subsequent deposition of fibrin and the development of a local hypercoagulable state. This chain of events leads to the clinical symptoms of tender hepatomegaly, ascites, jaundice, and fluid retention. These symptoms can develop any time during the first month after transplant, with the peak incidence at day 16. Predisposing factors include prior exposure to intensive chemotherapy, pre-transplant

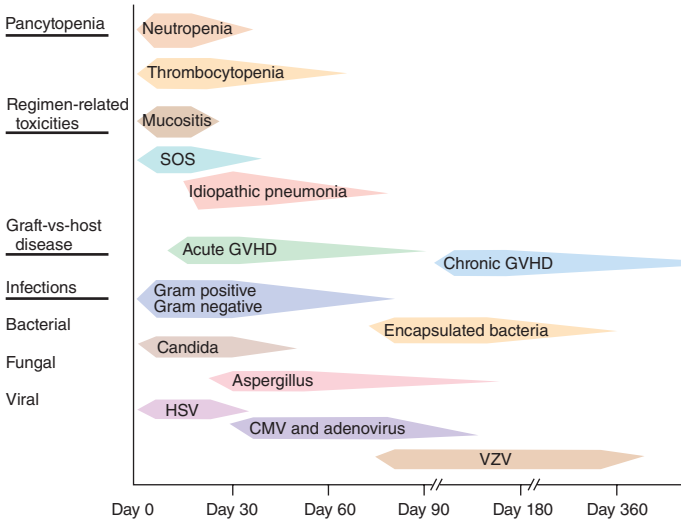

FIGURE 110-1 Major syndromes complicating marrow transplantation. CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; SOS, sinusoidal obstructive syndrome (formerly venoocclusive disease); VZV, varicella-zoster virus. The size of the shaded area roughly reflects the period of risk of the complication.

hepatitis of any cause, and use of more intense conditioning regimens. The mortality rate of sinusoidal obstruction syndrome is ~30%, with progressive hepatic failure culminating in a terminal hepatorenal syndrome. Treatment of severe SOS with defibrotide, a polydeoxyribonucleotide, can reduce mortality.

Although most pneumonias developing early after transplant are caused by infectious agents, in a small percent of patients a diffuse interstitial pneumonia will develop that is a result of direct toxicity of high-dose preparative regimens. Bronchoalveolar lavage usually shows alveolar hemorrhage, and biopsies are typically characterized by diffuse alveolar damage, although some cases may have a more clearly interstitial pattern. High-dose glucocorticoids or antitumor necrosis factor therapies are sometimes used as treatment, although randomized trials proving their utility have not been reported.

Late Direct Chemoradiotoxicities Two categories of chronic pulmonary disease occur in patients more than 3 months after HCT. Cryptogenic organizing pneumonia is a restrictive lung disease characterized by dry cough, shortness of breath, and chest imaging showing a diffuse, fluffy infiltrate. Biopsy shows granulation tissue within alveolar spaces and small airways and no infectious agents. The disease responds well to corticosteroids and is entirely reversible. Bronchiolitis obliterans is an obstructive disease presenting with cough, progressive dyspnea, and radiologic evidence of air trapping. Pathology shows collagen and granulation tissue in and around bronchial structures and eventually obliteration of small airways. The disease is usually associated with chronic GVHD and while it may respond to increasing immunosuppression, complete reversal is uncommon.

Other late complications of the preparative regimen include decreased growth velocity in children and delayed development of secondary sex characteristics. These complications can be partly ameliorated with the use of appropriate growth and sex hormone replacement. Most men become azoospermic, and most postpubertal women will develop ovarian failure, which should be treated. However, pregnancy is possible after transplantation, and patients should be counseled accordingly. Thyroid dysfunction, usually well compensated, is sometimes seen. Cataracts develop in 10–20% of patients and are most common in patients treated with total-body irradiation and those who receive glucocorticoid therapy after transplant for treatment of GVHD. Aseptic necrosis of the femoral head is seen in 10% of patients and is particularly frequent in those receiving chronic glucocorticoid therapy. Both acute and late chemoradiotoxicities (except those due to glucocorticoids and other agents used to treat GVHD) are less frequent in recipients of reduced-intensity compared to high-dose preparative regimens.

Graft Failure Although complete and sustained engraftment is usually seen after transplant, occasionally marrow function either does not return or, after a brief period of engraftment, is lost. Graft failure after autologous transplantation can be the result of inadequate numbers of stem cells being transplanted, damage during ex vivo treatment or storage, or exposure of the patient to myelotoxic agents after transplant. Infections with cytomegalovirus (CMV) or human herpesvirus type 6 have also been associated with loss of marrow function. Graft failure after allogeneic transplantation can also be due to immunologic rejection of the graft by immunocompetent host cells. Such rejection is generally thought to be mostly T-cell mediated, but the presence of pre-HCT of donor-specific HLA antibodies in the patient is associated with poor engraftment, leading to the recommendation for screening for donor-directed anti-HLA antibodies in recipients prior to transplant. Immunologically based graft rejection is more common following use of less immunosuppressive preparative regimens, in recipients of T cell–depleted stem cell products, and in patients receiving grafts from HLA-mismatched donors or cord blood.

Treatment of graft failure usually involves removing all potentially myelotoxic agents from the patient's regimen and attempting a short trial of a myeloid growth factor. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic rejection. Reinfusion of donor stem cells in such patients is usually unsuccessful unless preceded by a second immunosuppressive preparative regimen. Standard high-dose preparative regimens are generally tolerated poorly if administered within 100 days of a first transplant because of cumulative toxicities. However, use of reduced-intensity conditioning regimens has been effective in some cases.

Graft-versus-Host Disease Acute GVHD usually occurs within the first 3 months after allogeneic transplant with a peak onset around 4 weeks and is characterized by an erythematous maculopapular rash; by persistent anorexia or diarrhea, or both; and by liver disease with increased serum levels of bilirubin, alanine and aspartate aminotransferase, and alkaline phosphatase. Because many conditions can mimic acute GVHD, the diagnosis usually requires skin, liver, or endoscopic biopsy for confirmation. In all these organs, endothelial damage and lymphocytic infiltrates are seen. In skin, the epidermis and hair follicles are damaged; in liver, the small bile ducts show segmental disruption; and in intestines, destruction of the crypts and mucosal ulceration may be noted. A commonly used rating system for acute GVHD is shown in Table 110-2. Grade I acute GVHD is of little clinical significance, does not affect the likelihood of survival, and does not require treatment. In contrast, grades II to IV GVHD are associated with significant symptoms and a poorer probability of survival, and require aggressive therapy. The incidence of acute GVHD is higher in recipients of stem cells from mismatched or unrelated donors, in older patients, and in patients unable to receive full doses of drugs used to prevent the disease.

Currently, the standard approach to GVHD prevention is the administration of a calcinuerin inhibitor (cyclosporine or tacrolimus) combined with an antimetabolite (methotrexate or mycophenolate mofetil) following transplantation. The addition of anti T-cell immune globulin (ATG) may further reduce the incidence of GVHD but has not been shown to improve survival. Other approaches being tested in phase III studies include the addition of sirolimus to the standard two-drug regimen, the removal of subsets or all T cells from the stem cell inoculum, and the use of cyclophosphamide administered several days after transplant in an effort to deplete activated allo-reactive T cells.

Despite prophylaxis, significant acute GVHD will develop in ~30% of recipients of stem cells from matched siblings. Factors associated with a greater risk of acute GVHD include HLA-mismatching between

TABLE 110-2 Clinical Staging and Grading of Acute Graft-versus-Host Disease

CLINICAL STAGE	SKIN	LIVER—BILIRUBIN, μmol/L (mg/dL)	GUT
1	Rash <25% body surface	34–51 (2–3)	Diarrhea 500–1000 mL/d
2	Rash 25–50% body surface	51–103 (3–6)	Diarrhea 1000–1500 mL/d
3	Generalized erythroderma	103–257 (6–15)	Diarrhea >1500 mL/d
4	Desquamation and bullae	>257 (>15)	Ileus
OVERALL CLINICAL GRADE	**SKIN STAGE**	**LIVER STAGE**	**GUT STAGE**
I	1–2	0	0
II	1–3	1	1
III	1–3	2–3	2–3
IV	2–4	2–4	2–4

recipient and donor, patient and donor age, use of more intense preparative regimens and use of multiparous women as donors. Biomarkers, including ST2, REG32, and TNF R1 have been identified that are able to predict the severity of acute GVHD. The disease is usually treated with prednisone at a daily dose of 1–2 mg/kg. Patients who fail to respond to prednisone sometimes respond to alternative immunosuppressants or ATG.

Chronic GVHD occurs most commonly between 3 months and 2 years after allogeneic transplant, developing in 20–50% of recipients. The disease is more common in older patients, in recipients of mismatched or unrelated stem cells, and in those with a preceding episode of acute GVHD. The disease resembles an autoimmune disorder with malar rash, sicca syndrome, arthritis, obliterative bronchiolitis, and bile duct degeneration and cholestasis. Mild chronic GVHD can sometimes be managed using local therapies (topical glucocorticoids to skin and cyclosporine eye drops). More severe disease requires systemic therapy usually with prednisone alone or in combination with cyclosporine. Mortality rates from chronic GVHD average around 15%, but range from 5 to 50% depending on severity. In most patients, chronic GVHD resolves, but it may require 1–3 years of immunosuppressive treatment before these agents can be withdrawn without the disease recurring. Because patients with chronic GVHD are susceptible to significant infection, they should receive prophylactic trimethoprim-sulfamethoxazole, and all suspected infections should be investigated and treated aggressively.

Although onset before or after 3 months after transplant is often used to discriminate between acute and chronic GVHD, occasional patients will develop signs and symptoms of acute GVHD after 3 months (late-onset acute GVHD), whereas others will exhibit signs and symptoms of both acute and chronic GVHD (overlap syndrome). There are as yet no data to suggest that these patients should be treated differently than those with classic acute or chronic GVHD.

From 3 to 5% of patients will develop an autoimmune disorder following allogeneic HCT, most commonly autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura. Unrelated donor source and chronic GVHD are risk factors, but autoimmune disorders have been reported in patients with no obvious GVHD. Treatment is with prednisone, cyclosporine, or rituximab.

Infection Post-transplant patients, particularly recipients of allogeneic transplantation, require unique approaches to the problem of infection. Early after transplantation, patients are profoundly neutropenic, and because the risk of bacterial infection is so great, most centers place patients on broad spectrum antibiotics once the granulocyte count falls to <500/μL. Prophylaxis against fungal infections reduces rates of infection and improves overall survival. Fluconazole is often used for patients with standard risk, while prophylaxis with mold active agents (voriconizole or posaconazole) should be considered for patients at higher risk, such as those with a prior fungal infection. Patients seropositive for herpes simplex should receive acyclovir prophylaxis. One approach to infection prophylaxis is shown in Table 110-3. Despite these prophylactic measures, most patients will develop fever and signs of infection after transplant. The management of patients who become febrile despite bacterial and fungal prophylaxis is a difficult challenge and is guided by individual aspects of the patient and by the institution's experience.

TABLE 110-3 Approach to Infection Prophylaxis in Allogeneic Transplant Recipients

ORGANISM	AGENT	APPROACH
Bacterial	Levofloxacin	750 mg PO or IV daily
Fungal	Fluconazole	400 mg PO qd to day 75 posttransplant
Pneumocystis carinii	Trimethoprim-sulfamethoxazole	1 double-strength tablet PO bid 2 days/week until day 180 or off immunosuppression
Viral		
Herpes simplex	Acyclovir	800 mg PO bid to day 30
Varicella-zoster	Acyclovir	800 mg PO bid to day 365
Cytomegalovirus	Ganciclovir	5 mg/kg IV bid for 7 days, then 5 (mg/kg)/d 5 days/week to day 100

The general problem of infection in the immunocompromised host is discussed in Chap. 138.

Once patients engraft, the incidence of bacterial infection diminishes; however, patients, particularly allogeneic transplant recipients, remain at significant risk of infection. During the period from engraftment until about 3 months after transplant, the most common causes of infection are gram-positive bacteria, fungi (particularly *Aspergillus*), and viruses including CMV. CMV infection, which in the past was frequently seen and often fatal, can be prevented in seronegative patients transplanted from seronegative donors by the use of either seronegative blood products or products from which the white blood cells have been removed. In seropositive patients or patients transplanted from seropositive donors, the use of ganciclovir, either as prophylaxis beginning at the time of engraftment or initiated when CMV first reactivates as evidenced by development of antigenemia or viremia, can significantly reduce the risk of CMV disease. Foscarnet is effective for some patients who develop CMV antigenemia or infection despite the use of ganciclovir or who cannot tolerate the drug, but can be associated with severe electrolyte wasting.

Pneumocystis jiroveci pneumonia, once seen in 5–10% of patients, can be prevented by treating patients with oral trimethoprim-sulfamethoxazole for 1 week before transplant and resuming the treatment once patients have engrafted.

Respiratory viruses that cause community-acquired infections, including respiratory syncytial virus (RSV), parainfluenza virus, influenza virus and, metapneumovirus can be life threatening or fatal in the post-transplant patient. Protection of patients from infected visitors and staff by avoiding such contacts is critical. Neuraminidase inhibitors are effective for influenza infections. Inhaled ribavirin is sometimes used for RSV.

The risk of infection diminishes considerably beyond 3 months after transplant unless chronic GVHD develops, requiring continuous immunosuppression. Most transplant centers recommend continuing trimethoprim-sulfamethoxazole prophylaxis while patients are receiving any immunosuppressive drugs and also recommend careful monitoring for late CMV reactivation. In addition, many centers recommend prophylaxis against varicella-zoster, using acyclovir for 1 year after transplant. Patients should be revaccinated against tetanus, diphtheria, *Haemophilus influenzae*, polio, and pneumococcal pneumonia starting at 12 months after transplant and against measles, mumps, and rubella (MMR), varicella-zoster virus, and possibly pertussis at 24 months.

TREATMENT OF SPECIFIC DISEASES USING HEMATOPOIETIC CELL TRANSPLANTATION

TREATMENT

Nonmalignant Diseases

IMMUNODEFICIENCY DISORDERS

By replacing abnormal stem cells with cells from a normal donor, HCT can cure patients of a variety of immunodeficiency disorders including severe combined immunodeficiency, Wiskott-Aldrich syndrome, and Chédiak-Higashi syndrome. The widest experience has been with severe combined immunodeficiency disease, where cure rates of 90% can be expected with HLA-identical donors and success rates of 50–70% have been reported using haplotype-mismatched parents as donors **(Table 110-4)**.

APLASTIC ANEMIA

Transplantation from matched siblings after a preparative regimen of high-dose cyclophosphamide and antithymocyte globulin can cure up to 90% of patients age <40 years with severe aplastic anemia. Results in older patients and in recipients of mismatched family member or unrelated marrow are less favorable; therefore, a

TABLE 110-4 Estimated 5-Year Survival Rates Following Transplantation[a]

DISEASE	ALLOGENEIC, %	AUTOLOGOUS, %
Severe combined immunodeficiency	90	N/A
Aplastic anemia	90	N/A

trial of immunosuppressive therapy is generally recommended for such patients before considering transplantation. Transplantation is effective in all forms of aplastic anemia including, for example, the syndromes associated with paroxysmal nocturnal hemoglobinuria and Fanconi's anemia. Patients with Fanconi's anemia are abnormally sensitive to the toxic effects of alkylating agents, and so less intensive preparative regimens must be used in their treatment **(Chap. 98)**.

HEMOGLOBINOPATHIES

Marrow transplantation from an HLA-identical sibling following a preparative regimen of busulfan and cyclophosphamide can cure 80–90% of patients with thalassemia major. The best outcomes can be expected if patients are transplanted before they develop hepatomegaly or portal fibrosis and if they have been given adequate iron chelation therapy. Among such patients, the probabilities of 5-year survival and disease-free survival are 95 and 90%, respectively. Although prolonged survival can be achieved with aggressive chelation therapy, transplantation is the only curative treatment for thalassemia. Transplantation is potentially curative for patients with sickle cell anemia. Two-year survival and disease-free survival rates of 95 and 85%, respectively, have been reported following matched sibling or cord blood transplantation. Decisions about patient selection and the timing of transplantation remain difficult, but transplantation represents a reasonable option for children and young adults who have suffered complications of sickle cell anemia including stroke, recurrent vasoocclusive pain, sickle cell lung disease, or sickle nephropathy **(Chap. 94)**.

OTHER NONMALIGNANT DISEASES

Theoretically, HCT should be able to cure any disease that results from an inborn error of the lymphohematopoietic system. Transplantation has been used successfully to treat congenital disorders of white blood cells such as Kostmann's syndrome, chronic granulomatous disease, and leukocyte adhesion deficiency. Congenital anemias such as Blackfan-Diamond anemia can also be cured with transplantation. Since the penetrance of some congenital marrow failure states is variable, potential family member donors should be carefully screened before use to assure they are not affected. Infantile malignant osteopetrosis is due to an inability of the osteoclast to resorb bone, and because osteoclasts derive from the marrow, transplantation can cure this rare inherited disorder.

HCT has been used as treatment for a number of storage diseases caused by enzymatic deficiencies, such as Gaucher's disease, Hurler's syndrome, Hunter's syndrome, and infantile metachromatic leukodystrophy. Transplantation for these diseases has not been uniformly successful, but treatment early in the course of these diseases, before irreversible damage to extramedullary organs has occurred, increases the chance for success.

Transplantation is being explored as a treatment for severe acquired autoimmune disorders. These trials are based on studies demonstrating that transplantation can reverse autoimmune disorders in animal models and on the observation that occasional patients with coexisting autoimmune disorders and hematologic malignancies have been cured of both with transplantation.

TREATMENT

Malignant Diseases

ACUTE LEUKEMIA

Allogeneic HCT cures 15–20% of patients who do not achieve complete response after induction chemotherapy for acute myeloid leukemia (AML) and is the only form of therapy that can cure such patients. Thus, all patients with AML who are possible transplant candidates should have their HLA type determined soon after diagnosis to enable HCT for those who fail to enter remission. Cure rates of 30–35% are seen when patients are transplanted in second remission or in first relapse. The best results with allogeneic transplantation are achieved when applied during first remission, with disease-free survival rates averaging 55–60%. Meta-analyses of studies comparing matched related donor transplantation to chemotherapy for adult AML patients age <60 years show a survival advantage with transplantation. This advantage is greatest for those with unfavorable-risk AML and is lost in those with favorable-risk disease. While HCT can be performed in patients up to age 75 and possibly beyond, prospective trials comparing HCT with chemotherapy are lacking for older patients. The role of autologous transplantation in the treatment of AML is less well defined. The rates of disease recurrence with autologous transplantation are higher than those seen after allogeneic transplantation, and cure rates are somewhat less.

Similar to patients with AML, adults with acute lymphocytic leukemia who do not achieve a complete response to induction chemotherapy can be cured in 15–20% of cases with immediate transplantation. Cure rates improve to 30–50% in second remission, and therefore transplantation can be recommended for adults who have persistent disease after induction chemotherapy or who have subsequently relapsed. Transplantation in first remission results in cure rates about 55%. Transplantation appears to offer a survival advantage over chemotherapy for patients with high-risk disease, such as those with Philadelphia chromosome–positive disease. Debate continues about whether adults with standard-risk disease should be transplanted in first remission or whether transplantation should be reserved until relapse. Autologous transplantation is associated with a higher relapse rate but a somewhat lower risk of non-relapse mortality when compared to allogeneic transplantation. There is no obvious role of autologous transplantation for acute lymphocytic leukemia in first remission, and for second-remission patients, most experts recommend use of allogeneic stem cells if an appropriate donor is available.

CHRONIC LEUKEMIA

Allogeneic HCT is indicated for patients with chronic myeloid leukemia who are in chronic phase but have failed therapy with two or more tyrosine kinase inhibitors. In such patients, cure rates of 70% can be expected. HCT is also recommended for patients with CML

who present or progress to accelerated phase or blast crisis, although lower cure rates are seen in such patients **(Chap. 101)**.

Although allogeneic transplantation can cure patients with chronic lymphocytic leukemia (CLL), it has not been extensively studied because of the chronic nature of the disease, the age profile of patients and, more recently, the availability of multiple effective therapies. In those cases where it was studied, complete remissions were achieved in the majority of patients, with disease-free survival rates of ~50% at 3 years, despite the advanced stage of the disease at the time of transplant.

MYELODYSPLASIA AND MYELOPROLIFERATIVE DISORDERS

Between 20 and 65% of patients with myelodysplasia appear to be cured with allogeneic transplantation. Results are better among younger patients and those with less advanced disease. However, patients with early-stage myelodysplasia can live for extended periods without intervention, and so transplantation is generally reserved for patients with an International Prognostic Scoring System (IPSS) score of Int-2 or higher, or for selected patients with an IPSS score of Int-1 who have other poor prognostic features **(Chap. 98)**. Allogeneic HCT can cure patients with primary myelofibrosis or myelofibrosis secondary to polycythemia vera or essential thrombocythemia, with 5-year progression-free survival rates in excess of 65% being reported. It may require many months for the fibrosis to resolve.

LYMPHOMA

Patients with disseminated intermediate- or high-grade non-Hodgkin's lymphoma who have not been cured by first-line chemotherapy and are transplanted in first relapse or second remission can still be cured in 40–50% of cases. This represents a clear advantage over results obtained with conventional-dose salvage chemotherapy. It is unsettled whether patients with high-risk disease benefit from transplantation in first remission. Most experts favor the use of autologous rather than allogeneic transplantation for patients with intermediate- or high-grade non-Hodgkin's lymphoma, because fewer complications occur with this approach and survival appears equivalent. Although autologous transplantation results in high response rates in patients with recurrent disseminated indolent non-Hodgkin's lymphoma, the availability of newer agents for this category of patient leaves the role of transplantation unsettled. Reduced-intensity conditioning regimens followed by allogeneic transplantation result in high rates of complete and enduring complete responses in patients with recurrent indolent lymphomas.

The role of transplantation in Hodgkin's disease is similar to that in intermediate- and high-grade non-Hodgkin's lymphoma. With transplantation, 5-year disease-free survival is 20–30% in patients who never achieve a first remission with standard chemotherapy and up to 70% for those transplanted in second remission. Transplantation has no defined role in first remission in Hodgkin's disease.

MYELOMA

Patients with myeloma who have progressed on first-line therapy can sometimes benefit from allogeneic or autologous transplantation. Prospective randomized studies demonstrate that the inclusion of autologous transplantation as part of the initial therapy of patients results in improved disease-free survival and overall survival. Further benefit is seen with the use of lenalidomide maintenance therapy following transplantation. The use of autologous transplantation followed by non-myeloablative allogeneic transplantation has yielded mixed results.

SOLID TUMORS

Patients with testicular cancer in whom first-line platinum-containing chemotherapy has failed can still be cured in ~50% of cases if treated with high-dose chemotherapy with autologous stem cell support, an outcome better than that seen with low-dose salvage chemotherapy. The use of high-dose chemotherapy with autologous stem cell support is being studied for several other solid tumors, including neuroblastoma and pediatric sarcomas. As in most other settings, the best results have been obtained in patients with limited amounts of disease and where the remaining tumor remains sensitive to conventional-dose chemotherapy. Few randomized trials of transplantation in these diseases have been completed.

POSTTRANSPLANT RELAPSE

Patients who relapse following autologous transplantation sometimes respond to further chemotherapy and may be candidates for possible allogeneic transplantation, particularly if the remission following the initial autologous transplant was long. Several options are available for patients who relapse following allogeneic transplantation. Treatment with infusions of unirradiated donor lymphocytes results in complete responses in as many as 75% of patients with chronic myeloid leukemia, 40% in myelodysplasia, 25% in AML, and 15% in myeloma have been reported. Major complications of donor lymphocyte infusions include transient myelosuppression and the development of GVHD. These complications depend on the number of donor lymphocytes given and the schedule of infusions, with less GVHD seen with lower dose, fractionated schedules.

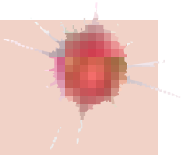
Section 3 Disorders of Hemostasis



111 Disorders of Platelets and Vessel Wall

Barbara A. Konkle

Hemostasis is a dynamic process in which the platelet and the blood vessel wall play key roles. Platelets become activated upon adhesion to von Willebrand factor (VWF) and collagen in the exposed subendothelium after injury. Platelet activation is also mediated through shear forces imposed by blood flow itself, particularly in areas where the vessel wall is diseased, and is also affected by the inflammatory state of the endothelium. The activated platelet surface provides the major physiologic site for coagulation factor activation, which results in further platelet activation and fibrin formation. Genetic and acquired

influences on the platelet and vessel wall, as well as on the coagulation and fibrinolytic systems, determine whether normal hemostasis or bleeding or clotting symptoms will result.

THE PLATELET

Platelets are released from the megakaryocyte, likely under the influence of flow in the capillary sinuses. The normal blood platelet count is 150,000–450,000/μL. The major regulator of platelet production is the hormone thrombopoietin (TPO), which is synthesized in the liver. Synthesis is increased with inflammation and specifically by interleukin 6. TPO binds to its receptor on platelets and megakaryocytes, by which it is removed from the circulation. Thus a reduction in platelet and megakaryocyte mass increases the level of TPO, which then stimulates platelet production. Platelets circulate with an average life span of 7–10 days. Approximately one-third of the platelets reside in the spleen, and this number increases in proportion to splenic size, although the platelet count rarely decreases to <40,000/μL as the spleen enlarges. Platelets are physiologically very active, but are anucleate, and thus have limited capacity to synthesize new proteins.

Normal vascular endothelium contributes to preventing thrombosis by inhibiting platelet function **(Chap. 61)**. When vascular endothelium is injured, these inhibitory effects are overcome, and platelets adhere to the exposed intimal surface primarily through VWF, a large multimeric protein present in both plasma and in the extracellular matrix of the subendothelial vessel wall. Platelet adhesion results in the generation of intracellular signals that lead to activation of the platelet glycoprotein (Gp) IIb/IIIa ($\alpha_{IIb}\beta_3$) receptor and resultant platelet aggregation.

Activated platelets undergo release of their granule contents, which include nucleotides, adhesive proteins, growth factors, and procoagulants that serve to promote platelet aggregation and blood clot formation and influence the environment of the forming clot. During platelet aggregation, additional platelets are recruited to the site of injury, leading to the formation of an occlusive platelet thrombus. The platelet plug is stabilized by the fibrin mesh that develops simultaneously as the product of the coagulation cascade.

THE VESSEL WALL

Endothelial cells line the surface of the entire circulatory tree, totaling $1–6 \times 10^{13}$ cells, enough to cover a surface area equivalent to about six tennis courts. The endothelium is physiologically active, controlling vascular permeability, flow of biologically active molecules and nutrients, blood cell interactions with the vessel wall, the inflammatory response, and angiogenesis.

The endothelium normally presents an antithrombotic surface **(Chap. 61)** but rapidly becomes prothrombotic when stimulated, which promotes coagulation, inhibits fibrinolysis, and activates platelets. In many cases, endothelium-derived vasodilators are also platelet inhibitors (e.g., nitric oxide) and, conversely, endothelium-derived vasoconstrictors (e.g., endothelin) can also be platelet activators. The net effect of vasodilation and inhibition of platelet function is to promote blood fluidity, whereas the net effect of vasoconstriction and platelet activation is to promote thrombosis. Thus, blood fluidity and hemostasis are regulated by the balance of antithrombotic/prothrombotic and vasodilatory/vasoconstrictor properties of endothelial cells.

DISORDERS OF PLATELETS

THROMBOCYTOPENIA

Thrombocytopenia results from one or more of three processes: (1) decreased bone marrow production; (2) sequestration, usually in an enlarged spleen; and/or (3) increased platelet destruction. Disorders of production may be either inherited or acquired. In evaluating a patient with thrombocytopenia, a key step is to review the peripheral blood smear and to first rule out "pseudothrombocytopenia," particularly in a patient without an apparent cause for the thrombocytopenia. Pseudothrombocytopenia **(Fig. 111-1*B*)** is an in vitro artifact resulting from platelet agglutination via antibodies (usually IgG, but also IgM and IgA) when the calcium content is decreased by blood collection in ethylenediamine tetraacetic (EDTA) (the anticoagulant present in tubes [purple top] used to collect blood for complete blood counts [CBCs]). If a low platelet count is obtained in EDTA-anticoagulated blood, a blood smear should be evaluated and a platelet count determined in blood collected into sodium citrate (blue top tube) or heparin (green top tube), or a smear of freshly obtained unanticoagulated blood, such as from a finger stick, can be examined.

APPROACH TO THE PATIENT

Thrombocytopenia

The history and physical examination, results of the CBC, and review of the peripheral blood smear are all critical components in the initial evaluation of thrombocytopenic patients **(Fig. 111-2)**. The overall health of the patient and whether he or she is receiving drug treatment will influence the differential diagnosis. A healthy young adult with thrombocytopenia will have a much more limited differential diagnosis than an ill hospitalized patient who is receiving multiple medications. Except in unusual inherited disorders, decreased platelet production usually results from bone marrow disorders that also affect red blood cell (RBC) and/or white blood cell (WBC) production. Because myelodysplasia can present with isolated thrombocytopenia, the bone marrow should be examined in patients presenting with isolated thrombocytopenia who are older than 60 years of age. While inherited thrombocytopenia is rare, any prior platelet counts should be retrieved and a family history regarding thrombocytopenia obtained. A careful history of drug ingestion should be obtained, including nonprescription and herbal remedies, because drugs are the most common cause of thrombocytopenia.

The physical examination can document an enlarged spleen, evidence of chronic liver disease, and other underlying disorders. Mild to moderate splenomegaly may be difficult to appreciate in many individuals due to body habitus and/or obesity but can be easily assessed by abdominal ultrasound. A platelet count of ~5000–10,000 is required to maintain vascular integrity in the microcirculation. When the count is markedly decreased, petechiae first appear in areas of increased venous pressure, the ankles and feet in an ambulatory patient. Petechiae are pinpoint, nonblanching hemorrhages and are usually a sign of a decreased platelet number and not platelet dysfunction. Wet purpura, blood blisters that form on the oral mucosa, are thought to denote an increased risk of life-threatening hemorrhage in the thrombocytopenic patient. Excessive bruising is seen in disorders of both platelet number and function.

Infection-Induced Thrombocytopenia Many viral and bacterial infections result in thrombocytopenia and are the most common noniatrogenic cause of thrombocytopenia. This may or may not be associated with laboratory evidence of disseminated intravascular coagulation (DIC), which is most commonly seen in patients with systemic infections with gram-negative bacteria. Infections can affect both platelet production and platelet survival. In addition, immune mechanisms can be at work, as in infectious mononucleosis and early HIV infection. Late in HIV infection, pancytopenia and decreased and dysplastic platelet production are more common. Immune-mediated thrombocytopenia in children usually follows a viral infection and almost always resolves spontaneously. This association of infection with immune thrombocytopenic purpura is less clear in adults.

Drug-Induced Thrombocytopenia Many drugs have been associated with thrombocytopenia. A predictable decrease in platelet count occurs after treatment with many chemotherapeutic drugs due to bone marrow suppression **(Chap. 69)**. Drugs that cause isolated thrombocytopenia and have been confirmed with positive laboratory testing are listed in **Table 111-1**, but all drugs should be suspect in a patient with thrombocytopenia without an apparent cause and should be stopped, or substituted, if possible. A helpful website, Platelets on the Internet (*http://www.ouhsc.edu/platelets/*), lists drugs and supplements reported to have caused thrombocytopenia and the level of evidence supporting the association. Although not as well studied, herbal and

over-the-counter preparations may also result in thrombocytopenia and should be discontinued in patients who are thrombocytopenic.

Classic drug-dependent antibodies are antibodies that react with specific platelet surface antigens and result in thrombocytopenia only when the drug is present. Many drugs are capable of inducing these

antibodies, but for some reason, they are more common with quinine and sulfonamides. Drug-dependent antibody binding can be demonstrated by laboratory assays, showing antibody binding in the presence of, but not without, the drug present in the assay. The thrombocytopenia typically occurs after a period of initial exposure (median length 21 days), or upon reexposure, and usually resolves in 7–10 days after drug withdrawal. The thrombocytopenia caused by the platelet Gp IIb/IIIa inhibitory drugs, such as abciximab, differs in that it may occur within 24 h of initial exposure. This appears to be due to the presence of naturally occurring antibodies that cross-react with the drug bound to the platelet.

Heparin-Induced Thrombocytopenia Drug-induced thrombocytopenia due to heparin differs from that seen with other drugs in two major ways. (1) The thrombocytopenia is not usually severe, with nadir counts rarely <20,000/μL. (2) Heparin-induced thrombocytopenia (HIT) is not associated with bleeding and, in fact, markedly increases the risk of thrombosis. HIT results from antibody formation to a complex of the platelet-specific protein platelet factor 4 (PF4) and heparin. The anti-heparin/PF4 antibody can activate platelets through the FcγRIIa receptor and also activate monocytes and endothelial cells. Many patients exposed to heparin develop antibodies to heparin/PF4, but do not appear to have adverse consequences. A fraction of those who develop antibodies will develop HIT, and a portion of those (up to 50%) will develop thrombosis (HITT).

HIT can occur after exposure to low-molecular-weight heparin (LMWH) as well as unfractionated heparin (UFH), although it is more common with the latter. Most patients develop HIT after exposure to heparin for 5–14 days **(Fig. 111-3)**. It occurs before 5 days in those who were exposed to heparin in the prior few weeks or months (<~100 days) and have circulating anti-heparin/PF4 antibodies. Rarely, thrombocytopenia and thrombosis begin several days after all heparin has been stopped (termed *delayed-onset HIT*). The "4T's" have been recommended to be used in a diagnostic algorithm for HIT: *t*hrombocytopenia, *t*iming of platelet count drop, *thrombosis* and other sequelae such as localized skin reactions, and o*t*her causes of thrombocytopenia not evident. Application of the 4T scoring system is very useful in excluding a diagnosis of HIT but will result in over-diagnosis of HIT in situations where thrombocytopenia and thrombosis due to other etiologies are common, such as in the intensive care unit.

LABORATORY TESTING FOR HIT HIT (anti-heparin/PF4) antibodies can be detected using two types of assays. The most widely available is an enzyme-linked immunoassay (ELISA) with PF4/polyanion complex as the antigen. Because many patients develop antibodies but do not develop clinical HIT, the test has a low specificity for the diagnosis of HIT. This is especially true in patients who have undergone cardiopulmonary bypass surgery, where ~50% of patients develop these antibodies postoperatively. IgG-specific ELISAs increase specificity but may decrease sensitivity. The other assay is a platelet activation assay, most commonly the serotonin release assay, which measures the ability of the patient's serum to activate platelets in the presence of heparin in a concentration-dependent manner. This test has lower sensitivity but higher specificity than the ELISA. However, HIT remains a clinical diagnosis.

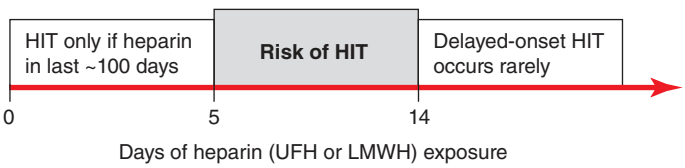

FIGURE 111-3 Time course of heparin-induced thrombocytopenia (HIT) development after heparin exposure. The timing of development after heparin exposure is a critical factor in determining the likelihood of HIT in a patient. HIT occurs early after heparin exposure in the presence of preexisting heparin/platelet factor 4 (PF4) antibodies, which disappear from circulation by ~100 days following a prior exposure. Rarely, HIT may occur later after heparin exposure (termed delayed-onset HIT). In this setting, heparin/PF4 antibody testing is usually markedly positive. HIT can occur after exposure to either unfractionated (UFH) or low-molecular-weight heparin (LMWH).

TREATMENT

Heparin-Induced Thrombocytopenia

Early recognition is key in treatment of HIT, with prompt discontinuation of heparin and use of alternative anticoagulants if bleeding risk does not outweigh thrombotic risk. Thrombosis is a common complication of HIT, even after heparin discontinuation, and can occur in both the venous and arterial systems. Patients with higher anti-heparin/PF4 antibody titers may have a higher risk of thrombosis. In patients diagnosed with HIT, imaging studies to evaluate the patient for thrombosis (at least lower extremity duplex Doppler imaging) are recommended. Patients requiring anticoagulation should be switched from heparin to an alternative anticoagulant. The direct thrombin inhibitor (DTI) argatroban is effective in HITT. The DTI bivalirudin and the antithrombin-binding pentasaccharide fondaparinux are also effective but not approved by the U.S. Food and Drug Administration (FDA) for this indication. Danaparoid, a mixture of glycosaminoglycans with anti-Xa activity, has been used extensively for the treatment of HITT; it is no longer available in the United States but is available in other countries. HIT antibodies cross-react with LMWH, and these preparations should not be used in the treatment of HIT.

Because of the high rate of thrombosis in patients with HIT, anticoagulation should be considered, even in the absence of thrombosis. In patients with thrombosis, patients can be transitioned to warfarin, with treatment usually for 3–6 months. In patients without thrombosis, the duration of anticoagulation needed is undefined. An increased risk of thrombosis is present for at least 1 month after diagnosis; however, most thromboses occur early, and whether thrombosis occurs later if the patient is initially anticoagulated is unknown. Options include continuing anticoagulation until a few days after platelet recovery or for 1 month. Introduction of warfarin alone in the setting of HIT or HITT may precipitate thrombosis, particularly venous gangrene, presumably due to clotting activation and severely reduced levels of proteins C and S. Warfarin therapy, if started, should be overlapped with a DTI or fondaparinux and started after resolution of the thrombocytopenia and lessening of the prothrombotic state. Evidence for use of an oral direct Xa inhibitor in this setting is growing, but more data are needed to establish efficacy.

Immune Thrombocytopenic Purpura Immune thrombocytopenic purpura (ITP; also termed *idiopathic thrombocytopenic purpura*) is an acquired disorder in which there is immune-mediated destruction of platelets and possibly inhibition of platelet release from the megakaryocyte. In children, it is usually an acute disease, most commonly following an infection, and with a self-limited course. In adults, it is a more chronic disease, although in some adults, spontaneous remission occurs, usually within months of diagnosis. ITP is termed *secondary* if it is associated with an underlying disorder; autoimmune disorders, particularly systemic lupus erythematosus (SLE), and infections, such as HIV and hepatitis C, are common causes. The association of ITP with *Helicobacter pylori* infection is unclear but appears to have a geographic distribution.

ITP is characterized by mucocutaneous bleeding and a low, often very low, platelet count, with an otherwise normal peripheral blood cells and smear. Patients usually present either with ecchymoses and petechiae, or with thrombocytopenia incidentally found on a routine CBC. Mucocutaneous bleeding, such as oral mucosa, gastrointestinal, or heavy menstrual bleeding, may be present. Rarely, life-threatening, including central nervous system, bleeding can occur. Wet purpura (blood blisters in the mouth) and retinal hemorrhages may herald life-threatening bleeding.

LABORATORY TESTING IN ITP Laboratory testing for antibodies (serologic testing) is usually not helpful due to the low sensitivity and specificity of the current tests. Bone marrow examination can be reserved for those who have other signs or laboratory abnormalities not explained by ITP or in patients who do not respond to initial therapy. The peripheral blood smear may show large platelets, with otherwise normal

morphology. Depending on the bleeding history, iron-deficiency anemia may be present.

Laboratory testing is performed to evaluate for secondary causes of ITP and should include testing for HIV infection and hepatitis C (and other infections if indicated). Serologic testing for SLE, serum protein electrophoresis, immunoglobulin levels to potentially detect hypogammaglobulinemia, selective testing for IgA deficiency or monoclonal gammopathies, and testing for *H. pylori* infection should be considered, depending on the clinical circumstance. If anemia is present, direct antiglobulin testing (Coombs' test) should be performed to rule out combined autoimmune hemolytic anemia with ITP (Evans' syndrome).

TREATMENT

Immune Thrombocytopenic Purpura

The treatment of ITP uses drugs that decrease reticuloendothelial uptake of the antibody-bound platelet, decrease antibody production, and/or increase platelet production. The diagnosis of ITP does not necessarily mean that treatment must be instituted. Patients with platelet counts >30,000/μL appear not to have increased mortality related to the thrombocytopenia.

Initial treatment in patients without significant bleeding symptoms, severe thrombocytopenia (<5000/μL), or signs of impending bleeding (such as retinal hemorrhage or large oral mucosal hemorrhages) can be instituted as an outpatient using single agents. Traditionally, this has been prednisone at 1 mg/kg, although Rh_0(D) immune globulin therapy (WinRho SDF), at 50–75 μg/kg, is also being used in this setting. Rh_0(D) immune globulin must be used only in Rh-positive patients because the mechanism of action is production of limited hemolysis, with antibody-coated cells "saturating" the Fc receptors, inhibiting Fc receptor function. Monitoring patients for 8 h after infusion is now advised by the FDA because of the rare complication of severe intravascular hemolysis. Intravenous gamma globulin (IVIgG), which is pooled, primarily IgG antibodies, also blocks the Fc receptor system, but appears to work primarily through different mechanism(s). IVIgG has more efficacy than anti-Rh_0(D) in postsplenectomized patients. IVIgG is dosed at 1–2 g/kg total, given over 1–5 days. Side effects are usually related to the volume of infusion and infrequently include aseptic meningitis and renal failure. All immunoglobulin preparations are derived from human plasma and undergo treatment for viral inactivation.

For patients with severe ITP and/or symptoms of bleeding, hospital admission and combined-modality therapy is given using high-dose glucocorticoids with IVIgG or anti-Rh_0(D) therapy and, as needed, additional immunosuppressive agents. Rituximab, an anti-CD20 (B cell) antibody, has shown efficacy in the treatment of refractory ITP, although long-lasting remission only occurs in ~30% of patients.

Splenectomy has been used for treatment of patients who relapse after glucocorticoids are tapered. Splenectomy remains an important treatment option; however, more patients than previously thought will go into a remission over time. Observation, if the platelet count is high enough, or intermittent treatment with anti-Rh_0(D) or IVIgG, or initiation of treatment with a TPO receptor agonist (see below) may be a reasonable approach to see if the ITP will resolve. Vaccination against encapsulated organisms (especially pneumococcus, but also meningococcus and *Haemophilus influenzae*, depending on patient age and potential exposure) is recommended before splenectomy. Accessory spleen(s) are a very rare cause of relapse.

TPO receptor agonists are available for the treatment of ITP. This approach stems from the finding that many patients with ITP do not have increased TPO levels, as was previously hypothesized. TPO levels reflect megakaryocyte mass, which is usually normal in ITP. TPO levels are not increased in the setting of platelet destruction. Two agents, one administered subcutaneously (romiplostim) and another orally (eltrombopag), are effective in raising platelet counts in patients with ITP and are recommended for adults at risk of bleeding who relapse after splenectomy or who have been unresponsive to at least one other therapy, particularly in those who have a contraindication to splenectomy. However, with the recognition that ITP will resolve spontaneously in some adult patients, short-term treatment with a TPO agonist can be considered before splenectomy in patients who need therapy. Eltrombopag is FDA approved for use in children over 1 year of age. Romiplostim is not yet FDA approved in children but a randomized trial supports efficacy.

Inherited Thrombocytopenia Thrombocytopenia is rarely inherited, either as an isolated finding or as part of a syndrome, and may be inherited in an autosomal dominant, autosomal recessive, or X-linked pattern. Many forms of autosomal dominant thrombocytopenia are now known to be associated with mutations in the nonmuscle myosin heavy chain *MYH9* gene. Interestingly, these include the May-Hegglin anomaly, and Sebastian, Epstein's, and Fechtner syndromes, all of which have distinct distinguishing features. A common feature of these disorders is large platelets (Fig. 111-1*C*). Autosomal recessive disorders include congenital amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii, and Bernard-Soulier syndrome. The latter is primarily a functional platelet disorder due to absence of Gp Ib-IX-V, the VWF adhesion receptor. X-linked disorders include Wiskott-Aldrich syndrome and a dyshematopoietic syndrome resulting from a mutation in *GATA-1*, an important transcriptional regulator of hematopoiesis.

THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC-UREMIC SYNDROME

Thrombotic thrombocytopenic microangiopathies are a group of disorders characterized by thrombocytopenia, a microangiopathic hemolytic anemia evident by fragmented RBCs (Fig. 111-1*D*) and laboratory evidence of hemolysis, and microvascular thrombosis. They include thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS), as well as syndromes complicating bone marrow transplantation, certain medications and infections, pregnancy, and vasculitis. In DIC, although thrombocytopenia and microangiopathy are seen, a coagulopathy predominates, with consumption of clotting factors and fibrinogen resulting in an elevated prothrombin time (PT) and often activated partial thromboplastin time (aPTT). The PT and aPTT are characteristically normal in TTP or HUS.

Thrombotic Thrombocytopenic Purpura TTP and HUS were previously considered overlap syndromes. However, with better understanding of the pathophysiology of both TTP and HUS they are clearly separate entities. TTP was first described in 1924 by Eli Moschcowitz and characterized by a pentad of findings that include microangiopathic hemolytic anemia, thrombocytopenia, renal failure, neurologic findings, and fever. The full-blown syndrome is less commonly seen now, probably due to earlier diagnosis. The introduction of treatment with plasma exchange markedly improved the prognosis in patients, with a decrease in mortality from 85–100% to 10–30%.

The pathogenesis of inherited (Upshaw-Schulman syndrome) and idiopathic TTP is related to a deficiency of, or antibodies to, the metalloprotease ADAMTS13, which cleaves VWF. VWF is normally secreted as ultra-large multimers, which are then cleaved by ADAMTS13. The persistence of ultra-large VWF molecules is thought to contribute to pathogenic platelet adhesion and aggregation **(Fig. 111-4)**. This defect alone, however, is not sufficient to result in TTP because individuals with a congenital absence of ADAMTS13 develop TTP only episodically. The level of ADAMTS13 activity, as well as antibodies, can be detected by laboratory assays. ADAMTS13 activity levels of <10% are more clearly associated with idiopathic (antibody-mediated) TTP.

Idiopathic TTP appears to be more common in women than in men. No geographic or racial distribution has been defined. TTP is more common in patients with HIV infection and in pregnant women. Medication-related microangiopathic hemolytic anemia may be secondary to antibody formation (ticlopidine and possibly clopidogrel) or direct endothelial toxicity (cyclosporine, mitomycin C, tacrolimus, quinine), although this is not always so clear, and fear of withholding treatment, as well as lack of other treatment alternatives, may result in initial application of plasma exchange. However, withdrawal, or

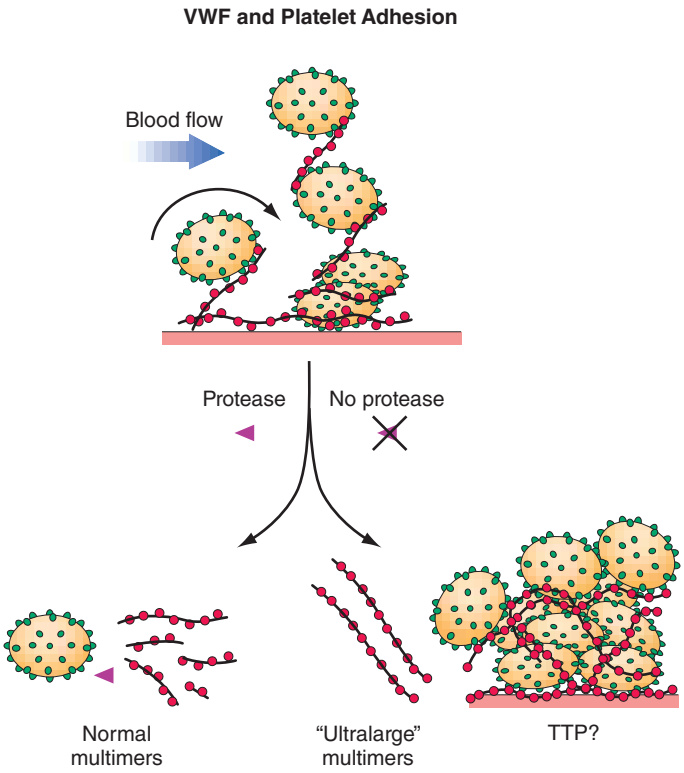

FIGURE 111-4 Pathogenesis of thrombotic thrombocytopenic purpura (TTP). Normally the ultra-high-molecular-weight multimers of von Willebrand factor (VWF) produced by the endothelial cells are processed into smaller multimers by a plasma metalloproteinase called ADAMTS13. In TTP, the activity of the protease is inhibited, and the ultra-high-molecular-weight multimers of VWF initiate platelet aggregation and thrombosis.

reduction in dose, of endothelial toxic agents usually decreases the microangiopathy.

TREATMENT

Thrombotic Thrombocytopenic Purpura

TTP is a devastating disease if not diagnosed and treated promptly. In patients presenting with new thrombocytopenia, with or without evidence of renal insufficiency and other elements of classic TTP, laboratory data should be obtained to rule out DIC and to evaluate for evidence of microangiopathic hemolytic anemia. Findings to support the TTP diagnosis include an increased lactate dehydrogenase and indirect bilirubin, decreased haptoglobin, and increased reticulocyte count, with a negative direct antiglobulin test. The peripheral smear should be examined for evidence of schistocytes (Fig. 111-1*D*). Polychromasia is usually also present due to the increased number of young red blood cells, and nucleated RBCs are often present, which is thought to be due to infarction in the microcirculatory system of the bone marrow.

Plasma exchange remains the mainstay of treatment of TTP. ADAMTS13 antibody-mediated TTP (idiopathic TTP) appears to respond best to plasma exchange. Plasma exchange is continued until the platelet count is normal and signs of hemolysis are resolved for at least 2 days. Although never evaluated in clinical trials, the use of glucocorticoids seems a reasonable approach, but should only be used as an adjunct to plasma exchange. Additionally, other immunomodulatory therapies have been reported to be successful in refractory or relapsing TTP, including rituximab, vincristine, cyclophosphamide, and splenectomy, with rituximab having the most evidence for efficacy. A significant relapse rate is noted; 25–45% of patients relapse within 30 days of initial "remission," and 12–40% of patients have late relapses. Relapses are more frequent in patients with severe ADAMTS13 deficiency at presentation.

Hemolytic-Uremic Syndrome HUS is a syndrome characterized by acute renal failure, microangiopathic hemolytic anemia, and thrombocytopenia. It is seen preceded by an episode of diarrhea, often hemorrhagic in nature, predominantly in children. *Escherichia coli* O157:H7 is the most frequent, although not only, etiologic serotype. HUS not associated with diarrhea is more heterogeneous in presentation and course. Atypical HUS (aHUS) is usually due to genetic defects that result in chronic complement activation or antibodies directed against complement regulatory proteins. Laboratory testing for DNA variants in complement regulatory genes is available, although assigning pathogenicity to variants remains challenging. Currently there is not a functional assay that is diagnostic of the disease.

TREATMENT

Hemolytic-Uremic Syndrome

Treatment of HUS is primarily supportive. In HUS associated with diarrhea, many (~40%) children require at least some period of support with dialysis; however, the overall mortality is <5%. In HUS not associated with diarrhea, the mortality is higher, ~26%. Plasma infusion or plasma exchange has not been shown to alter the overall course. ADAMTS13 levels are generally reported to be normal in HUS, although occasionally they have been reported to be decreased. In patients with aHUS, eculizumab, a humanized monoclonal antibody against C5 that blocks terminal complement, has efficacy in resolution of HUS and improving or preserving renal function. Patients with aHUS may initially be treated with plasma exchange, until the ADAMTS13 level is returned and the diagnosis more clear, since aHUS remains a diagnosis of exclusion. However, plasma exchange has not been shown to affect clinical outcomes in aHUS.

THROMBOCYTOSIS

Thrombocytosis is almost always due to (1) iron deficiency; (2) inflammation, cancer, or infection (reactive thrombocytosis); or (3) an underlying myeloproliferative process (essential thrombocythemia or polycythemia vera) (Chap. 99) or, rarely, the 5q– myelodysplastic process (Chap. 98). Patients presenting with an elevated platelet count should be evaluated for underlying inflammation or malignancy, and iron deficiency should be ruled out. Thrombocytosis in response to acute or chronic inflammation has not been clearly associated with an increased thrombotic risk. In fact, patients with markedly elevated platelet counts (>1.5 million), usually seen in the setting of a myeloproliferative disorder, have an increased risk of bleeding. This appears to be due, at least in part, to acquired von Willebrand disease (VWD) due to platelet-VWF binding and removal from the circulation.

QUALITATIVE DISORDERS OF PLATELET FUNCTION

Inherited Disorders of Platelet Function Inherited platelet function disorders are thought to be relatively rare, although the prevalence of mild disorders of platelet function is unclear, in part because our testing for such disorders is suboptimal. Rare qualitative disorders include the autosomal recessive disorders Glanzmann's thrombasthenia (absence of the platelet Gp IIb/IIIa receptor) and Bernard-Soulier syndrome (absence of the platelet Gp Ib-IX-V receptor). Both are inherited in an autosomal recessive fashion and present with bleeding symptoms in childhood.

Platelet storage pool disorder (SPD) is the classic autosomal dominant qualitative platelet disorder. This results from abnormalities of platelet granule formation. It is also seen as a part of inherited disorders of granule formation, such as Hermansky-Pudlak syndrome. Bleeding symptoms in SPD are variable, but often are mild. The most common inherited disorders of platelet function prevent normal secretion of granule content and are termed *secretion defects*. Few of these abnormalities have been dissected at the molecular level, but they likely result from various DNA variants.

TREATMENT

Inherited Disorders of Platelet Dysfunction

Bleeding symptoms or prevention of bleeding in patients with severe platelet dysfunction frequently requires platelet transfusion. Care is taken to limit the risk of alloimmunization by limiting exposure, using HLA-matched leuko-depleted platelet concentrates for transfusion. Platelet disorders associated with milder bleeding symptoms frequently respond to desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]). DDAVP increases plasma VWF and factor VIII levels; it may also have a direct effect on platelet function. Particularly for mucosal bleeding symptoms, antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) is used alone or in conjunction with DDAVP or platelet therapy.

Acquired Disorders of Platelet Function Acquired platelet dysfunction is common, usually due to medications, either intentionally as with antiplatelet therapy or unintentionally as with high-dose penicillins. Acquired platelet dysfunction occurs in uremia. This is likely multifactorial, but the resultant effect is defective adhesion and activation. The platelet defect is improved most by dialysis but may also be improved by increasing the hematocrit to 27–32%, giving DDAVP (0.3 μg/kg), or use of conjugated estrogens. Platelet dysfunction also occurs with cardiopulmonary bypass due to the effect of the artificial circuit on platelets, and bleeding symptoms respond to platelet transfusion. Platelet dysfunction seen with underlying hematologic disorders can result from nonspecific interference by circulating paraproteins or intrinsic platelet defects in myeloproliferative and myelodysplastic syndromes.

VON WILLEBRAND DISEASE

VWD is the most common inherited bleeding disorder. Estimates from laboratory data suggest a prevalence of ~1%, but data based on symptomatic individuals suggest that it is closer to 0.1% of the population. VWF serves two roles: (1) as the major adhesion molecule that tethers the platelet to the exposed subendothelium; and (2) as the binding protein for factor VIII (FVIII), resulting in significant prolongation of the FVIII half-life in circulation. The platelet-adhesive function of VWF is critically dependent on the presence of large VWF multimers, whereas FVIII binding is not. Most of the symptoms of VWD are "platelet-like" except in more severe VWD when the FVIII is low enough to produce symptoms similar to those found in FVIII deficiency (hemophilia A).

VWD has been classified into three major types, with four subtypes of type 2 (Table 111-2; Fig. 111-5). By far the most common type of VWD is type 1 disease, with a parallel decrease in VWF protein, VWF function, and FVIII levels, accounting for at least 80% of cases. Patients have predominantly mucosal bleeding symptoms, although postoperative bleeding can also be seen. Bleeding symptoms are very uncommon in infancy and usually manifest later in childhood with excessive bruising and epistaxis. Because these symptoms occur commonly in childhood, the clinician should particularly note bruising at sites unlikely to be traumatized and/or prolonged epistaxis requiring medical attention. Menorrhagia is a common manifestation of VWD. Menstrual bleeding resulting in anemia should warrant an evaluation for VWD and, if negative, functional platelet disorders. Frequently, mild type 1 VWD first manifests with dental extractions, particularly wisdom tooth extraction, or tonsillectomy.

Not all patients with low VWF levels have bleeding symptoms. Whether patients bleed or not will depend on the overall hemostatic balance they have inherited, along with environmental influences and the type of hemostatic challenges they experience. Although the inheritance of VWD is autosomal, many factors modulate both VWF levels and bleeding symptoms. These have not all been defined, but include blood type, thyroid hormone status, race, stress, exercise, hormonal (both endogenous and exogenous) influences, and modulators of VWF clearance. Patients with type O blood have VWF protein levels of approximately one-half that of patients with AB blood type; and, in fact, the normal range for patients with type O blood overlaps that which has been considered diagnostic for VWD. A mildly decreased VWF level should be viewed more as a risk factor for bleeding than as an actual disease.

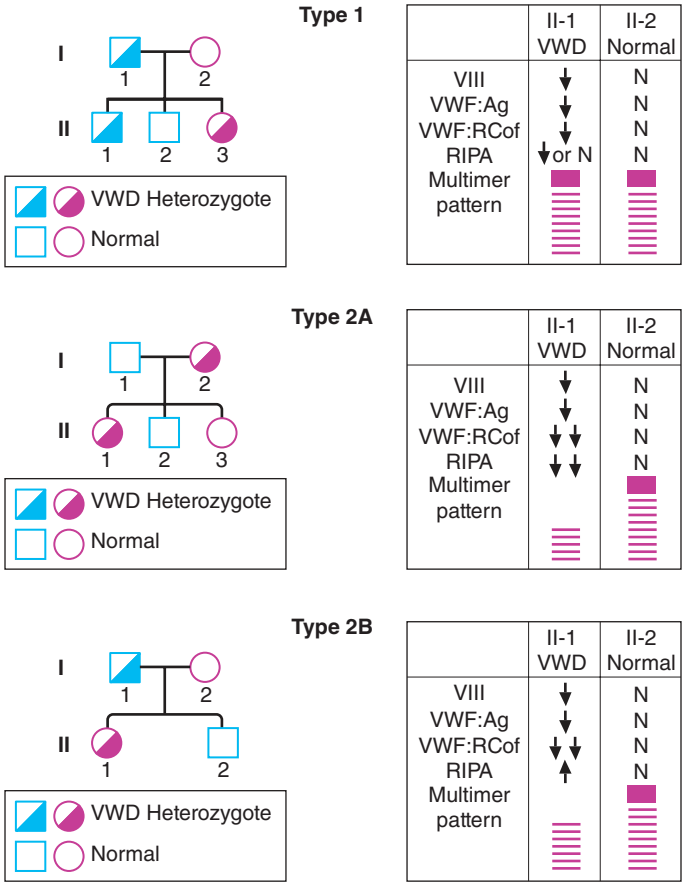

FIGURE 111-5 Pattern of inheritance and laboratory findings in von Willebrand disease (VWD). The assays of platelet function include a coagulation assay of factor VIII bound and carried by von Willebrand factor (VWF), abbreviated as VIII; immunoassay of total VWF protein (VWF:Ag); bioassay of the ability of patient plasma to support ristocetin-induced agglutination of normal platelets (VWF:RCoF), a measure of VWF activity; and ristocetin-induced aggregation of patient platelets, abbreviated RIPA. The multimer pattern illustrates the multimer bands present when plasma is electrophoresed in a polyacrylamide gel. The II-1 and II-2 columns refer to the phenotypes of the second-generation offspring.

TABLE 111-2 Laboratory Diagnosis of von Willebrand Disease (VWD)

TYPE	APTT	VWF ANTIGEN	VWF ACTIVITY	FVIII ACTIVITY	MULTIMER
1	NI or ↑	↓	↓	↓	Normal distribution, decreased in quantity
2A	NI or ↑	↓	↓↓	↓	Loss of high- and intermediate-MW multimers
2B[a]	NI or ↑	↓	↓↓	↓	Loss of high-MW multimers
2M	NI or ↑	↓	↓↓	↓	Normal distribution, decreased in quantity
2N	↑↑	NI or ↓[b]	NI or ↓[b]	↓↓	Normal distribution
3	↑↑	↓↓	↓↓	↓↓	Absent

[a]Usually also decreased platelet count. [b]For type 2N, in the homozygous state, FVIII is very low; in the heterozygous state, it is only seen in conjunction with type 1 VWD.

Abbreviations: aPTT, activated partial thromboplastin time; F, factor; MW, molecular weight; NI, normal; VWF, von Willebrand factor.

Patients with type 2 VWD have functional defects; thus, the VWF antigen measurement is significantly higher than the test of function. For types 2A, 2B, and 2M VWD, platelet-binding and/or collagen-binding VWF activity is decreased. In type 2A VWD, the impaired function is due either to increased susceptibility to cleavage by ADAMTS13, resulting in loss of intermediate- and high-molecular-weight multimers, or to decreased production of these multimers by the cell. Type 2B VWD results from gain-of-function mutations that result in increased spontaneous binding of VWF to platelets in circulation, with increased cleavage by ADAMTS13 and clearance of this complex by the reticuloendothelial system. The resulting VWF in the patients' plasma lacks the highest molecular-weight multimers, and the platelet count is usually modestly reduced. Type 2M occurs as a consequence of a group of DNA variants that cause dysfunction but do not affect multimer structure.

Type 2N VWD is due to variants in the *VWF* gene that affect binding of FVIII. As FVIII is stabilized by binding to VWF, the FVIII in patients with type 2N VWD has a very short half-life, and the FVIII level is markedly decreased. This is sometimes termed *autosomal hemophilia*. Type 3 VWD, or severe VWD, describes patients with virtually no VWF protein and FVIII levels <10%. Patients experience mucosal and joint bleeding, surgery-related bleeding, and other bleeding symptoms. Some patients with type 3 VWD, particularly those with large VWF gene deletions, are at risk of developing antibodies to infused VWF.

Acquired VWD is a rare disorder, most commonly seen in patients with underlying lymphoproliferative disorders, including monoclonal gammopathies of underdetermined significance (MGUS), multiple myeloma, and Waldenström's macroglobulinemia. It is seen most commonly in the setting of MGUS and should be suspected in patients, particularly elderly patients, with a new onset of severe mucosal bleeding symptoms. Laboratory evidence of acquired VWD is found in some patients with aortic valvular disease. Heyde's syndrome (aortic stenosis with gastrointestinal bleeding) is attributed to the presence of angiodysplasia of the gastrointestinal tract in patients with aortic stenosis. The shear stress on blood passing through the stenotic aortic valve appears to unfold VWF, making it susceptible to proteolysis. Consequently, large multimer forms are lost, leading to an acquired type 2 VWD, but return when the stenotic valve is replaced.

TREATMENT

von Willebrand Disease

The mainstay of treatment for type 1 VWD is DDAVP (desmopressin), which results in release of VWF and FVIII from endothelial stores. DDAVP can be given intravenously or by a high-concentration intranasal spray (1.5 mg/mL). The peak activity when given intravenously is ~30 min, whereas it is 2 h when given intra-nasally. The usual dose is 0.3 μg/kg intravenously or two squirts (one in each nostril) for patients >50 kg (one squirt for those <50 kg). It is recommended that patients with VWD be tested with DDAVP to assess their response before using it. In patients who respond well (increase in laboratory values of two- to fourfold), it can be used for procedures with minor to moderate risk of bleeding. Depending on the procedure, additional doses may be needed; it is usually given every 12–24 h. Less frequent dosing may result in less tachyphylaxis, which occurs when synthesis cannot compensate for the released stores. The major side effect of DDAVP is hyponatremia due to decreased free water clearance. This occurs most commonly in the very young and the very old, but fluid restriction should be advised for all patients for the 24 h following each dose.

Some patients with types 2A and 2M VWD respond to DDAVP such that it can be used for minor procedures. For the other subtypes, for type 3 disease, and for major procedures requiring longer periods of normal hemostasis, VWF replacement can be given. Virally inactivated VWF-plasma-derived and recombinant factor concentrates are safer than cryoprecipitate as the replacement product.

Antifibrinolytic therapy using either ε-aminocaproic acid or tranexamic acid is an important therapy, either alone or in an adjunctive capacity, particularly for the prevention or treatment of mucosal bleeding. These agents are particularly useful in treatment of menorrhagia and post partum hemorrhage, prophylaxis for dental procedures, and with DDAVP or factor concentrate for dental extractions, tonsillectomies, and prostate procedures. Antifibrinolytic agents are contraindicated in the setting of upper urinary tract bleeding, due to the risk of ureteral obstruction.

DISORDERS OF THE VESSEL WALL

The vessel wall is an integral part of hemostasis, and separation of a fluid phase is artificial, particularly in disorders such as TTP or HIT that clearly involve the endothelium as well. Inflammation localized to the vessel wall, such as vasculitis, and inherited connective tissue disorders are abnormalities inherent to the vessel wall.

METABOLIC AND INFLAMMATORY DISORDERS Acute febrile illnesses may result in vascular damage. This can result from immune complexes containing viral antigens or the viruses themselves. Certain pathogens, such as the rickettsiae causing Rocky Mountain spotted fever, replicate in endothelial cells and damage them. Vascular purpura may occur in patients with polyclonal gammopathies but more commonly in those with monoclonal gammopathies, including Waldenström's macroglobulinemia, multiple myeloma, and cryoglobulinemia. Patients with mixed cryoglobulinemia develop a more extensive maculopapular rash due to immune complex–mediated damage to the vessel wall.

Patients with scurvy (vitamin C deficiency) develop painful episodes of perifollicular skin bleeding as well as more systemic bleeding symptoms. Vitamin C is needed to synthesize hydroxyproline, an essential constituent of collagen. Patients with Cushing's syndrome or on chronic glucocorticoid therapy develop skin bleeding and easy bruising due to atrophy of supporting connective tissue. A similar phenomenon is seen with aging, where following minor trauma, blood spreads superficially under the epidermis. This has been termed *senile purpura*. It is most common on skin that has been previously damaged by sun exposure.

Henoch-Schönlein, or anaphylactoid, purpura is a distinct, self-limited type of vasculitis that occurs in children and young adults. Patients have an acute inflammatory reaction with IgA and complement components in capillaries, mesangial tissues, and small arterioles leading to increased vascular permeability and localized hemorrhage. The syndrome is often preceded by an upper respiratory infection, commonly with streptococcal pharyngitis, or is triggered by drug or food allergies. Patients develop a purpuric rash on the extensor surfaces of the arms and legs, usually accompanied by polyarthralgias or arthritis, abdominal pain, and hematuria from focal glomerulonephritis. All coagulation tests are normal, but renal impairment may occur. Glucocorticoids can provide symptomatic relief but do not alter the course of the illness.

INHERITED DISORDERS OF THE VESSEL WALL Patients with inherited disorders of the connective tissue matrix, such as Marfan's syndrome, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum, frequently report easy bruising. Inherited vascular abnormalities can result in increased bleeding. This is notably seen in hereditary hemorrhagic telangiectasia (HHT, or Osler-Weber-Rendu disease), a disorder where abnormal telangiectatic capillaries result in frequent bleeding episodes, primarily from the nose and gastrointestinal tract. Arteriovenous malformation (AVM) in the lung, brain, and liver may also occur in HHT. The telangiectasia can often be visualized on the oral and nasal mucosa. Signs and symptoms develop over time. Epistaxis begins, on average, at the age of 12 and occurs in >95% of affected individuals by middle age. Approximately 25% have GI bleeding usually beginning after the age of 50. HHT is caused by pathogenic DNA variants in number of genes involved in the TGFβ/BMP signaling cascade.

112 Coagulation Disorders

Valder R. Arruda, Katherine A. High

Deficiencies of coagulation factors have been recognized for centuries. Patients with genetic deficiencies of plasma coagulation factors exhibit lifelong recurrent bleeding episodes into joints, muscles, and closed spaces, either spontaneously or following an injury. The most common inherited factor deficiencies are the hemophilias, X-linked diseases caused by deficiency of factor (F) VIII (hemophilia A) or FIX (hemophilia B). Rare congenital bleeding disorders due to deficiencies of other factors, including FII (prothrombin), FV, FVII, FX, FXI, FXIII, and fibrinogen, are commonly inherited in an autosomal recessive manner **(Table 112-1)**. Advances in characterization of the molecular bases of clotting factor deficiencies have contributed to better understanding of the disease phenotypes and may eventually allow more targeted therapeutic approaches through the development of small molecules, recombinant proteins, or cell- and gene-based therapies.

Commonly used tests of hemostasis provide the initial screening for clotting factor activity **(Fig. 112-1)**, and disease phenotype often correlates with the level of clotting activity. An isolated abnormal prothrombin time (PT) suggests FVII deficiency, whereas a prolonged activated partial thromboplastin time (aPTT) indicates most commonly hemophilia or FXI deficiency (Fig. 112-1). The prolongation of both PT and aPTT suggests deficiency of FV, FX, FII, or fibrinogen abnormalities. The addition of the missing factor at a range of doses to the subject's plasma will correct the abnormal clotting times; the result is expressed as a percentage of the activity observed in normal subjects.

Acquired deficiencies of plasma coagulation factors are more frequent than congenital disorders; the most common disorders include hemorrhagic diathesis of liver disease, disseminated intravascular coagulation (DIC), and vitamin K deficiency. In these disorders, blood coagulation is hampered by the deficiency of more than one clotting factor, and the bleeding episodes are the result of perturbation of both primary (e.g., platelet and vessel wall interactions) and secondary (coagulation) hemostasis.

The development of alloantibodies to coagulation plasma proteins, clinically termed *inhibitors*, is a relatively rare disease that often affects hemophilia A or B and FXI-deficient patients on repetitive exposure to the missing protein to control bleeding episodes. Inhibitory autoantibodies also occur among subjects without genetic deficiency of clotting factors (e.g., in the postpartum setting as a manifestation of underlying autoimmune or neoplastic disease, or idiopathically). Rare cases of inhibitors to thrombin or FV have been reported in patients receiving topical bovine thrombin preparation as a local hemostatic agent in complex surgeries. The diagnosis of inhibitors is based on the same tests as those used to diagnose inherited plasma coagulation factor deficiencies. However, the addition of the missing protein to the plasma of a subject with an inhibitor does not correct the abnormal aPTT and/or PT tests (known as mixing tests). This is the major laboratory difference between deficiencies and inhibitors. Additional tests are required to measure the specificity of the inhibitor and its titer.

The treatment of these bleeding disorders often requires replacement of the deficient protein using recombinant or purified plasma-derived products or fresh-frozen plasma (FFP). Therefore, it is imperative to arrive at a proper diagnosis to optimize patient care without unnecessary exposure to suboptimal treatment and the risks of bloodborne disease.

HEMOPHILIA

PATHOGENESIS AND CLINICAL MANIFESTATIONS

Hemophilia is an X-linked recessive hemorrhagic disease due to mutations in the *F8* gene (hemophilia A or classic hemophilia) or *F9* gene (hemophilia B). The disease affects 1 in 10,000 males worldwide, in all ethnic groups; hemophilia A represents 80% of all cases. Male subjects are clinically affected; women, who carry a single mutated gene, are generally asymptomatic. Family history of the disease is absent in ~30% of cases, and in these cases, 80% of the mothers are carriers of the de novo mutated allele. More than 500 different mutations have been identified in the *F8* or *F9* genes of patients with hemophilia A or B,

TABLE 112-1 Genetic and Laboratory Characteristics of Inherited Coagulation Disorders

CLOTTING FACTOR DEFICIENCY	INHERITANCE	PREVALENCE IN GENERAL POPULATION	LABORATORY ABNORMALITY[a]			MINIMUM HEMOSTATIC LEVELS	TREATMENT	PLASMA HALF-LIFE
			aPTT	PT	TT			
Fibrinogen	AR	1 in 1,000,000	+	+	+	100 mg/dL	Cryoprecipitate	2–4 d
Prothrombin	AR	1 in 2,000,000	+	+	–	20–30%	FFP/PCC	3–4 d

[a]Values within normal range (–) or prolonged (+). [b]No risk for bleeding; treatment is not indicated. [c]Since platelets contain FV, platelet transfusion can be used as therapy.

Abbreviations: aPTT, activated partial thromboplastin time; AR, autosomal recessive; FFP, fresh-frozen plasma; HK, high-molecular-weight kininogen; ND, not determined; PCC, prothrombin complex concentrates; PT, prothrombin time; TT, thrombin time.

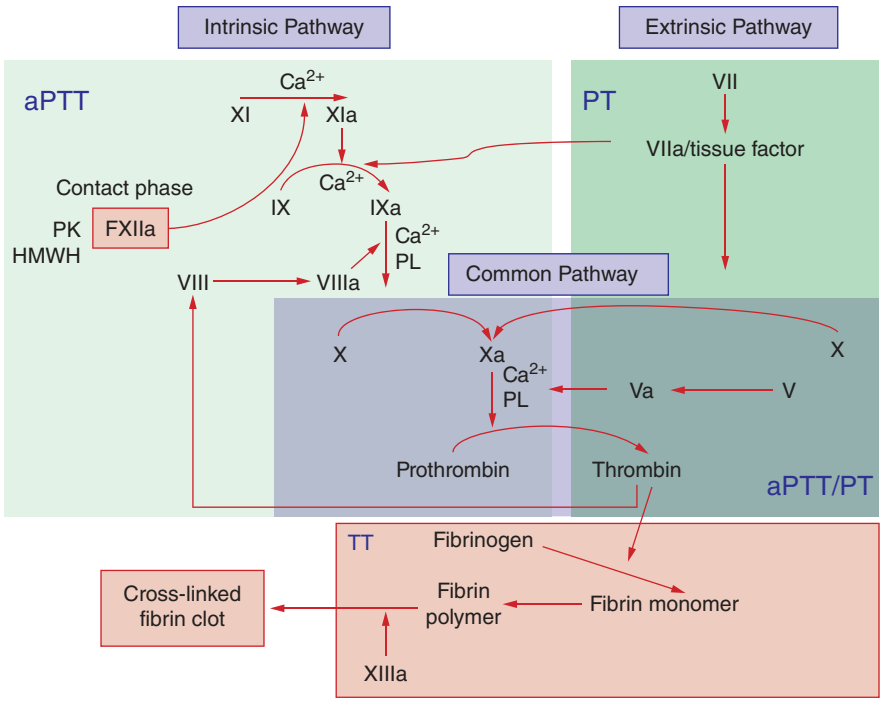

FIGURE 112-1 Coagulation cascade and laboratory assessment of clotting factor deficiency by activated partial prothrombin time (aPTT), prothrombin time (PT), thrombin time (TT), and phospholipid (PL).

respectively. One of the most common hemophilia A mutations results from an inversion of the intron 22 sequence, and it is present in 40% of cases of severe hemophilia A. Advances in molecular diagnosis now permit precise identification of mutations, allowing accurate diagnosis of women carriers of the hemophilia gene in affected families.

Clinically, hemophilia A and hemophilia B are indistinguishable. The disease phenotype correlates with the residual activity of FVIII or FIX and can be classified as severe (<1%), moderate (1–5%), or mild (6–30%). In the severe and moderate forms, the disease is characterized by bleeding into the joints (hemarthrosis), soft tissues, and muscles after minor trauma or even spontaneously. Patients with mild disease experience infrequent bleeding that is usually secondary to trauma. Among those with residual FVIII or FIX activity >25% of normal, the disease is discovered only by bleeding after major trauma or during routine presurgery laboratory tests. Typically, the global tests of coagulation show only an isolated prolongation of the aPTT assay. Patients with hemophilia have normal bleeding times and platelet counts. The diagnosis is made after specific determination of FVIII or FIX clotting activity.

Early in life, bleeding may present after circumcision or rarely as intracranial hemorrhages. The disease is more evident when children begin to walk or crawl. In the severe form, the most common bleeding manifestations are the recurrent hemarthroses, which can affect every joint but mainly affect knees, elbows, ankles, shoulders, and hips. Acute hemarthroses are painful, and clinical signs are local swelling and erythema. To avoid pain, the patient may adopt a fixed position, which leads eventually to muscle contractures. Very young children unable to communicate verbally show irritability and a lack of movement of the affected joint. Chronic hemarthroses are debilitating, with synovial thickening and synovitis in response to the intraarticular blood. After a joint has been damaged, recurrent bleeding episodes result in the clinically recognized "target joint," which then establishes a vicious cycle of bleeding, resulting in progressive joint deformity that in critical cases requires surgery as the only therapeutic option. Hematomas into the muscle of distal parts of the limbs may lead to external compression of arteries, veins, or nerves that can evolve to a compartment syndrome.

Bleeding into the oropharyngeal spaces, central nervous system (CNS), or retroperitoneum is life threatening and requires immediate therapy. Retroperitoneal hemorrhages can accumulate large quantities of blood with formation of masses with calcification and inflammatory tissue reaction (pseudotumor syndrome) and also result in damage to the femoral nerve. Pseudotumors can also form in bones, especially long bones of the lower limbs. Hematuria is frequent among hemophilia patients, even in the absence of genitourinary pathology. It is often self-limited and may not require specific therapy.

TREATMENT

Hemophilia

Without treatment, severe hemophilia may limit life expectancy. Advances in the blood fractionation industry during World War II resulted in the realization that plasma could be used to treat hemophilia, but the volumes required to achieve even modest elevation of circulating factor levels limit the utility of plasma infusion as an approach to disease management. The discovery in the 1960s that the cryoprecipitate fraction of plasma was enriched for FVIII, and the eventual purification of FVIII and FIX from plasma, led to the introduction of home infusion therapy with factor concentrates in the 1970s. The availability of factor concentrates resulted in a dramatic improvement in life expectancy and in quality of life for people with severe hemophilia. However, the contamination of the blood supply with hepatitis viruses and, subsequently, HIV resulted in widespread transmission of these bloodborne infections within the hemophilia population; complications of HIV and of hepatitis C are now the leading causes of death among U.S. adults with severe hemophilia. The introduction of viral inactivation steps in the preparation of plasma-derived products in the mid-1980s greatly reduced the risk of HIV and hepatitis, and the risks were further reduced by the successful production of recombinant FVIII and FIX proteins, both licensed in the 1990s. It is uncommon for hemophilic patients born after 1985 to have contracted either hepatitis or HIV, and for these individuals, life expectancy is ~65 years. In fact, since 1998, no evidence of new infections with viral hepatitis or HIV has been reported in patients using blood products. Factor replacement therapy for hemophilia can be provided either in response to a bleeding episode or as a prophylactic treatment. Primary prophylaxis is

defined as a strategy for maintaining the missing clotting factor at levels ~1% or higher on a regular basis in order to prevent bleeds, especially the onset of hemarthroses. Hemophilic boys receiving regular infusions of FVIII (3 days/week) or FIX (2 days/week) can reach puberty without detectable joint abnormalities. Prophylaxis has become gradually more common in young patients. The Centers for Disease Control and Prevention reported that 51% of children with severe hemophilia who are aged <6 years receive prophylaxis, increasing considerably from 33% in 1995. Prophylaxis is the standard care for children; however, teenagers and young adults do not always maintain the treatment regularly. Although highly recommended, the high cost and difficulties in accessing peripheral veins in young patients and the potential infectious and thrombotic risks of long-term central vein catheters are important limiting factors for many young patients. Prophylaxis is also increasing among adults with severe hemophilia.

General considerations regarding the treatment of bleeds in hemophilia include the following: (1) Treatment should begin as soon as possible because symptoms often precede objective evidence of bleeding; because of the superior efficacy of early therapeutic intervention, classic symptoms of bleeding into the joint in a reliable patient, headaches, or automobile or other accidents require prompt replacement and further laboratory investigation. (2) Drugs that hamper platelet function, such as aspirin or aspirin-containing drugs, should be avoided; to control pain, drugs such as ibuprofen or propoxyphene are preferred. FVIII and FIX are dosed in units. One unit is defined as amount of FVIII (100 ng/mL) or FIX (5 μg/mL) in 1 mL of normal plasma. One unit of FVIII per kilogram of body weight increases the plasma FVIII level by 2%. One can calculate the dose needed to increase FVIII levels to 100% in a 70-kg severe hemophilia patient (<1%) using the simple formula below. Thus, 3500 units of FVIII will raise the circulating level to 100%.

$$\text{FVIII dose (IU)} = \text{Target FVIII levels} - \text{FVIII baseline levels} \times \text{body weight (kg)} \times 0.5 \text{ unit/kg}$$

The doses for FIX replacement are different from those for FVIII, because FIX recovery after infusion is usually only 50% of the predicted value. Therefore, the formula for FIX replacement is as follows:

$$\text{FIX dose (IU)} = \text{Target FIX levels} - \text{FIX baseline levels} \times \text{body weight (kg)} \times 1 \text{ unit/kg}$$

The FVIII half-life of 8–12 h requires injections twice a day to maintain therapeutic levels, whereas the FIX half-life is longer, ~24 h, so that once-a-day injection is sufficient. In specific situations such as after surgery, continuous infusion of factor may be desirable because of its safety in achieving sustained factor levels at a lower total cost.

Cryoprecipitate is enriched with FVIII protein (each bag contains ~80 IU of FVIII) and was commonly used for the treatment of hemophilia A decades ago; it is still in use in some developing countries, but because of the risk of bloodborne diseases, this product should be avoided in hemophilia patients when factor concentrates are available.

Mild bleeds such as uncomplicated hemarthroses or superficial hematomas require initial therapy with factor levels of 30–50%. Additional doses to maintain levels of 15–25% for 2 or 3 days are indicated for severe hemarthroses, especially when these episodes affect the "target joint." Large hematomas, or bleeds into deep muscles, require factor levels of 50% or even higher if the clinical symptoms do not improve, and factor replacement may be required for a period of 1 week or longer. The control of serious bleeds including those that affect the oropharyngeal spaces, CNS, and the retroperitoneum require sustained protein levels of 50–100% for 7–10 days. Prophylactic replacement for surgery is aimed at achieving normal factor levels (100%) for a period of 7–10 days; replacement can then be tapered depending on the extent of the surgical wounds. Oral surgery is associated with extensive tissue damage that usually requires factor replacement for 1–3 days coupled with oral antifibrinolytic drugs.

NONTRANSFUSION THERAPY IN HEMOPHILIA

DDAVP (1-Amino-8-D-Arginine Vasopressin) DDAVP is a synthetic vasopressin analog that causes a transient rise in FVIII and von Willebrand factor (VWF), but not FIX, through a mechanism involving release from endothelial cells. Patients with moderate or mild hemophilia A should be tested to determine if they respond to DDAVP before a therapeutic application. DDAVP at doses of 0.3 μg/kg body weight, over a 20-min period, is expected to raise FVIII levels by two- to threefold over baseline, peaking between 30 and 60 min after infusion. DDAVP does not improve FVIII levels in severe hemophilia A patients because there are no stores to release. Repeated dosing of DDAVP results in tachyphylaxis because the mechanism is an increase in release rather than de novo synthesis of FVIII and VWF. More than three consecutive doses become ineffective, and if further therapy is indicated, FVIII replacement is required to achieve hemostasis.

Antifibrinolytic Drugs Bleeding in the gums, gastrointestinal tract, and during oral surgery requires the use of oral antifibrinolytic drugs such as ε-amino caproic acid (EACA) or tranexamic acid to control local hemostasis. The duration of the treatment depending on the clinical indication is 1 week or longer. Tranexamic acid is given at doses of 25 mg/kg three to four times a day. EACA treatment requires a loading dose of 200 mg/kg (maximum of 10 g) followed by 100 mg/kg per dose (maximum 30 g/d) every 6 h. These drugs are not indicated to control hematuria because of the risk of formation of an occlusive clot in the lumen of genitourinary tract structures.

COMPLICATIONS

Inhibitor Formation The formation of alloantibodies to FVIII or FIX is currently the major complication of hemophilia treatment. The prevalence of inhibitors to FVIII is estimated to be ~30% of severe hemophilia A patients and 10% among patients with nonsevere hemophilia A. Inhibitors to FIX are detected in only 3–5% of all hemophilia B patients. The high-risk group for inhibitor formation includes severe deficiency (>80% of all cases of inhibitors), familial history of inhibitor, African descent, mutations in the FVIII or FIX gene resulting in deletion of large coding regions, or gross gene rearrangements. Inhibitors usually appear early in life, at a median of 2 years of age, and after 10 cumulative days of exposure. However, intensive replacement therapy such as for major surgery, intracranial bleeding, or trauma increases the risk of inhibitor formation for patients of all ages and degree of clinical severity, which requires close laboratory monitoring in the following weeks.

The clinical diagnosis of an inhibitor is suspected when patients do not respond to factor replacement at therapeutic doses. Inhibitors increase both morbidity and mortality in hemophilia. Because early detection of an inhibitor is critical to a successful correction of the bleeding or to eradication of the antibody, most hemophilia centers perform annual screening for inhibitors. The laboratory test required to confirm the presence of an inhibitor is an aPTT with a mix (with normal plasma). In most hemophilia patients, a 1:1 mix with normal plasma completely corrects the aPTT. In inhibitor patients, the aPTT on a 1:1 mix is abnormally prolonged because the inhibitor neutralizes the FVIII clotting activity of the normal plasma. The Bethesda assay uses a similar principle and defines the specificity of the inhibitor and its titer. The results are expressed in Bethesda units (BU), in which 1 BU is the amount of antibody that neutralizes 50% of the FVIII or FIX present in normal plasma after 2 h of incubation at 37°C. Clinically, inhibitor patients are classified as low responders or high responders, which provides guidelines for optimal therapy. Therapy for inhibitor patients has two goals: the control of acute bleeding episodes and the eradication of the inhibitor. For the control of bleeding episodes, low responders, those with titer <5 BU, respond well to high doses of human FVIII (50–100 U/kg), with minimal or no increase in the inhibitor titers. However, high-responder patients,

those with initial inhibitor titer >5 BU or an anamnestic response in the antibody titer to >5 BU, even if low titer initially, do not respond to FVIII. The control of bleeding episodes in high-responder patients can be achieved by using concentrates enriched for prothrombin, FVII, FIX, FX (prothrombin complex concentrates [PCCs] or activated PCCs [aPCCs]), and recombinant activated factor VII (FVIIa) known as "bypass agents" (Fig. 112-1). For FIX inhibitor patients, high doses of FIX can be used (<5 BU); however, allergic or anaphylactic reactions are common in FIX inhibitors, thus the use of bypass products should be used to treat or prevent bleeding as well as for those cases of high titer inhibitors. For eradication of the inhibitory antibody, immunosuppression alone is not effective. The most effective strategy is the immune tolerance induction (ITI) based on daily infusion of missing protein until the inhibitor disappears, typically requiring periods >1 year, with success rates of ~60%. The management of patients with severe hemophilia and inhibitors resistant to ITI is challenging. The use of anti-CD20 monoclonal antibody (rituximab) combined with ITI was thought to be effective. Although this therapy may reduce the inhibitor titers in some cases, sustained eradication is uncommon.

Novel Therapeutic Approaches in Development for Hemophilia

Clinical studies using long-acting clotting factors with enhanced half-lives are in the late phase of clinical testing, and these new-generation products (for FVIII and FIX) may facilitate prophylaxis by requiring fewer injections to maintain circulating levels >1%. In hemophilia A, the use of these products reduced the frequency of injections of FVIII from 3 to 2 days a week, and notably for hemophilia B, most patients will require once-a-week injections of long-acting FIX.

The use of recombinant interleukin 11 in patients with moderate or mild hemophilia A unresponsive to DDAVP has been tested in early-phase clinical trials and may be an alternate therapeutic strategy for clinical situations that require transient increases in FVIII levels.

Gene therapy trials for hemophilia A and B using adeno-associated viral vectors are ongoing **(Chap. 458)**.

INFECTIOUS DISEASES

Hepatitis C virus (HCV) infection is the major cause of morbidity and the second leading cause of death in hemophilia patients exposed to older clotting factor concentrates. The vast majority of young patients treated with plasma-derived products from 1970 to 1985 became infected with HCV. It has been estimated that >80% of patients aged >20 years are HCV antibody positive as of 2006. The comorbidity of the underlying liver disease in hemophilia patients is clear when these individuals require invasive procedures; correction of both genetic and acquired (secondary to liver disease) deficiencies may be needed. Infection with HIV also swept the population of patients using plasma-derived concentrates two decades ago. Co-infection of HCV and HIV, present in almost 50% of hemophilia patients, is an aggravating factor for the evolution of liver disease. The response to HCV antiviral therapy in hemophilia is restricted to <30% of patients and even poorer among those with both HCV and HIV infection. The development of effective direct-acting antivirals for the treatment of HCV may change this scenario. End-stage liver disease requiring organ transplantation may be curative for both the liver disease and for hemophilia

EMERGING CLINICAL PROBLEMS IN AGING HEMOPHILIA PATIENTS

There has been continuous improvement of the management of hemophilia since the increase in the population of adults living beyond middle age in the developing world. The life expectancy of a patient with severe hemophilia is only ~10 years shorter than the general male population. In patients with mild or moderate hemophilia, life expectancy is approaching that of the male population without coagulopathy. Elderly hemophilia patients have different problems compared to the younger generation; they have more severe arthropathy and chronic pain, due to suboptimal treatment, and high rates of HCV and/or HIV infections.

Early data indicate that mortality from coronary artery disease is lower in hemophilia patients than the general male population. The underlying hypocoagulability probably provides a protective effect against thrombus formation, but it does not prevent atherogenesis. Similar to the general population, these patients are exposed to cardiovascular risk factors such as age, obesity, and smoking. Moreover, physical inactivity, hypertension, and chronic renal disease are commonly observed in hemophilia patients. In HIV patients on combined antiretroviral therapy, there may be a further increase in the risk of cardiovascular disease. Therefore, these patients should be carefully considered for preventive and therapeutic approaches to minimize the risk of cardiovascular disease.

Excessive replacement therapy should be avoided, and it is prudent to slowly infuse factor concentrates. Continuous infusion of clotting factor is preferable to bolus dosing in patients with cardiovascular risk factors undergoing invasive procedures. The management of an acute ischemic event and coronary revascularization should include the collaboration of hematologists and internists. The early assumption that hemophilia would protect against occlusive vascular disease may change in this aging population. Cancer is a common cause of mortality in aging hemophilia patients because they are at risk for HIV- and HCV-related malignancies. Hepatocellular carcinoma (HCC) is the most prevalent primary liver cancer and a common cause of death in HIV-negative patients. The recommendations for cancer screening for the general population should be the same for age-matched hemophilia patients. Among those with high-risk HCV, a semiannual or annual ultrasound and α fetoprotein are recommended for HCC. Screening for urogenital neoplasm in the presence of hematuria or hematochezia may be delayed due to the underlying bleeding disease, thus preventing early intervention. Multidisciplinary interaction should facilitate the attempts to ensure optimal cancer prevention and treatment recommendations for those with hemophilia.

MANAGEMENT OF CARRIERS OF HEMOPHILIA

Usually hemophilia carriers, with factor levels of ~50% of normal, have not been considered to be at risk for bleeding. However, a wide range of values (22–116%) have been reported due to random inactivation of the X chromosomes (*lyonization*). Therefore, it is important to measure the factor level of carriers to recognize those at risk of bleeding and to optimize preoperative and postoperative management. During pregnancy, both FVIII and FIX levels increase gradually until delivery. FVIII levels increase approximately two- to threefold compared to nonpregnant women, whereas an FIX increase is less pronounced. After delivery, there is a rapid fall in the pregnancy-induced rise of maternal clotting factor levels. This represents an imminent risk of bleeding that can be prevented by infusion of factor concentrate to levels of 50–70% for 3 days in the setting of vaginal delivery and up to 5 days for cesarean section. In mild cases, the use of DDAVP and/or antifibrinolytic drugs is recommended.

FACTOR XI DEFICIENCY

Factor XI is a zymogen of an active serine protease (FIXa) in the intrinsic pathway of blood coagulation that activates FIX (Fig. 112-1). There are two pathways for the formation of FXIa. In an aPTT-based assay, the protease is the result of activation by FXIIa in conjunction with high-molecular-weight kininogen and kallikrein. In vivo data suggest that thrombin is the physiologic activator of FXI. The generation of thrombin by the tissue factor/factor VIIa pathway activates FXI on the platelet surface that contributes to additional thrombin generation after the clot has formed and thus augments resistance to fibrinolysis through a thrombin-activated fibrinolytic inhibitor (TAFI).

Factor XI deficiency is a rare bleeding disorder that occurs in the general population at a frequency of one in a million. However, the disease is highly prevalent among Ashkenazi and Iraqi Jewish populations, reaching a frequency of 6% as heterozygotes and 0.1–0.3% as homozygotes. More than 65 mutations in the FXI gene have been reported, whereas fewer mutations (two to three) are found among affected Jewish populations.

Normal FXI clotting activity levels range from 70 to 150 U/dL. In heterozygous patients with moderate deficiency, FXI ranges from 20 to 70 U/dL, whereas in homozygous or double heterozygote patients, FXI levels are <1–20 U/dL. Patients with FXI levels <10% of normal have a high risk of bleeding, but the disease phenotype does not always correlate with residual FXI clotting activity. A family history is indicative of the risk of bleeding in the propositus. Clinically, the presence of mucocutaneous hemorrhages such as bruises, gum bleeding, epistaxis, hematuria, and menorrhagia are common, especially following trauma. This hemorrhagic phenotype suggests that tissues rich in fibrinolytic activity are more susceptible to FXI deficiency. Postoperative bleeding is common but not always present, even among patients with very low FXI levels.

FXI replacement is indicated in patients with severe disease required to undergo a surgical procedure. A negative history of bleeding complications following invasive procedures does not exclude the possibility of an increased risk for hemorrhage.

TREATMENT

Factor XI Deficiency

The treatment of FXI deficiency is based on the infusion of FFP at doses of 15–20 mL/kg to maintain trough levels ranging from 10 to 20%. Because FXI has a half-life of 40–70 h, the replacement therapy can be given on alternate days. The use of antifibrinolytic drugs is beneficial to control bleeds, with the exception of hematuria or bleeds in the bladder. The development of an FXI inhibitor was observed in 10% of severely FXI-deficient patients who received replacement therapy. Patients with severe FXI deficiency who develop inhibitors usually do not bleed spontaneously. However, bleeding following a surgical procedure or trauma can be severe. In these patients, FFP and FXI concentrates should be avoided. The use of PCC/aPCC or recombinant activated FVII has been effective.

RARE BLEEDING DISORDERS

Collectively, the inherited disorders resulting from deficiencies of clotting factors other than FVIII, FIX, and FXI (Table 112-1) represent a group of rare bleeding diseases. The bleeding symptoms in these patients vary from asymptomatic (dysfibrinogenemia or FVII deficiency) to life-threatening (FX or FXIII deficiency). There is no pathognomonic clinical manifestation that suggests one specific disease, but overall, in contrast to hemophilia, hemarthrosis is a rare event and bleeding in the mucosal tract or after umbilical cord clamping is common. Individuals heterozygous for plasma coagulation deficiencies are often asymptomatic. The laboratory assessment for the specific deficient factor following screening with general coagulation tests (Table 112-1) will define the diagnosis.

Replacement therapy using FFP or PCCs (containing prothrombin, FVII, FIX, and FX) provides adequate hemostasis in response to bleeds or as prophylactic treatment. The use of PCC should be carefully monitored and avoided in patients with underlying liver disease, or those at high risk for thrombosis because of the risk of DIC.

FAMILIAL MULTIPLE COAGULATION DEFICIENCIES

There are several bleeding disorders characterized by the inherited deficiency of more than one plasma coagulation factor. To date, the genetic defects in two of these diseases have been characterized, and they provide new insights into the regulation of hemostasis by gene-encoding proteins outside blood coagulation.

Combined Deficiency of FV and FVIII Patients with combined FV and FVIII deficiency exhibit ~5% of residual clotting activity of each factor. Interestingly, the disease phenotype is a mild bleeding tendency, often following trauma. An underlying mutation has been identified in the *lectin mannose binding 1* (*LMAN1*) gene, a mannose-binding protein localized in the Golgi apparatus that functions as a chaperone for both FV and FVIII. In other families, mutations in the multiple coagulation factor deficiency 2 (*MCFD2*) gene have been defined; this gene encodes a protein that forms a Ca^{2+} dependent complex with LMAN1 and provides cofactor activity in the intracellular mobilization of both FV and FVIII. The replacement therapy to control or prevent bleeding consisted of FFP to maintain FV levels and DDAVP or FVIII concentrate to achieve FVIII levels of 20–40%. Alternatively, since platelets contain FV, transfusion of platelets can also be used.

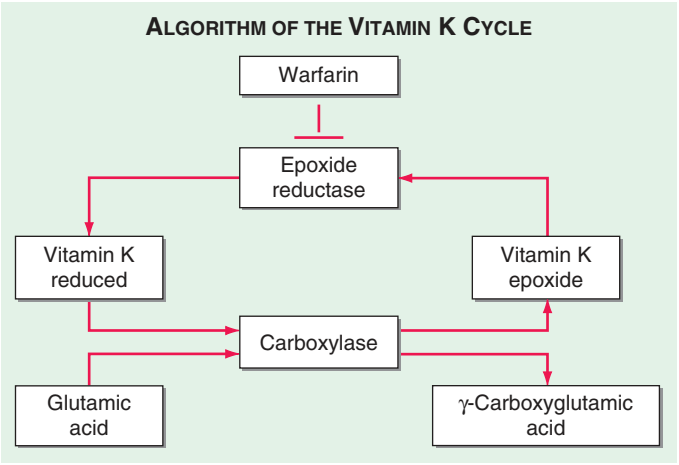

FIGURE 112-2 The vitamin K cycle. Vitamin K is a cofactor for the formation of γ-carboxyglutamic acid residues on coagulation proteins. Vitamin K–dependent γ-glutamylcarboxylase, the enzyme that catalyzes the vitamin K epoxide reductase, regenerates reduced vitamin K. Warfarin blocks the action of the reductase and competitively inhibits the effects of vitamin K.

Multiple Deficiencies of Vitamin K–Dependent Coagulation Factors Two enzymes involved in vitamin K metabolism have been associated with combined deficiency of all vitamin K–dependent proteins, including the procoagulant proteins prothrombin, VII, IX, and X and the anticoagulant proteins C and S. Vitamin K is a fat-soluble vitamin that is a cofactor for carboxylation of the gamma carbon of the glutamic acid residues in the vitamin K–dependent factors, a critical step for calcium and phospholipid binding of these proteins (Fig. 112-2). The enzymes γ-glutamylcarboxylase and epoxide reductase are critical for the metabolism and regeneration of vitamin K. Mutations in the genes encoding the γ-carboxylase (GGCX) or vitamin K epoxide reductase complex 1 (VKORC1) result in defective enzymes and thus in vitamin K–dependent factors with reduced activity, varying from 1 to 30% of normal. The disease phenotype is characterized by mild to severe bleeding episodes present from birth. Some patients respond to oral administration of vitamin K1 (5–20 mg/d), or in poor responders parenteral vitamin K1 at doses of 5–20 mg/week could be considered. For severe bleeding, replacement therapy with FFP or PCC may be necessary to achieve full hemostatic control.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a clinicopathologic syndrome characterized by widespread intravascular fibrin formation in response to excessive blood protease activity that overcomes the natural anticoagulant mechanisms. There are several underlying pathologies associated with DIC (Table 112-2).

The most common causes are bacterial sepsis, malignant disorders such as solid tumors or acute promyelocytic leukemia, and obstetric causes. DIC is diagnosed in almost one-half of pregnant women with abruptio placentae or with amniotic fluid embolism. Trauma, particularly to the brain, can also result in DIC. The exposure of blood to phospholipids from damaged tissue, hemolysis, and endothelial damage are all contributing factors to the development of DIC in this setting. Purpura fulminans is a severe form of DIC resulting from thrombosis of extensive areas of the skin; it affects predominantly young children following viral or bacterial infection, particularly those with inherited or acquired hypercoagulability due to deficiencies of the components of the protein C pathway. Neonates homozygous for protein C

TABLE 112-2 Common Clinical Causes of Disseminated Intravascular Coagulation

SEPSIS	IMMUNOLOGIC DISORDERS
• Bacterial: Staphylococci, streptococci, pneumococci, meningococci, gram-negative bacilli • Viral • Mycotic • Parasitic • Rickettsial	• Acute hemolytic transfusion reaction • Organ or tissue transplant rejection • Immunotherapy • Graft-versus-host disease
TRAUMA AND TISSUE INJURY	**DRUGS**
• Brain injury (gunshot) • Extensive burns • Fat embolism • Rhabdomyolysis	• Fibrinolytic agents • Aprotinin • Warfarin (especially in neonates with protein C deficiency) • Prothrombin complex concentrates • Recreational drugs (amphetamines)
VASCULAR DISORDERS	**ENVENOMATION**
• Giant hemangiomas (Kasabach-Merritt syndrome) • Large vessel aneurysms (e.g., aorta)	• Snake • Insects
OBSTETRICAL COMPLICATIONS	**LIVER DISEASE**
• Abruptio placentae • Amniotic fluid embolism • Dead fetus syndrome • Septic abortion	• Fulminant hepatic failure • Cirrhosis • Fatty liver of pregnancy
CANCER	**MISCELLANEOUS**
• Adenocarcinoma (prostate, pancreas, etc.) • Hematologic malignancies (acute promyelocytic leukemia)	• Shock • Respiratory distress syndrome • Massive transfusion

deficiency also present high risk for purpura fulminans with or without thrombosis of large vessels.

The central mechanism of DIC is the uncontrolled generation of thrombin by exposure of the blood to pathologic levels of tissue factor (Fig. 112-3). Simultaneous suppression of physiologic anticoagulant mechanisms and abnormal fibrinolysis further accelerate the process. Together, these abnormalities contribute to systemic fibrin deposition in small and midsize vessels. The duration and intensity of the fibrin deposition can compromise the blood supply of many organs, especially the lung, kidney, liver, and brain, with consequent organ failure. The sustained activation of coagulation results in consumption of clotting factors and platelets, which in turn leads to systemic bleeding. This is further aggravated by secondary hyperfibrinolysis. Studies in animals demonstrate that the fibrinolytic system is indeed suppressed at the time of maximal activation of coagulation. Interestingly, in patients with acute promyelocytic leukemia, a severe hyperfibrinolytic state often occurs in addition to the coagulation activation. The release of several proinflammatory cytokines such as interleukin 6 and tumor necrosis factor α plays a central role in mediating the coagulation defects in DIC and symptoms associated with systemic inflammatory response syndrome (SIRS).

Clinical manifestations of DIC are related to the magnitude of the imbalance of hemostasis, to the underlying disease, or to both. The most common findings are bleeding ranging from oozing from venipuncture sites, petechiae, and ecchymoses to severe hemorrhage from the gastrointestinal tract, lung, or into the CNS. In chronic DIC, the bleeding symptoms are discrete and restricted to skin or mucosal surfaces. The hypercoagulability of DIC manifests as the occlusion of vessels in the microcirculation and resulting organ failure. Thrombosis of large vessels and cerebral embolism can also occur. Hemodynamic complications and shock are common among patients with acute DIC. The mortality ranges from 30 to >80% depending on the underlying disease, the severity of the DIC, and the age of the patient.

The diagnosis of clinically significant DIC is based on the presence of clinical and/or laboratory abnormalities of coagulation or thrombocytopenia. The laboratory diagnosis of DIC should prompt a search for the underlying disease if it is not already apparent. There is no single test that establishes the diagnosis of DIC. The laboratory investigation should include coagulation tests (aPTT, PT, thrombin time [TT]) and markers of fibrin degradation products (FDPs), in addition to platelet and red cell count and analysis of the blood smear. These tests should be repeated over a period of 6–8 h because an initially mild abnormality can change dramatically in patients with severe DIC.

Common findings include the prolongation of PT and/or aPTT; platelet counts μ100,000/μL, or a rapid decline in platelet numbers; the presence of schistocytes (fragmented red cells) in the blood smear; and elevated levels of FDP. The most sensitive test for DIC is the FDP

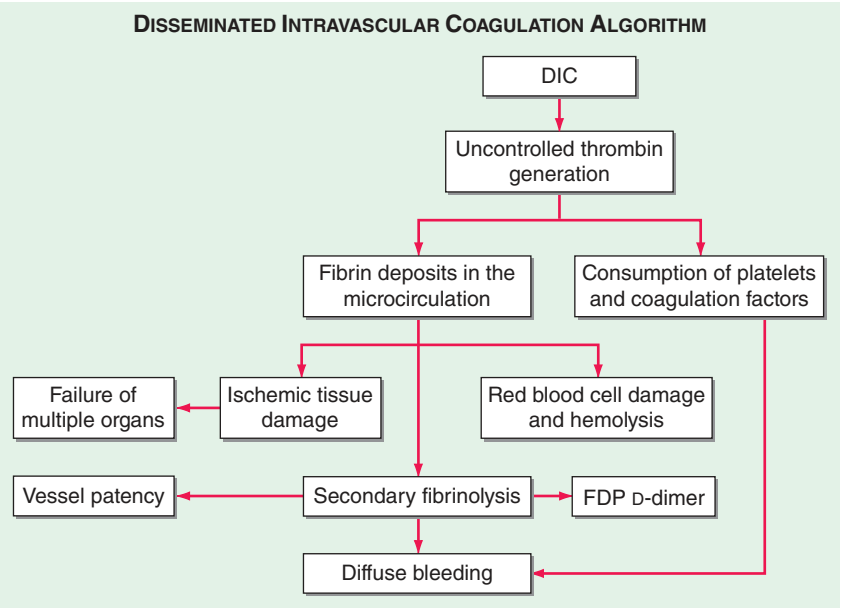

FIGURE 112-3 The pathophysiology of disseminated intravascular coagulation (DIC). Interactions between coagulation and fibrinolytic pathways result in bleeding and thrombosis in the microcirculation in patients with DIC. FDP, fibrin degradation product.

level. DIC is an unlikely diagnosis in the presence of normal levels of FDP. The D-dimer test is more specific for detection of fibrin—but not fibrinogen—degradation products and indicates that the cross-linked fibrin has been digested by plasmin. Because fibrinogen has a prolonged half-life, plasma levels diminish acutely only in severe cases of DIC. High-grade DIC is also associated with levels of antithrombin III or plasminogen activity <60% of normal.

Chronic DIC Low-grade, compensated DIC can occur in clinical situations including giant hemangioma, metastatic carcinoma, or the dead fetus syndrome. Plasma levels of FDP or D-dimers are elevated. aPTT, PT, and fibrinogen values are within the normal range or high. Mild thrombocytopenia or normal platelet counts are also common findings. Red cell fragmentation is often detected but at a lower degree than in acute DIC.

Differential Diagnosis The differential diagnosis between DIC and severe liver disease is challenging and requires serial measurements of the laboratory parameters of DIC. Patients with severe liver disease are at risk for bleeding and manifest laboratory features including thrombocytopenia (due to platelet sequestration, portal hypertension, or hypersplenism), decreased synthesis of coagulation factors and natural anticoagulants, and elevated levels of FDP due to reduced hepatic clearance. However, in contrast to DIC, these laboratory parameters in liver disease do not change rapidly. Other important differential findings include the presence of portal hypertension or other clinical or laboratory evidence of an underlying liver disease.

Microangiopathic disorders such as thrombotic thrombocytopenic purpura present an acute clinical onset of illness accompanied by thrombocytopenia, red cell fragmentation, and multiorgan failure. However, there is no consumption of clotting factors or hyperfibrinolysis.

Over the last few years, several clinical trials on immune therapies for neoplasias using monoclonal antibodies or gene-modified T cells targeting tumor-specific antigens showed unwanted inflammatory responses with increased cytokine release. These complications are sometimes associated with increased D-dimers and decreased fibrinogen levels, cytopenias, and liver dysfunction; thus, careful screening tests for DIC are indicated.

TREATMENT

Disseminated Intravascular Coagulation

The morbidity and mortality associated with DIC are primarily related to the underlying disease rather than the complications of the DIC. The control or elimination of the underlying cause should therefore be the primary concern. Patients with severe DIC require control of hemodynamic parameters, respiratory support, and sometimes invasive surgical procedures. Attempts to treat DIC without accompanying treatment of the causative disease are likely to fail.

MANAGEMENT OF HEMORRHAGIC SYMPTOMS

Administration of FFP and/or platelet concentrates is indicated for patients with active bleeding or at high risk of bleeding, such as in preparation for invasive procedures or after chemotherapy. The control of bleeding in DIC patients with marked thrombocytopenia (platelet counts <10,000–20,000/μL) and low levels of coagulation factors will require replacement therapy. The PT (>1.5 times the normal) provides a good indicator of the severity of the clotting factor consumption. Replacement with FFP is indicated (1 unit of FFP increases most coagulation factors by 30% in an adult without DIC). Low levels of fibrinogen (<100 mg/dL) or brisk hyperfibrinolysis will require infusion of cryoprecipitate (plasma fraction enriched for fibrinogen, FVIII, and VWF). The replacement of 10 U of cryoprecipitate for every 2–3 U of FFP is sufficient to correct the hemostasis. The transfusion scheme must be adjusted according to the patient's clinical and laboratory evolution. Platelet concentrates at a dose of 1–2 U/10 kg body weight are sufficient for most DIC patients with severe thrombocytopenia. Clotting factor concentrates are not recommended for control of bleeding in DIC because of the limited efficacy afforded by replacement of single factors (FVIII or FIX concentrates) and the high risk of products containing traces of aPCCs that further aggravate the disease.

REPLACEMENT OF COAGULATION OR FIBRINOLYSIS INHIBITORS

Drugs to control coagulation such as heparin, antithrombin III (ATIII) concentrates, or antifibrinolytic drugs have all been tried in the treatment of DIC. Low doses of continuous-infusion heparin (5–10 U/kg per h) may be effective in patients with low-grade DIC associated with solid tumor, acute promyelocytic leukemia, or in a setting with recognized thrombosis. Heparin is also indicated for the treatment of purpura fulminans during the surgical resection of giant hemangiomas and during removal of a dead fetus. In acute DIC, the use of heparin is likely to aggravate bleeding. To date, the use of heparin in patients with severe DIC has no proven survival benefit. The use of antifibrinolytic drugs, EACA, or tranexamic acid to prevent fibrin degradation by plasmin may reduce bleeding episodes in patients with DIC and confirmed hyperfibrinolysis. However, these drugs can increase the risk of thrombosis, and concomitant use of heparin is indicated. Patients with acute promyelocytic leukemia or those with chronic DIC associated with giant hemangiomas are among the few patients who may benefit from this therapy. The use of protein C concentrates to treat purpura fulminans associated with acquired protein C deficiency or meningococcemia has been proven efficacious. The results from the replacement of ATIII in early-phase studies are promising but require further study.

Guidance for diagnosis and treatment of DIC had been proposed by the International Society of Thrombosis and Haemostasis. This initiative will permit more detailed clinical data on diagnosis and treatment of DIC. The clinical utility of these scoring systems and therapeutic recommendations contained in these guidelines is not yet known.

VITAMIN K DEFICIENCY
